## PAPERS COMMUNICATED TO THE CHEMICAL SOCIETY

	PAGE
I.—Stereoisomerism of Disulphoxides and Related Substances. Part V. The Dioxides of 3 : 5-Dimethylthiolbenzoic Acid. By ERNEST VERE BELL and GEORGE MACDONALD BENNETT . . . . .	1
II.—Pellitorine, the Pungent Principle of <i>Anacyclus pyrethrum</i> . By JOHN MASSON GULLAND and GERALD UERN HOPTON . . . . .	6
III.—1 : 3-Dithiolan. By DAVID T. GIBSON . . . . .	12
IV.—The Influence of Substituents on the Benzoin Reaction. By HERBERT HENRY HODGSON and WOLF ROSENBERG . . . . .	14
V.— <i>dl</i> - $\beta$ -Phenylisopropylamine and Related Compounds. By DONALD HOLROYDE HEY . . . . .	18
VI.—Natural Glucosides. Part I. The Constitution of Phloridzin. By FRANCIS RABAN JOHNSON and ALEXANDER ROBERTSON . . . . .	21
VII.—The Nitration of Aromatic Thiocyanates. By FREDERICK CHALLENGER, CONSTANCE HIGGINBOTTOM, and ALFRED HUNTINGTON . . . . .	26
VIII.—The Parachor of Chlorine Dioxide. By GEOFFREY HERBERT CHEESMAN . . . . .	35
IX.—The Chlorination of Anilides. Part VI The Rates of N-Chlorination of benzylamides and the Effects of 1503 de-chain Re- activity. By GWILLIAM IARI . . . . .	37
X.—The Dehydration of hydrate. By WILLIAM E. GARNER . . . . .	47
XI.—Low-temperature . . . . . The Ignition of Some Hydrocarbons in Oxygen. By JOHN STANLEY LEWIS . . . . .	58
XII.—The Hydrides of Boron. By BERTRAM DILLON STEINLE and JAMES EDWARD MILLS . . . . .	74
XIII.—Acid and Salt Effects in Catalysed Reactions. Part XXIII. The Catalytic Activity of Acid Salts with Reference to the Catalytic Effects produced by Potassium Hydrogen Oxalate in the Acetone-Iodine Reaction. By HARRY MEDFORTH DAWSON and JESSE FYRE SMITH . . . . .	79

	PAGE
XIV.—The Routine Preparation of Conductivity Water. Part II. By JOHN M. STUART and FRANK WORMWELL .	85
XV.—The Interaction of Butyl Chloral Hydrate and 2 : 4-Di- halogen-substituted Phenylhydrazines. By FREDERICK DANIEL CHATTAWAY and HARRY IRVING . . . . .	87
XVI.—The Formation of Glyoxalosazonones by the Interaction of Dichloroacetaldehyde and Aryl Hydrazines. By FREDERICK DANIEL CHATTAWAY and LARKIN HUNDLEY FARINHOLT . . . . .	94
XVII.—2-Thiol-4(5)- $\beta$ -aminoethylglyoxalino (2-Thiolhist- amine). By FRANK LEE PYMAN. . . . .	98
XVIII.—Comparison of Some Physical Constants of Thio- cyanate, Azide, and Nitrite Solutions. By P. GÜNTHER and W. PERSCHKE . . . . .	100
XIX.—The Inhibition of Chemical Reactions. Part III. The Inhibition by Sulphur of the Atmospheric Oxidation of Benzaldehyde. By KENNETH CLAUDE BAILEY . . . . .	104
XX.—The Conversion of <i>N</i> -Chloroacetanilide into <i>p</i> -Chloro- acetanilide by Hydrogen and Chlorine Ions. By JOSEPH WATKIN BELTON . . . . .	116
XXI.—The Unsaturation and Tautomeric Mobility of Hetero- cyclic Compounds. Part I. Benzthiazole and Dihydro- benzthiazole Derivatives. By ROBERT FERGUS HUNTER . . . . .	125
XXII.—Nitration of 2'- and 4'-Nitro-1-phenylpiperidines. By RAYMOND JAMES WOOD LE FÈVRE . . . . .	147
XXIII.—Sugar Carbonates. Part IV. The Dicarbonates of Glucose, Fructose, Mannose, Galactose, and Arabinose. By WALTER NORMAN HAWORTH and CHARLES RAYMOND PORTER . . . . .	151
XXIV.—The Action of Bromine upon the <i>p</i> -Tolylhydrazones of Benzaldehyde and of the Nitrobenzaldehydes. By FREDERICK DANIEL CHATTAWAY and ARTHUR B. ADAMSON . . . . .	157
Second Liversidge Lecture. Delivered before the Chemical Society on December 12th, 1929. By HERBERT FREUND- LICH . . . . .	164
NOTES.—An Apparatus for the Determination of Solubility. By ALAN N. CAMPBELL . . . . .	179
2'-Nitro-2- and -4-aminodiphenyl Sulphides and 4'-Nitro-2- and -4-aminodiphenyl Sulphides. By HERBERT HENRY HODGSON and WOLF ROSENBERG . . . . .	180
The Solubility of Sodium Thiocyanate in Alcohol. By JAMES RIDDICK PARTINGTON . . . . .	181

	PAGE
An Improved Receiver for Vacuum Distillation. By GEORGE ARMAND ROBERT KON . . . . .	182
Preparation of 4- and 6-Hydroxy-3-nitrophenylarsinic Acids. By ISIDORE ELKANAH BALABAN . . . . .	183
Anserine. By FRANK LEE PYMAN . . . . .	183
The Mechanism of Cyanoacetamide and Cyanoacetic Ester Condensations. By CHRISTOPHER KELK INGOLD . . . . .	184
XXV.—The Influence of Hydrogen and of Water Vapour on the Ignition of Carbon Monoxide. By ARTHUR SMITH- ELLS, HENRY WHITAKER, and THEODORA HOLMES . . . . .	185
XXVI.—The Effect of Hydrogen-ion Concentration on the Electrode Potential of Iron. By A. L. MCAULAY and G. L. WHITE . . . . .	194
XXVII.—The Pyrophosphate Method for the Determination of Magnesium. By STANKO STANKOV MIHOLOČ . . . . .	200
XXVIII.—The Absorption Spectra of Diphenyl and Some Derivatives. By THOMAS C. C. ADAM and ALFRED RUSSELL . . . . .	202
XXIX.—Studies in Keto-lactol Tautomerism. Part IV. Chemistry of 5-Acetyl-1:1:2-trimethylcyclopentane-2- carboxylic Acid. Observations on the Constitutions of the Acid Esters of Camphoric Acid, and a Synthesis of Homoepicamphor. By MUHAMMAD QUDRAT-I-KHUDA . . . . .	206
XXX.—The <i>cis-trans</i> Ethenoid Transformation. By GEORGE ROGER CLEMO and STANLEY BROWN GRAHAM . . . . .	213
XXXI.—The Methylation of the Oximes of Benzil. Part II. The Monomethyl Ethers of the Benzildioximes. By OSCAR L. BRADY and MORRIS MARCUS MUERS . . . . .	216
XXXII.—The Isomerism of the Oximes. Part XXXVII. Allyl- <i>p</i> -nitrobenzaldoximes, <i>O</i> - and <i>N</i> -Allylhydroxyl- amines, and Sulphime <i>S</i> -Ethers. By OSCAR L. BRADY and FRANK HERBERT PEAKIN . . . . .	226
XXXIII.—The Parachor and Chemical Constitution. Part XIV. Tellurium Compounds. By FRANCIS HERREWARD BURSTALL and SAMUEL SUGDEN . . . . .	229
XXXIV.—The Photochemical Interaction of Acetaldehyde and Oxygen. By EDMUND JOHN BOWEN and EDMUND LAGESEN TIETZ . . . . .	234
XXXV.—Extinction of Methane Flames by Water Vapour. By HUBERT FRANK COWARD and JOHN JERSON GLEADALL . . . . .	243
XXXVI.—Mobile Anion Tautomerism. Part IV. The Stability of Some $\alpha$ - and $\gamma$ -Alkylallyl Alcohols and their Esters. 2:4-Dimethylcinnamyl Alcohol. By HAROLD BURTON . . . . .	248

	PAGE
XXXVII.—Some Trinitroethylbenzenes. By JAMES NELSON EDMUND DAY . . . . .	252
XXXVIII.—The Reactions of Malonic Esters with Form- aldehyde. Part I. By KENNETH NORMAN WELCH . . . . .	257
XXXIX.—Colloidal Phenoxides. Part II. Some Phen- anthraxanthones. By WILSON BAKER . . . . .	261
XL.—An Investigation into the Formation of 4(5)-Amino- glyoxalines. Part I. By ISIDORE ELKANAH BALABAN . . . . .	268
XLI.—Internal Equilibrium in Sulphur. Part II. Amor- phous Sulphur ( $S_\mu$ ) as a Gel, and the Tyndall Effect in Liquid Sulphur. By DALZIEL LLEWELLYN HAMMICK and MICHAEL ZVEGINTZOV . . . . .	273
XLII.—Nitrous Acid as a Nitrating Agent. Part I. The Nitration of Dimethyl- <i>p</i> -toluidine. By HERBERT HENRY HODGSON and ARNOLD KERSHAW . . . . .	277
XLIII.—The Variation of Phenol Coefficients in Homologous Series of Phenols. By CHARLES EDWARD COULTHARD, JOSEPH MARSHALL, and FRANK LEE PYMAN . . . . .	280
XLIV.—Reduction Products of the Hydroxyanthraquinones. Part XI. By EDWIN JOHN CROSS and ARTHUR GEORGE PERKIN . . . . .	292
XLV.—The Development of Colour by Photochemical Change in Concentrated Solutions of Ammonium Thiocyanate. By B. S. SHARMA ✓ . . . . .	308
XLVI.—Hydroxyamino-acids. By WILLIAM JOHN NOBBS BURCH . . . . .	310
XLVII.—Lichen Acids. Part I. Derivatives of $\beta$ -Orcinol. By ALEXANDER ROBERTSON and RICHARD JOHN STEPHEN- SON . . . . .	313
NOTES.—The Interaction of Sodamide and Alkyl Iodides with Acetophenone and its Homologues. By ALFRED RUSSELL The Structure of the Isomeric Methyl Ferrocyanides. By S. GLASSTONE . . . . .	321
XLVIII.—The Catalytic Hydrogenation of Different Types of Unsaturated Compounds. Part V. The Hydrogenation of Cyclic Ethylenic Derivatives and of their Mixtures. By SERGUEY V. LEBEDEV and MICHAÏL PLATONOV . . . . .	321
XLIX.—On Active Nitrogen. Part VII. Further Studies upon the Decay of the Nitrogen After-glow. By ERIC JOHN BAXTER WILLEY . . . . .	336
L.—A New Interpretation of the Isomerism amongst Co- ordination Compounds of Platinum. By FREDERICK GEORGE ANGELL, HARRY DUGALD KEITH DREW, and WILLIAM WARDLAW . . . . .	349

LI.—The Partial Esterification of Polyhydric Alcohols. Part X. The Discovery of the First True $\beta$ -Glyceride, and the Untrustworthiness of the Supposed Structures of Certain Diglycerides. By ARTHUR FAIRBOURNE . . . . .	369
LII.—Strychnine and Brucine. Part IX. Preparation of Some Isomerides of Dinitrostrychnol and Trinitrostrychnol. By JULIUS NICHOLSON ASHLEY, (the late) WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON . . . . .	382
LIII.—The Reaction between Cupric Chloride and Hydrazine Sulphate. By THOMAS IREDALE and CATHERINE ELEANOR MALLEN . . . . .	395
LIV.—Nitration of Phenyl Substituents of Heterocyclic Nuclei. By ROBERT FORSYTH and FRANK LEE PYMAN . . . . .	397
LY.—The Constitution of Cryptal. By ARTHUR RAMON PENFOLD and JOHN LIONEL SIMONSEN . . . . .	403
LVI.—Derivatives of 3-Keto-2 : 3-dihydrothionaphthen 1 : 1-Dioxide. By AARON COHEN and SAMUEL SMILES . . . . .	406
LVII.—The Interaction of Ethyl <i>l</i> -Mandelate and Thionyl Chloride in the Presence of Pyridine. The Mechanism of the Replacement of Hydroxyl by Chlorine by Means of Thionyl Chloride. By JOSEPH KENYON, ALFRED GEORGE LIPSCOMB, and HENRY PHILLIPS . . . . .	415
LVIII.—Synthesis of Alkyl Naphthalenes. Part I. 5-, 6-, and 7-Ethyl-1-methylnaphthalenes. By JOHN HARVEY, ISIDOR MORRIS HEILBRON, and DONALD GRAHAM WILKINSON . . . . .	423
LIX.—The Nature of the Alternating Effect in Carbon Chains. Part XXXII. The Directive Influence of $\psi$ -Basic Systems in Aromatic Substitution. Nitration of Benzylidene- <i>m</i> -nitroaniline. By JOHN WILLIAM BAKER and CHRISTOPHER KELK INGOLD . . . . .	431
LX.—Primary and Associated Results of Replacement of Hydrogen directly attached to 4-Co-ordinated Carbon. By WESLEY COCKER, ARTHUR LAPWORTH, and ARTHUR WALTON . . . . .	440
LXI.—Substituted Diaryl Ethers. Part III. A New Synthesis of Substituted Xanthhydrols. By JOSEPH REILLY and PETER J. DRUMM . . . . .	455
LXII.—Photomicrographic Methods applied to Two-component Salt Mixtures. By WALTER MATTHEW MADGIN . . . . .	458
LXIII.—The Interaction between Alkyl Grignard Reagents and Antimony Trichloride. By WILFRED JAMES CREIL DYKE, WALTER CULE DAVIES, and WILLIAM JACOB JONES . . . . .	463

	PAGE
LXIV.—Syntheses by Means of Magnesium Amyl Halides. By WALTER CULE DAVIES, ROBERT SINCLAIR DIXON, and WILLIAM JACOB JONES . . . . .	468
LXV.—The Reduction of Triphenylhalogenomethanes. By JAMES CLIFFORD THOMAS, SYDNEY THOMAS BOWDEN, and WILLIAM JACOB JONES . . . . .	473
LXVI.—The Passivity of Metals. Part IV. The Influence of Acids in Passivity and Corrosion. By ULICK R. EVANS .	478
LXVII.— <i>N</i> -Acylpyrazolones as Acylating Agents. By JOTI SARUP AGGARWAL and JNANENDRA NATH RAY . . . . .	492
LXVIII.—The Vapour Density of Zirconium Tetrachloride. By JOHN ALBERT NEWTON FRIEND, ALBERT THOMAS WILLIAM COLLEY, and RICHARD SIDNEY HAYES . . . . .	494
LXIX.—3-Halogeno-6-nitro- and -6-amino-dimethylammones. By HERBERT HENRY HODGSON and ARNOLD KERSHAW .	497
LXX.— $\gamma$ -Phenyl- $\alpha$ -methylpropyldimethylarsine, $\beta$ -Benzyl- butyldimethylarsine, and Some Related Compounds. By ALBERT BREWIN and EUSTACE EBENEZER TURNER . . . . .	502
LXXI.—The Reactivity of Halogen Atoms in Compounds of the Pyridine Series. Part I. The Halides of 2-Stilbazole. By JOHN WALTER BLOOD and BRIAN DUNCAN SHAW . . . . .	504
LXXII.—Digoxin, a New Digitalis Glucoside. By SYDNEY SMITH . . . . .	508
LXXIII.—Properties of Conjugated Compounds. Part VIII. Addition of Bromine to $\alpha\delta$ -, $\alpha\gamma$ -, and $\beta\gamma$ -Dimethylbuta- dienes. By ERNEST HAROLD FARMER, CYRIL DUNN LAW- RENCE, and WILLIAM DALLAS SCOTT . . . . .	510
LXXIV.—Properties of Conjugated Compounds. Part IX. The Formation of Bimolecular Reduction Products of Butadiene Acids. By CHARLES MILLS CAWLEY, JOHN TREVOR EVANS, and ERNEST HAROLD FARMER . . . . .	522
LXXV.—The Electrical Conductivities of Solutions of Tetra- ethylammonium Iodide in Benzonitrile. By AUSTIN RAYMOND MARTIN . . . . .	530
LXXVI.—Investigations on the Bivalency of Carbon. Part III. Some Experiments on Xanthhydrol, Dixanthhydrol Ether, and Xanthhydrol Chloride. By FREDERIC GORONWY KNY-JONES and ALLAN MILES WARD . . . . .	535
LXXVII.—The Apparent Hydration of Ions. Part IV. The Densities and Viscosities of Saturated Solutions of Silver Nitrate in Nitric Acid. By JOHN WILLIAM INGHAM . . . . .	542
LXXVIII.—Experiments on the Constitution of the Aloins. Part II. By CHARLES STANLEY GIBSON and JOHN LIONEL SIMONSEN . . . . .	553

LXXIX.—The Action of Nitric Acid on Some Metals. By ERNEST SYDNEY HEDGES . . . . .	561
LXXX.—The Measurement of the Dielectric Constants of Organic Liquids. By ALFRED OWENS BALL . . . . .	570
LXXXI.—The Photolysis of Aqueous Hydrogen Peroxide Solutions. Part I. Experimental Methods. By ARTHUR JOHN ALLMAND and DERRICK WILLIAM GRAHAM STYLE . . . . .	596
LXXXII.—The Photolysis of Aqueous Hydrogen Peroxide Solutions. Part II. Experimental Results. By ARTHUR JOHN ALLMAND and DERRICK WILLIAM GRAHAM STYLE . . . . .	606
LXXXIII.—The Angles of Floating Lenses. By CHARLES E. LYONS . . . . .	623
LXXXIV.—The Determination of the Dissociation Pressures of Hydrated Salts by a Dynamical Method. Part III. By JAMES RIDDICK PARTINGTON and REGINALD JOSEPH WINTERTON . . . . .	635
LXXXV.—The Ternary System Zinc Oxide-Zinc Chloride-Water. By HAROLD CECIL HOLLAND . . . . .	643
LXXXVI.—Crystalline $\alpha$ -Methylmannofuranoside ( $\gamma$ -Methylmannoside). Part I. By WALTER NORMAN HAWORTH and CHARLES RAYMOND PORTER . . . . .	649
LXXXVII.—Crystalline $\alpha$ -Methylmannofuranoside ( $\gamma$ -Methylmannoside). Part II. By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and JOHN IVOR WEBB . . . . .	651
LXXXVIII.—Derivatives of Lyxofuranose. By HAROLD GRAHAM BOTT, EDMUND LANGLEY HIRST, and JAMES ANDREW BUCHAN SMITH . . . . .	658
LXXXIX.—Trypanocidal Action and Chemical Constitution. Part IX. Aromatic Acids containing an Amide Group. By GEORGE ALECK CROCKER GOUGH and HAROLD KING . . . . .	669
XC.—The Heats of Association of Acetic and Heptoic Acids in the Vapour State. By TEMPE M. FENTON and WILLIAM EDWARD GARNER . . . . .	694
XCI.—A Simple Method for the Preparation of Maleic Anhydride. By FREDERICK ALFRED MASON . . . . .	700
XCII.—Further Degradative Experiments in the Morphine Group. By ROBERT SIDNEY CAHN . . . . .	702
XCIII.—Influence of Poles and Polar Linkings on the Course pursued by Elimination Reactions. Part VII. A Generalised Form of the Olefinic Degradation of Sulphones. By GEOFFREY WILLIAM FENTON and CHRISTOPHER KELK INGOLD . . . . .	705

- XCIV.—Influence of Poles and Polar Linkings on the Course pursued by Elimination Reactions. Part VIII. The Methylenic and Paraffinic Degradations of Sulphones. By CHRISTOPHER KELK INGOLD and JOE ARTHUR JESSOP . 708
- XCv.—Influence of Poles and Polar Linkings on the Course pursued by Elimination Reactions. Part IX. Isolation of a Substance believed to contain a Semipolar Double Linking with Participating Carbon. By CHRISTOPHER KELK INGOLD and JOE ARTHUR JESSOP . 713
- XCvI.—The Occurrence of Iron Pentacarbonyl in Coal Gas stored under Pressure for 30 Years. By JOHN ALBERT NEWTON FRIEND and REECE HENRY VALLANCE . 718
- XCvII.—The Reaction between Acid Chlorides and Nitrosylsulphuric Acid. By WILLIAM JAMES DEVERALL and HARRY WILLIAM WEBB . 720
- XCvIII.—Studies in Polymorphism. Part I. A Preliminary Investigation of the Polymorphism of *o*-Nitroaniline. By JOHN FREDERICK JAMES DIPPY and NORMAN HOLT HARTSHORNE . 725
- XCIX.—The "Uniform Movement" of Flame in Mixtures of Ethylene, Propylene, or Butylene with Air. By (Miss) ELIZABETH HELEN MACLEOD GEORGESON and FRANCIS JOHN HARTWELL . 733
- C.—Aromatic Stibinic Acids containing Phenyl and Quinolyl Radicals. By GILBERT T. MORGAN and JAMES WILFRED COOK . 737
- CI.—A Synthesis of Certain Higher Aliphatic Compounds. Part III. A Variation of the Keto-acid Synthesis, constituting an Improved Method for the Extension of Normal Carbon Chains. By (Mrs.) GERTRUDE MAUD ROBINSON . 745
- CII.—The Constitution of Carthamin. Part I. By (Miss) CHIKA KURODA . 752
- CIII.—The Constitution of Carthamin. Part II.  $\beta$ -Carthaminidin Pentamethyl Ether and its Synthesis. By (Miss) CHIKA KURODA . 765
- CIV.—Syntheses of Cyclic Compounds. Part VI. 3- and 4-Methylcyclohexanones. By ARTHUR ISRAEL VOGEL and MARIAM P. OOMMEN . 768
- CV.—The Chemistry of the Three-carbon System. Part XXIV. The Regeneration of Esters from their Sodio-derivatives. By WILFRED EYNON HUGH and GEORGE ARMAND ROBERT KON . 775

CVI.—The Properties of the Chlorides of Sulphur. Part III. Dielectric Constants. By THOMAS MARTIN LOWRY and GILBERT JESSOP . . . . .	782
CVII.—A Synthesis of Pyrylium Salts of Anthocyanidin Type. Part XIX. A Synthesis of Delphinidin Chloride not involving a Demethylation Process, and Syntheses of Hirsutidin Chloride and of Delphinidin Chloride 3'-Methyl Ether, possibly identical with Petunidin Chloride. By WILLIAM BRADLEY, ROBERT ROBINSON, and GEROLD SCHWARZENBACH . . . . .	793
CVIII.—Anthoxanthins. Part XI. A Synthesis of Diosmetin and of Luteolin 3-Methyl Ether. By ALBERT LOVECY, ROBERT ROBINSON, and SHIGEHICO SUGASAWA . . . . .	817
CIX.—Anthoxanthins. Part XII. Transition from a Flavylum Salt to a Flavone, illustrated by a New Synthesis of Scutellarein Tetramethyl Ether. By ROBERT ROBINSON and GEROLD SCHWARZENBACH . . . . .	822
CX.—Strychnine and Brucine. Part X. The Degradation of Dinitrostrycholcarboxylic Acid: its Recognition as a Derivative of Quinoline and the Consequent Modifications of the Constitutional Formulæ for the Strychnos Bases proposed in Part VII. By KOTTIAZATH NARAYANA MENON, (the late) WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON . . . . .	830
CXI.—Intramolecular Rearrangement in the Isomeric Tetrachloro-derivatives of <i>p</i> -Tolylhydrazones. By FREDERICK DANIEL CHATTAWAY and ARTHUR B. ADAMSON . . . . .	843
ANNUAL GENERAL MEETING . . . . .	851
PRESIDENTIAL ADDRESS . . . . .	872
OBITUARY NOTICES . . . . .	888
CXII.—The Isomerism of the Butylideneacetones. By EUSTACE NEVILL ECCOTT and REGINALD PATRICK LINSTED . . . . .	905
CXIII.—The Action of Benzenediazonium Chloride on $\beta$ -Nitroethyl Alcohol and its Derivatives. By EDWARD CHARLES SNELL JONES and JAMES KENNER . . . . .	919
CXIV.—The Scission of Diaryl Ethers and Related Compounds by Means of Piperidine. Part III. The Nitration of 2:4-Dibromo-2':4'-dinitrodiphenyl Ether and of 2:4-Dibromophenyl <i>p</i> -Toluenesulphonate and Benzoate. The Chlorination and Bromination of <i>m</i> -Nitrophenol. By ROSALIND VENETIA HENLEY and EUSTACE EBENEZER TURNER . . . . .	928

	PAGE
CXV.—The Unsaturation and Tautomeric Mobility of Heterocyclic Compounds. Part II. $\alpha$ - and $\beta\beta$ -Naphthathiazoles. By ROBERT FERGUS HUNTER and JOHN WILLIAM THOMAS JONES . . . . .	941
CXVI.—The Calculation of Activity Coefficients from Solubility Measurements: Thallous Chloride. By HERBERT EDWARD BLAYDEN and CECIL WHITFIELD DAVIES . . . . .	949
CXVII.— <i>iso</i> - $\beta$ -Naphthol Sulphide. By LEONARD ARTHUR WARREN and SAMUEL SMILES . . . . .	956
CXVIII.—The Nitrosation of Phenols. Part VIII. Resorcinol Monoethyl Ether. By HERBERT HENRY HODGSON and HUBERT CLAY . . . . .	963
CXIX.—The Nitrosation of Phenols. Part IX. Further Study of the Nitrosation of <i>m</i> -Bromophenol. By HERBERT HENRY HODGSON and ARNOLD KERSHAW . . . . .	967
CXX.—Symmetrical Triad Prototropic Systems. Part VI. The Effect of Substitution on Tautomeric Mobility and Equilibrium in the $\alpha\gamma$ -Diphenylpropene System. By CHARLES WILLIAM SHOPPEE . . . . .	968
CXXI.— <i>Cannabis Indica</i> Resin. Part I. The Constitution of Nitrocannabinolactone (Oxycannabin). By ROBERT SIDNEY CAHN . . . . .	986
CXXII.—The Preparation of Secondary Alkylarylamines and their Purification. By WILFRED JOHN HICKINBOTTOM . . . . .	992
CXXIII.—Attempts to prepare Cyanine Dyes from Quaternary Salts of 2-Methylacenaphthpyridine and of 5-Methylacridine. By FRANCES MARY HAMER . . . . .	995
CXXIV.—Tetrachloriodides of the Alkaloids. By FREDERICK DANIEL CHATTAWAY and GEORGE DAVID PARKES . . . . .	1003
CXXV.—The Properties of the Chlorides of Sulphur. Part IV. Density and Surface Tension, with an Appendix on the Parachors of Mixtures. By THOMAS MARTIN LOWRY and GILBERT JESSOP . . . . .	1005
CXXVI.—2-Arylcoumaranones. By WILSON BAKER . . . . .	1015
CXXVII.—Organic Derivatives of Silicon. Part XLII. <i>cyclo</i> Hexyl Derivatives of Silicane and Silicoethane. By KEITH WILLIAM PALMER and FREDERIC STANLEY KIPPING . . . . .	1020
CXXVIII.—Organic Derivatives of Silicon. Part XLIII. The Formation of Tri- and Tetra-phenylsilicane by the Action of Sodium on Triphenylsilyl Chloride. By FREDERIC STANLEY KIPPING and JOHN FRANCIS SHORT . . . . .	1029

CXXIX.—The Mechanism of, and Constitutional Factors controlling, the Hydrolysis of Carboxylic Esters. Part I. The Constitutional Significance of Hydrolytic Stability Maxima. By CHRISTOPHER KELK INGOLD .	1032
CXXX.—The Mechanism of, and Constitutional Factors controlling, the Hydrolysis of Carboxylic Esters. Part II. Hydrolytic Stability Maxima of some Glyceric Esters. By CONSTANCE MARY GROOCCOCK, CHRISTOPHER KELK INGOLD, and ARTHUR JACKSON . . . . .	1039
CXXXI.—The Anomalous Fifth Carbon Atom in <i>n</i> -Fatty Nitriles. By ROBERT AVERY FULTON and WILLIAM BELL LEE . . . . .	1057
CXXXII.—The Addition of Halogens to Unsaturated Acids and Esters. Part III. The Velocity of Bromine-addition. By NORMAN WILLIAM HANSON and DAVID MATTHEW WILLIAMS . . . . .	1059
CXXXIII.—The Behaviour of Hydrogen Chloride in Different Solvents. By W. E. KENRICK WYNNE-JONES .	1064
CXXXIV.—Investigations in the Diphenyl Series. Part IX. Further Experiments with Sulphonamides. By FRANK BELL . . . . .	1071
CXXXV.—Oxidation of <i>p</i> -Aminophenyltrimethylammonium Methosulphate and Some Quaternary Ammonium Derivatives. By AHMAD ZAKI . . . . .	1078
CXXXVI.—The Action of Fuming Nitric Acid on the 4-Halogeno-2 : 6-dibromo-phenols and -anisoles. Anomalous Behaviour of Fluorine Derivatives. By HERBERT HENRY HODGSON and JOSEPH NIXON . . . . .	1085
CXXXVII.—Polycyclic Aromatic Hydrocarbons. Part I. 1- and 2-Phenylanthracenes and Derivatives of 1 : 2-Benzanthracene. By JAMES WILFRED COOK . . . . .	1087
CXXXVIII.—The Dismutation of Some Disulphides. By ERNEST WILSON MCCLELLAND and LEONARD ARTHUR WARREN . . . . .	1095
CXXXIX.—The Production of Fog in the Neutralisation of Alkali with Hydrogen Halides. Part II. The Significance of the Presence of Ammonia. By RICHARD WALTER ALDIS and JAMES CHARLES PHILIP . . . . .	1103
CXL.—The Constitution of Santonin. Part II. The Synthesis of Racemic <i>desmotropo</i> Santonin. By GEORGE ROGER CLEMO, ROBERT DOWNS HAWORTH, and ERIC WALTON . . . . .	1110

	PAGE
CXLI.—The Scission of Diaryl Ethers and Related Compounds by Means of Piperidine. Part IV. Elimination of Halogen Atoms and Scission Reactions during Substitution Processes. By DOROTHY LILIAN FOX and EUSTACE EBENEZER TURNER . . . . .	1115
CXLII.—10-Chloro-5 : 10-dihydrophenarsazine and its Derivatives. Part XII. Further Experiments in the Investigation of the 1- and 3-Methyl Derivatives. By CHARLES STANLEY GIBSON and JOHN DOBNEY ANDREW JOHNSON . . . . .	1124
CXLIII.— <i>ortho</i> - and <i>meta</i> -Derivatives of Simple Alkyl Phenyl Ketones. By LESLIE ALDERMAN ELSON, CHARLES STANLEY GIBSON, and JOHN DOBNEY ANDREW JOHNSON . . . . .	1128
CXLIV.—The Synthesis of Glucosides. Part IV. Alizarin Glucoside. By ALEXANDER ROBERTSON . . . . .	1136
CXLV.—The Octammines, with Special Reference to Tin. By ARTHUR JAMES COOPER and WILLIAM WARDLAW . . . . .	1141
CXLVI.—On Active Nitrogen. Part VIII. (i) The Influence of Photogens and of Surfaces upon Glow Phenomena in Nitrogen. (ii) The Effects of Addition of Other Gases to Luminous Nitrogen. By ERIC JOHN BAXTER WILLEY . . . . .	1146
CXLVII.—Orientation Effects in the Diphenyl Series. Part VIII. The Nitration of 4 : 4'-Difluorodiphenyl. By RAYMOND JAMES WOOD LE FÈVRE and EUSTACE EBENEZER TURNER . . . . .	1158
CXLVIII.—Studies in "Strainless" Rings. Part II. The Effect of the <i>trans</i> -Decalin Nucleus on the Carbon Tetrahedral Angle. By KESHAVIAH ASWATH NARAIN RAO . . . . .	1162
CXLIX.—The Essential Oil of <i>Backhousia angustifolia</i> . Part II. The Isolation of Naturally Occurring $\beta$ -Diketones: Angustione and Dehydroangustione. By CHARLES STANLEY GIBSON, ARTHUR RAMON PENFOLD, and JOHN LIONEL SIMONSEN . . . . .	1184
CL.—The Effect of Gas Pressure on the Colour of Halogen Vapours. By ALEXANDER SHEARER and ROBERT WRIGHT . . . . .	1201
CLI.—The Bromination of 2-Nitro- and 2-Acetamido-diphenyl Ether. By HAMILTON MCCOMBIE, WILLIAM GEORGE MACMILLAN, and HAROLD ARCHIBALD SCARBOROUGH . . . . .	1202
CLII.—Quinoline Compounds containing Arsenic. Part I. Synthesis of 6-Methoxyquinoline Derivatives of Aminophenylarsinic Acids. By ROBERT HENRY SLATER . . . . .	1209

CLIII.—Some Derivatives of <i>m</i> -Xylene. By ERNEST G. BOYCE, WILLIAM P. RANKINE, and ALEXANDER ROBERTSON . . . . .	1216
CLIV.—The Formation of Phenoxazines. By OSCAR L. BRADY and CECIL WALLER . . . . .	1218
CLV.—The Preparation of Diphenyl Ethers. By (Miss) ROSALIND VENETIA HENLEY . . . . .	1222
CLVI.—The Preparation of Compounds analogous in Structure to Sulphinic Acids but containing <i>p</i> -Toluenesulphonimido-groups in Place of Oxygen Atoms. Phenyl- and Methyl- <i>p</i> -toluenesulphonimidodisulphine- <i>p</i> -toluenesulphonylimines. By SIDNEY GEORGE CLARKE, JOSEPH KENYON, and HENRY PHILLIPS . . . . .	1225
CLVII.—Nor- <i>dl</i> -ephedrine and Nor- <i>dl-ψ</i> -ephedrine. By DONALD HOLROYDE HEY . . . . .	1232
CLVIII.—The Constitution of Sinactine (1-Tetrahydroepiberberine). By KAKUJI GOTO and ZENJIRO KITASATO . . . . .	1234
CLIX.—Studies of Electrolytic Polarisation. Part IX. Complex Cyanides: (c) Zinc, Cadmium, and Mercury. By SAMUEL GLASSSTONE . . . . .	1237
CLX.—The Acetates of Ruthenium. By (the late) ALFRED WILLIAM MOND . . . . .	1247
CLXI.—Physicochemical Studies of Complex Acids. Part I. Tungstic Acid. By HUBERT THOMAS STANLEY BRITTON and WILLIAM LESLIE GERMAN . . . . .	1249
CLXII.—Physicochemical Studies of Complex Acids. Part II. Vanadic Acid. By HUBERT THOMAS STANLEY BRITTON and ROBERT ANTHONY ROBINSON . . . . .	1261
NOTES.—The Supposed Mandelaisonitrile. By WILSON BAKER and RANDAL GEORGE ARTHUR NEW . . . . .	1274
Syntheses of 1-Methylantraquinones. By ARTHUR FAIRBOURNE and GRAHAM EDWARD FOSTER . . . . .	1275
CLXIII.—A Revision of the Atomic Weight of Tantalum. Determination of the Ratios TaBr <sub>5</sub> :5Ag:5AgBr and TaCl <sub>5</sub> :5Ag:5AgCl. By KOLAR RAMAKRISHNAIYER KRISHNASWAMI . . . . .	1277
CLXIV.—4-Sulpho-3-hydroxybenzoic Acid. By MADHAVLAL SUKHLAL SHAH . . . . .	1293
CLXV.—The Action of Substituted Aromatic Amines on Camphoric Anhydride. Hydroxy-, Methoxy-, and Ethoxy-camphoranilic Acids and Camphoromethoxy- and -ethoxy-phenylimides. By MAHAN SINGH and RAM SINGH . . . . .	1301

	PAGE
CLXVI.—The Validity of the Interference Method for the Measurement of the Specific Area of a Copper Surface. By FREDERICK JAMES WILKINS . . . . .	1304
CLXVII.—The Lower Trialkyl Orthophosphates. Part I. By DAVID PHILIP EVANS, WALTER CULE DAVIES, and WILLIAM JACOB JONES . . . . .	1310
CLXVIII.—Studies in the Reactivity of Aromatic Hydroxyl Groups. Part I. By HAROLD LLEWELYN BASSETT . . . . .	1313
CLXIX.—The Critical Solution Temperature of the System Methyl Alcohol- <i>cyclo</i> Hexane as a Means of detecting and estimating Water in Methyl Alcohol. By DAVID CHARLES JONES and SIMON AMSTELL . . . . .	1316
CLXX.—The System <i>cyclo</i> Hexanol and Water. By NEVIL VINCENT SIDGWICK and LESLIE ERNEST SUTTON . . . . .	1323
CLXXI.—Dehydro-2-naphtholsulphone. By LEONARD ARTHUR WARREN and SAMUEL SMILES . . . . .	1327
CLXXII.—The Solubilities of Nitrophenols in Aqueous Ethyl-alcoholic Solutions. By JAMES COOPER DUFF and EDWIN JOHN BILLS . . . . .	1331
CLXXIII.—Glucosides. Part III. The Abnormal Replacement of Halogen in Glucosyl Halides: The Formation of $\beta$ -Glucosides from $\beta$ -Glucosyl Chlorides. By WILFRED JOHN HICKINBOTTOM. . . . .	1338
CLXXIV.—The Synthesis of <i>meso</i> -Alkyl and <i>meso</i> -Aryl Anthracene Derivatives. Part VII. By EDWARD DE BARRY BARNETT and NORMAN FREDERICK GOODWAY . . . . .	1348
CLXXV.—The Space Configuration of the Trithioacetaldehydes. By FREDERICK DANIEL CHATTAWAY and EDWIN GEOFFREY KELLETT . . . . .	1352
CLXXVI.—Attempts to find New Antimalarials. Part V. Some Piperidino- and Piperazino-derivatives of Quinoline. By WILLIAM OGILVIE KERMACK and JAMES FERGUS SMITH . . . . .	1356
CLXXVII.—The Passivity of Metals. Part V. The Potential-Time Curves of Some Iron Alloys. By L. C. BANNISTER and ULICK R. EVANS . . . . .	1361
CLXXVIII.—The Mechanism of, and Constitutional Factors controlling, the Hydrolysis of Carboxylic Esters. Part III. The Calculation of Molecular Dimensions from Hydrolytic Stability Maxima. By CHRISTOPHER KELK INGOLD . . . . .	1375
CLXXIX.—Conversion of Hydroaromatic into Aromatic Compounds. Part IV. The Influence of the Nitro-group in Nitrophenyldihydroresorcinols. By LEONARD ERIC HINKEL and JOHN FREDERICK JAMES DIPPY . . . . .	1387

CLXXX.—The Alkaloids of Ergot. Part I. By SYDNEY SMITH and GEOFFREY MILLWARD TIMMIS . . . . .	1390
CLXXXI.—The Development of a Novel Form of Isomerism in the Sugar Series. Part II. The Third Variety of Tetra-acetyl Methylmannoside. By HAROLD GRAHAM BOTT, WALTER NORMAN HAWORTH, and EDMUND LANGLEY HIRST . . . . .	1395
CLXXXII.—The Conversion of 1:2:3:4-Tetra-acetyl $\beta$ - <i>d</i> -Glucose into 2:3:4:6-Tetra-acetyl $\beta$ -Methylglucoside. By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and ETHEL GERTRUDE TEECE . . . . .	1405
CLXXXIII.—The Hydrolysis of Diacetyl- <i>o</i> -diamines. By MONTAGUE ALEXANDRA PHILLIPS . . . . .	1409
CLXXXIV.—The Sulphonation of <i>m</i> -Chlorophenol and Some New Halogenophenols. By HERBERT HENRY HODGSON and ARNOLD KERSHAW . . . . .	1419
CLXXXV.—A General (Exact) Equation to the Potentiometric-titration Curve. By BERNARD CAVANAGH . . . . .	1425
CLXXXVI.—Colloidal Platinum. Part VII. The Effect of Electrolytes upon the Cataphoretic Velocity of Platinum Particles, and its Bearing on Stability. By STUART W. PENNYCUICK . . . . .	1447
CLXXXVII.—A Simple Electrically Controlled Thermostat. By JOHN ARNOLD CRANSTON . . . . .	1458
CLXXXVIII.—The Constitution of Some Organic Derivatives of Thallium. By NEVIL VINCENT SIDGWICK and LESLIE ERNEST SUTTON . . . . .	1461
CLXXXIX.—The Polysulphides of the Alkali Metals. Part I. Sodium (i). By THOMAS GIBSON PEARSON and PERCY LUCOCK ROBINSON . . . . .	1473
CXC.—Heterocyclic Systems Containing Selenium. Part III. <i>cyclo</i> Selenopropane. By GILBERT T. MORGAN and FRANCIS HEReward BURSTALL . . . . .	1497
CXCI.—Pyrolysis of Diazoamino- <i>p</i> -toluene. By GILBERT T. MORGAN and LESLIE PERCY WALLS . . . . .	1502
NOTES.—The Mechanism of Cyanoacetamide and Cyanoacetic Ester Condensations. A Reply. By JOGENDRA CHANDRA BARDHAN . . . . .	1509
The Preparation of Anhydrous Oxalic Acid. By ERIC IAN JOHNSON and JAMES RIDDICK PARTINGTON . . . . .	1510
CXCII.—A New Isomerism of Halogenohydroxybenzoyl-toluic Acids. Part II. 2-(5'-Chloro-2'-hydroxybenzoyl)-5(4?)-methylbenzoic Acid. By MOSUKE HAYASHI . . . . .	1513

	PAGE
CXCIII.—A New Isomerism of Halogenohydroxybenzoyl-toluic Acids. Part III. 2-(3'-Chloro-4'-hydroxybenzoyl)-3(or 6)-methylbenzoic Acid. By MOSUKE HAYASHI . . . . .	1520
CXCIV.—A New Isomerism of Halogenohydroxybenzoyl-toluic Acids. Part IV. 2-(4'-Chloro-2'-hydroxybenzoyl)-3(or 6)-methylbenzoic Acid and 2-(2'-Chloro-4'-hydroxybenzoyl)-3(or 6)-methylbenzoic Acid. By MOSUKE HAYASHI . . . . .	1524
CXCV.—The Application of a New Type of Triode Valve to the Determination of Hydrogen-ion Concentration with Glass Electrodes. By GEOFFREY B. HARRISON . . . . .	1528
CXCVI.—Complex Formation amongst the Nitrates. Part II. The Ternary System Phenol-Silver Nitrate-Water. By CHARLES REYNOLDS BAILEY . . . . .	1534
CXCVII.—On the Dielectric Strengths of Some Explosive Mixtures containing Carbonic Oxide. By BERNARD WILLIAM BRADFORD and GEORGE INGLE FINCH . . . . .	1540
CXCVIII.—The Influence of a Soluble Fluoride on the Corrosion of Iron. By ARTHUR WILLIAM CHAPMAN . . . . .	1546
CXCIX.—The Solubility of Silver Chloride, Silver Bromide, and Silver Iodide and the Normal Potentials of Chlorine, Bromine, and Iodine in Methyl Alcohol and Ethyl Alcohol. By FREDERICK KARL VICTOR KOCH . . . . .	1551
CC.—The Rearrangement of the Alkylanilines. Part II. The Course of the Rearrangement in Presence of Metallic Salts. By WILFRED JOHN HICKINBOTTOM and (in part) ALLAN COLEY WAINE . . . . .	1558
CCI.—The Rearrangement of the Alkylanilines. Part III. The Formation of <i>p</i> -Aminoisobutylbenzene and of <i>p</i> -Amino- <i>tert</i> .-butylbenzene from <i>iso</i> Butylaniline. By WILFRED JOHN HICKINBOTTOM and GRAHAM HOLMES PRESTON . . . . .	1566
CCII.—Application of Thallium Compounds in Organic Chemistry. Part V. Thallous Ethoxide and Dimethylthallium Ethoxide. By ROBERT CHARLES MENZIES . . . . .	1571
CCIII.—Adsorption by Silicic Acid Gel in the System <i>n</i> -Butyl Alcohol-Benzene. By DAVID CHARLES JONES and LIONEL OUTRIDGE . . . . .	1574
CCIV.—Investigations on the Reactivity of Halogens in Various Types of Naphthalene Derivatives. Part II. By JOHN BALDWIN SHOESMITH and ALEXANDER MACKIE . . . . .	1584
CCV.—The Dissociation Constants of Quinine, Cinchonine, and Cinchonidine. By EDMUND BRYDGES RUDHALL PRIDEAUX and FRANCIS THOMAS WINFIELD . . . . .	1587

CCVI.—The Structures of the Octahydrocarbazoles. By SYDNEY GLENN PRESTON PLANT . . . . .	1595
CCVII.—The Co-ordination Compounds of Oximes. By OSCAR L. BRADY and MORRIS MARCUS MUERS . . . . .	1599
CCVIII.—Investigations of the Olefinic Acids. Part II. Preliminary Observations on the Occurrence of Spontaneous Tautomeric Change at Temperatures near the Boiling Point. By REGINALD PATRICK LINSTED . . . . .	1603
CCIX.—Properties of Conjugated Compounds. Part X. Variability in the Mode of Ester Addition to Butadiene Esters and Ketones. By ERNEST HAROLD FARMER and THAKORBHAI NARANJI MEHTA . . . . .	1610
CCX.—The Purification of Some Sensitive Ketones. By GEORGE ARMAND ROBERT KON . . . . .	1616
CCXI.—On the Spatial Configuration of the Single Valencies of Allene. By CHRISTOPHER KELK INGOLD and CHARLES WILLIAM SHOPPEE . . . . .	1619
CCXII.—10-Chloro-5 : 10-dihydrophenarsazine and its Derivatives. Part XIII. Absorption Spectra. By CHARLES STANLEY GIBSON, EDWARD STANLEY HISCOCKS, JOHN DOBNEY ANDREW JOHNSON, and JOHN LLOYD JONES . . . . .	1622
CCXIII.—The Solubility of Neodymium Sulphate in Water and in Sulphuric Acid Solutions at Various Temperatures. A New Hydrate. By JOHN ALBERT NEWTON FRIEND . . . . .	1633
CCXIV.—Studies in Complex Salts. Part III. The Effect of Alkyl Substitution on the Stability of the Dimalonate- cupriate Ion. By HARRY LISTER RILEY . . . . .	1642
CCXV.—The Vapour Pressure of Nickel Carbonyl. By JOHN STUART ANDERSON . . . . .	1653
CCXVI.—The Action of Aqueous Hydrofluoric Acid on Silica. By WILLIAM GEORGE PALMER . . . . .	1656
CCXVII.—The Electrical Conductivity of Butyric Acid- Water Mixtures. By JOHN GRINDLEY and CHARLES R. BURY . . . . .	1665
CCXVIII.—Stereoisomerism of Disulphoxides and Related Substances. Part VI. Co-ordination Compounds of Some Disulphides and Diamines. By G. MACDONALD BENNETT, A. NEVILLE MOSSES, and F. SYDNEY STATHAM . . . . .	1668
CCXIX.—The Optical Instability of Tervalent Carbonium Kations. The Transformation of <i>l</i> -Phenylmethylcarb- inyl <i>dl</i> - <i>p</i> -Toluenesulphinate into Optically Inactive <i>p</i> -Tolyl- $\alpha$ -phenylethylsulphone. By JOSEPH KENYON and HENRY PHILLIPS . . . . .	1676

	PAGE
CCXX.—3-Acetamido-4-hydroxyphenylstibinic Acid. By ISIDORE ELKANAH BALABAN . . . . .	1685
CCXXI.—The Solubilities of the Octahydrates of the Rare-earth Sulphates. By KENNETH S. JACKSON and KÜNTHER RIENÄCKER . . . . .	1687
CCXXII.—The Reaction between Aminophenylarsinic Acids and Carbon Disulphide. By JOHN GARWOOD EVERETT . . . . .	1691
CCXXIII.—Syntheses of Glucosides. Part V. Two New Syntheses of Rubiadin and Syntheses of 1-O-Methyl-rubiadin and of Rubiadin Glucoside. By ELFED THOMAS JONES and ALEXANDER ROBERTSON . . . . .	1699
NOTES.—Tetrabromodimethylquinoxaline. By GEORGE MACDONALD BENNETT and GERVAASE HEWITSON WILLIS . . . . .	1709
Compounds of Arsenious Chloride and Pyridine. By CHARLES STANLEY GIBSON, JOHN DORNEY ANDREW JOHNSON, and (the late) DUDLEY CLOETE VINING . . . . .	1710
CCXXIV.—Electrical Conductivity of Solutions in Phenol. By RICHARD MALCOLM DOLBY and PHILIP WILFRED ROBERTSON . . . . .	1711
CCXXV.—The Nature of the Alternating Effect in Carbon Chains. Part XXXIII. The Nitration of some Aromatic Sulphonium and Selenonium Salts. By JOHN WILLIAM BAKER and WILLIAM GEORGE MOFFITT . . . . .	1722
CCXXVI.—The Reaction of Bromine with Aliphatic Acids. Part IV. Succinic Acid. By EDWARD DAVID HUGHES and HERBERT BEN WATSON . . . . .	1733
CCXXVII.— $\beta$ -Naphtha-1-thioquinone and Dehydro-2-naphthol 1-Disulphide. By HERBERT AUBREY STEVENSON and SAMUEL SMILES . . . . .	1740
CCXXVIII.—The Constitution of Complex Metallic Salts. By FREDERICK GEORGE MANN . . . . .	1745
CCXXIX.—Studies in the Naphthalene Series. Part I. The Methylation of $\alpha$ -Naphthylamine. By BASKER GOKHLE and FREDERICK ALFRED MASON . . . . .	1757
CCXXX.—The Optical Resolution of 2:4-Dinitro-2'-methyl-diphenyl-6-carboxylic Acid. By (Miss) MARY STEPHEN LESSLIE and EUSTACE EBENEZER TURNER . . . . .	1758
CCXXXI.—The Orienting Influence of Free and Bound Ionic Charges on Attached Simple or Conjugated Unsaturated Systems. Part V. Nitration of Benzyl-diethylsulphonium Picrate. By ALFRED POLLARD and ROBERT ROBINSON . . . . .	1765
CCXXXII.—Strychnine and Brucine. Part XI. Note on Dihydrobrucine and Some Derivatives. By OSMAN ACHMATOWICZ, REGINALD CLIFFORD FAWCETT, (the late) WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON . . . . .	1769

CCXXXIII.—The Passivity of Metals. Part VI. A Comparison between the Penetrating Powers of Anions. By SIDNEY CHARLES BRITTON and ULICK RICHARDSON EVANS . . . . .	1773
CCXXXIV.—A Phase-rule Study of the Cobalt Chloride Colour Change. By HENRY BASSETT and (in part) HERBERT HARRY CROUCHER . . . . .	1784
CCXXXV.—The Mechanism of Thermal Decomposition of the Normal Olefins. By RICHARD VERNON WHEELER and WILLIAM LAURENCE WOOD. . . . .	1819
CCXXXVI.—The Asymmetric Photochemical Decomposition of Humulene Nitrosite by Circularly Polarised Light. By STOTHERD MITCHELL . . . . .	1829
CCXXXVII.—Studies on Hydrogen Cyanide. Part II. The Compounds formed by the Action of the Hydrogen Halides on Hydrogen Cyanide. By LEONARD ERIC HINKEL and RICHARD TREVOR DUNN . . . . .	1834
CCXXXVIII.—Stereoisomerism in Polycyclic Systems. Part VII. The Reduction of 7:8:9:10-Tetrahydroheptaquinoline. By SYDNEY GLENN PRESTON PLANT and REGINALD JOHN ROSSER . . . . .	1840
CCXXXIX.—The Constitution of Phenolphthalein. Part II. The Fading of Phenolphthalein in Alkaline Solution. By HAKON LUND . . . . .	1844
CCXL.—The Scission of Diaryl Ethers and Related Compounds by Means of Piperidine. Part V. The Nitration of Methyl-, Dimethyl-, and Polyhalogeno-derivatives of Diphenyl Ether. By (Miss) DOROTHY LILLIAN FOX and EUSTACE EBENEZER TURNER . . . . .	1853
CCXLI.—Studies in Aromatic Substitution. Part II. The Action of Fuming Nitric Acid on the 4-Fluoro-2:6-dihalogeno-phenols and -anisoles. By HERBERT HENRY HODGSON and JOSEPH NIXON . . . . .	1868
CCXLII.—Studies in Aromatic Substitution. Part III. The Action of Fuming Nitric Acid on the 3-Fluoro-2:4:6-trihalogeno-phenols and -anisoles. By HERBERT HENRY HODGSON and JOSEPH NIXON . . . . .	1870
CCXLIII.—The Action of Nitrous Acid on Resorcinol Diethyl Ether. By HERBERT HENRY HODGSON and HUBERT CLAY . . . . .	1872
CCXLIV.—Structure of the <i>iso</i> Cyanides and Other Compounds of Bivalent Carbon. By DALZIEL LL. HAMMICK, RANDAL C. A. NEW, NEVIL V. SIDGWICK, and LESLIE E. SUTTON . . . . .	1876

	PAGE
CCXLV.—Optical Activity and the Polarity of Substituent Groups. Part XIV. Influence of Substituent Poles and Dipoles on the Rotatory Power of 1-Menthyl Acetate. By H. GORDON RULE, R. H. THOMPSON, and (in part) A. ROBERTSON . . . . .	1887
CCXLVI.—Optical Activity and the Polarity of Substituent Groups. Part XV. Phenyl-substituted Esters and Ethers of 1-Menthol and $\beta$ -Octyl Alcohol. By H. GORDON RULE and JAMES BAIN . . . . .	1894
CCXLVII.—Solubility of Magnesium Neodymium Nitrate in Water, Nitric Acid, and Magnesium Nitrate Solutions. By JOHN ALBERT NEWTON FRIEND . . . . .	1903
CCXLVIII.—The Treatment of Cedrene with Mercuric Acetate. By JAMES BELL . . . . .	1908
CCXLIX.—The Arsinic Acids of <i>p</i> -Aminophenol. By MONTAGUE ALEXANDRA PHILLIPS . . . . .	1910
CCL.—Syntheses by Means of Magnesium Amyl Halides. Part II. The Reduction of Benzophenone. By WALTER CULE DAVIES, ROBERT SINCLAIR DIXON, and WILLIAM JACOB JONES . . . . .	1916
CCLI.—Organic Antimonial Compounds. Part II. By WILFRED JAMES CECIL DYKE and WILLIAM JACOB JONES . . . . .	1921
CCLII.—The Equilibrium between Acetone and Salts. By W. R. G. BELL, C. B. ROWLANDS, I. J. BAMFORD, W. G. THOMAS, and W. J. JONES . . . . .	1927
CCLIII.—Anthracene-1-carboxylic and -1:5-dicarboxylic Acids and their Derivatives. By EDWARD AUTY COULSON . . . . .	1931
Theodore William Richards Memorial Lecture. By SIR HAROLD HARTLEY, M.C., C.B.E., F.R.S. . . . .	1937
CCLIV.—The Nitrosation of Phenols. Part X. Further Study of the Nitrosation of <i>m</i> -Iodophenol. By HERBERT HENRY HODGSON and ARNOLD KERSHAW . . . . .	1969
CCLV.—The Chemistry of the Caryophyllene Series. Part III. Clovene Alcohol and $\alpha$ -Caryophyllene Alcohol. By JAMES BELL and GEORGE GERALD HENDERSON . . . . .	1971
CCLVI.—The Conditions determining the Thermodynamic Stability of Cyanohydrins of Carbonyl Compounds. Part II. Dissociation Constants of some Cyanohydrins derived from Methyl Alkyl and Phenyl Alkyl Ketones. By ARTHUR LAPWORTH and RICHARD HELMUTH FRED MANSKE . . . . .	1976

CCLVII.—The Migration of Acyl Groups in <i>o</i> -Aminophenols. By FRANK BELL . . . . .	1981
CCLVIII.—The Structure of the Tungstic Acids. By ARTHUR MILNES MORLEY . . . . .	1987
CCLIX.—Syntheses in the Indole Series. Part IV. De- rivatives of 2:3-Benz- $\gamma$ -carboline. By WILLIAM OGILVY KERMACK and JAMES FERGUS SMITH . . . . .	1999
CCLX.—The Ternary System Carbamide-Ammonium Nitrate-Sodium Nitrate. By WILLIAM JOHN HOWELLS . . . . .	2010
CCLXI.—The Walden Inversion. Part III. By HANS NICOLAI KELLERMANN RÖRDAM . . . . .	2017
CCLXII.—The Parachor of Co-ordinated Hydrogen in the Ortho-substituted Phenols. By NEVIL V. SIDGWICK and NOEL S. BAYLISS . . . . .	2027
NOTES.—Methylfurfuraldehyde Oxide as a By-product in the Preparation of Hydroxymethylfurfuraldehyde. By J. R. C. CHANDRASENA . . . . .	2035
The Action of Freshly Precipitated Mercuric Oxide on a Suspension of 3:5-Dinitrotoluene in Aqueous Sodium Hydroxide. A Novel Preparation of 3:5-Dinitro- <i>p</i> - cresol. By H. H. HODGSON and E. W. SMITH . . . . .	2035
CCLXIII.—The Catalytic Action of Hydrogen on the Carbon Monoxide Flame. By W. E. GARNER and D. A. HALL . . . . .	2037
CCLXIV.—Aromatic Arsenic Compounds containing Sulphur Groups attached to the Nucleus. Part I. Sulphonic Acids and their Derivatives. By HARRY JAMES BARBER . . . . .	2047
CCLXV.—A Simple Electrochemical Method for the Simul- taneous Determination of the Constitution and Equi- librium Constant of Complex Ions in Solution. Applica- tion to Complex Silver Ions. By FREDERICK KARL VICTOR KOCH . . . . .	2053
CCLXVI.—Investigations of the Olefinic Acids. Part III. Homologues of Teraconic, Terebic, and Pyroterebic Acids. Further Evidence of the Effect of Two $\gamma$ -Alkyl Groups on Three-carbon Tautomerism. By REGINALD PATRICK LINSTAD and JASON THOMAS WILLIAM MANN . . . . .	2064
CCLXVII.—The Photochemical Reaction between Oxygen and Hydrogen Chloride. By ARTHUR JOHN ALLMAND and REGINALD GEORGE FRANKLIN . . . . .	2073
CCLXVIII.—Heats of Adsorption and Isotherms in the System Platinum-Hydrogen. By EDWARD BRADFORD MAXTED . . . . .	2093

	PAGE
CCLXIX.—The Behaviour of Molybdenum Pentachloride in Organic Solvents. By WILLIAM WARDLAW and HARRY WILLIAM WEBB . . . . .	2100
CCLXX.—Degradation of Quaternary Ammonium Salts. Part II. By THOMAS STEVENS STEVENS . . . . .	2107
CCLXXI.—Degradation of Quaternary Ammonium Salts. Part III. By THOMAS STEVENS STEVENS, WILLIAM WHITELAW SNEDDEN, ERIC THOMAS STILLER, and THOMAS THOMSON . . . . .	2119
CCLXXII.—Conductivity Measurements of the Comparative Rates of Hydrolysis of Lactones Derived from Simple Sugars. By SYDNEY RAYMOND CARTER, WALTER NORMAN HAWORTH, and ROBERT ANTHONY ROBINSON . . . . .	2125
CCLXXIII.—The Synthesis of <i>iso</i> Indenoquinolines. Part I. By GEORGE ROGER CLEMO and HERBERT JOHN JOHNSON . . . . .	2133
CCLXXIV.—The Titrimetric Determination of Primary Arsinic Acids. By HAROLD KING and GEORGE VICTOR RUTTERFORD . . . . .	2138
CCLXXV.—Investigations on the Bivalency of Carbon. Part IV. Halogen Displacements from <i>s</i> -Tetra-bromo- and -chloro-ethane and Tri-bromo- and -chloro-ethylene. By ALLAN MILES WARD . . . . .	2143
CCLXXVI.—Syntheses of Cyclic Compounds. Part VII. The Stereoisomeric $\beta\gamma$ -Diphenyladipic Acids. By MARIAM P. OOMMEN and ARTHUR ISRAEL VOGEL . . . . .	2148
CCLXXVII.—Physicochemical Studies of Complex Acids. Part III. Molybdic Acid. By HUBERT THOMAS STANLEY BRITTON and WILLIAM LESLIE GERMAN . . . . .	2154
CCLXXVIII.—The Methylation of Phenols by Methyl Sulphate. A Suggested Mechanism. By HERBERT HENRY HODGSON and JOSEPH NIXON . . . . .	2166
CCLXXIX.—The Dinitration of Monosulphonated <i>m</i> -Chlorophenol and the Sulphonation and Subsequent Further Nitration of 3-Chloro-2- and -6-nitro-phenols. By HERBERT HENRY HODGSON and ARNOLD KERSHAW . . . . .	2169
CCLXXX.—Studies of the Boron-Carbon Linkage. Part I. The Oxidation and Nitration of Phenylboric Acid. By ARTHUR DONALD AINLEY and FREDERICK CHALLENGER . . . . .	2171
CCLXXXI.—Acid and Salt Effects in Catalysed Reactions. Part XXIV. A Study of the Catalytic Effects produced by Acetic Acid and Acetate Buffers under Conditions of Effectively Constant Ionic Environment. By HARRY MEDFORTH DAWSON and ERIC SPIVEY . . . . .	2180

CCLXXXII.—The Unsaturation and Tautomeric Mobility of Heterocyclic Compounds. Part III. The Effect of Substituents on the Mobility of the Aminobenzthiazole System and on the Bromination of <i>s</i> -Diarylthiocarbamides. The Ultra-violet Absorption of Mobile and of Static Semicyclic Amidines of the Benzthiazole Group. By ROBERT FERGUS HUNTER and JOHN WILLIAM THOMAS JONES . . . . .	2190
NOTES.—Note on the Drying of Gas Streams. By LOUIS LEIGHTON BIRCUMSHAW . . . . .	2213
Action of Monochlorodimethyl Ether on Magnesium Benzyl Chloride. By ARTHUR CECIL BOTTOMLEY, ARTHUR LAPWORTH, and ARTHUR WALTON . . . . .	2215
CCLXXXIII.—The Chemistry of the Three-Carbon System. Part XXV. The Effect of the Methyl Group on the Tautomerism of Acids and Ketones of the <i>cyclo</i> Pentane and <i>cyclo</i> Hexane Series. By GEORGE ARMAND ROBERT <del>KERR</del> and RAJ SINGHA THAKUR . . . . .	2217
CCLXXXIV.—Direct Meta-substitution in the Toluene Nucleus. By JOHN BALDWIN SHOESMITH and JOHN FINNIE MCGEEHEN . . . . .	2231
CCLXXXV.—Comparison of the Directive Powers of Elements having Consecutive Atomic Numbers. Part II. The Mononitrations of 2-Phenylquinoline and its Methosulphate. By RAYMOND JAMES WOOD LE FEVRE and FAQIR CHAND MATHUR . . . . .	2236
CCLXXXVI.—Low-temperature Oxidation. Part III. The Lag in Ignition of Some Hydrocarbons. By JOHN STANLEY LEWIS . . . . .	2241
CCLXXXVII.—Hydrochloric Acid Solutions of Iodine Monochloride. By FREDERICK ARTHUR PHILBRICK . . . . .	2254
CCLXXXVIII.—The Preparation of the Optically Active Phenylmethylcarbinols. By ARMAND JOSEPH HENRI HOUSSA and JOSEPH KENYON . . . . .	2260
CCLXXXIX.—The Partial Specific Volume of Potassium <i>n</i> -Octoate in Aqueous Solution. By DAVID GWYNNE DAVIES and CHARLES R. BURY . . . . .	2263
CCXC.—Investigations in the Diphenylene Oxide Series. Part II. By NICHOLAS MICHAEL CULLINANE . . . . .	2267
CCXCI.—Benzoic Esters and Electronic Affinities of Radicals. Part II. The Halogenoalkyl Benzoates. By AHMAD ZAKI . . . . .	2269

*List of Physico-chemical Symbols adopted by the Chemical Society.*

[See J.C.S., 1921, 119, 502—512.]

1. *Mathematical Symbols.*

	Usual symbol.	Alternative symbol.
Base of natural (Napierian) logarithms ...	$e$	
Diameter	$d$	
Radius .....	$r$	
Ratio of circumference to diameter	$\pi$	
Summation.....	$\Sigma$	
Variation .....	$\delta$	
Total differential .....	$d$	
Partial differential .....	$\partial$	

2. *Universal Constants.*

Acceleration due to gravity.....	$g$
Mechanical equivalent of heat .....	$J$
Avogadro's constant [number of molecules in 1 gram-molecule (mole)] .....	$N$
Gas constant per mole .....	$R$
Faraday's constant (number of coulombs per gram-equivalent of an ion) .....	$F$
Charge on an electron .....	$e$

3. *General Physics and Chemistry.*

Length .....	$l$	
Height.....	$h$	
Mass .....	$m$	
Time .....	$t$	
Volume .....	$v, V$	
Density (mass per unit volume) .....	$d$	$D$
Pressure .....	$p, P$	
Concentration .....	$c, C$	
Mole fraction .....	$x$	
Critical constants: pressure, volume, tem- perature (centigrade), temperature (absolute), density .....	$\left\{ \begin{array}{l} p_c, v_c \\ t_c, T_c \\ d_c \end{array} \right.$	
Reduced quantities: pressure, volume, temperature, density .....	$\left\{ \begin{array}{l} p_r, v_r \\ t_r, T_r, d \end{array} \right.$	
van der Waals's constants .....	$a, b$	
Fluidity .....	$\phi$	
Viscosity .....	$\eta$	
Surface tension .....	$\gamma$	
Diffusion coefficient .....	$\Delta$	
Atomic weight .....	$A$	
Molecular weight .....	$M$	
Velocity coefficient of reaction .....	$k$	
Equilibrium constant .....	$K, (K_p, K_c)$	
van 't Hoff coefficient .....	$i$	
Degree of dissociation (electrolytic, thermal, etc.) .....		

## 4. Heat and Thermodynamics.

	Usual symbol.	Alternative symbol.
Temperature (centigrade) .....	$t$	
Temperature (absolute) .....	$T$	
Critical temperature .....	$t_c, T_c$	
Reduced temperature .....	$t_r, T_r$	
Critical solution temperature .....	$t_{cs}, T_{cs}$	
Quantity of heat .....	$Q$	
Entropy .....	$S$	
Specific heat .....	$c$	
Specific heat at constant pressure .....	$c_p$	
Specific heat at constant volume .....	$c_v$	
Ratio of specific heats, $c_p : c_v$ .....	$\gamma$	
Molecular heat .....	$O$	
Molecular heat at constant pressure .....	$C_p$	
Molecular heat at constant volume .....	$C_v$	
Latent heat per gram .....	$l$	
Latent heat per mole .....	$L$	
Maximum work (diminution of free energy) .....	$A$	

## 5. Optics.

Wave-length of light .....	$\lambda$	
Refractive index .....	$n$	
Specific refractive power (Gladstone and Dale) .....	$r_g, [r_g]_\lambda^D$	
Specific refractive power (Lorentz and Lorenz) ..	$r_L, [r_L]_\lambda^D$	
Molecular refractive power ..	$R_g, R_L$ $[R_g]_\lambda^D, [R_L]_\lambda^D$	
Angle of optical rotation .....	$[\alpha]$	
Specific rotatory power .....	$M[\alpha]$	
Molecular rotatory power ..	$[\omega]$	
Specific magnetic rotation ..	$M[\omega]$	

## 6. Electricity and Magnetism.

Quantity of electricity ..	$Q$	
Current intensity .....	$I$	
Resistance .....	$R$	$W$
Electromotive force .....	$E$	
Electrode potential, or discharge potential of an ion .....	$E$	$\epsilon$
Electrode potential referred to the normal hydrogen or normal calomel electrode respectively, the potential of which is taken as zero .....	$E_h, E_c$	$\epsilon_h, \epsilon$
Normal potential, i.e., the electrode potential referred to the normal hydrogen or normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration .....	${}_0E_h, {}_0E_c$	${}_0\epsilon_h, {}_0\epsilon$
Dielectric constant .....	$\epsilon$	
Conductivity (specific conductance) .....	$\kappa$	
Equivalent conductivity .....	$\Lambda$	
Equivalent conductivity at different dilutions—volumes in litres containing 1 gram equivalent .....	$\Lambda_{10}, \Lambda_{20}, \Lambda_{\infty}$	

6. *Electricity and Magnetism*—(continued).

	Usual symbol.	Alternative symbol.
Equivalent conductivity of cation and of anion .....	$\Lambda_k, \Lambda_a$	
Equivalent conductivity of specified ions...	$\Lambda_K, \Lambda_{Cl}$	
Molecular conductivity .....	$\mu$	
Velocity of cation and of anion in cm./sec. when the potential gradient is 1 volt per cm. ....	$U_k, U_a$	
Transport number of kation and of anion ...	$n_k, n_a$	
Magnetic permeability .....	$\mu$	
Magnetic susceptibility .....	$\kappa$	

*List of Symbols, Arranged Alphabetically.*

Symbol.	Name of quantity.
$A$	Atomic weight; maximum work.
$a$	Van der Waals's constant.
$b$	Van der Waals's constant.
$C$	Concentration; molecular heat.
$c$	Concentration; specific heat.
$C_p, C_v$	Molecular heat at constant pressure, and at constant volume.
$c_p, c_v$	Specific heat at constant pressure, and at constant volume.
$D$	Alternative symbol for density.
$d$	Diameter; total differential; density.
$d_c$	Critical density.
$d$	Reduced density.
$E$	Electromotive force; electrode potential.
$e$	Base of Napierian logarithms; charge on an electron.
$E_h, E_c$	Electrode potential referred to the normal hydrogen or the normal calomel electrode, respectively, the potential of which is taken as zero.
${}_0E_h, {}_0E_c$	Normal potential, that is, the electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration.
$F$	Faraday's constant (number of coulombs per gram-equivalent of an ion).
$g$	Acceleration due to gravity.
$h$	Height.
$I$	Current.
$i$	Van 't Hoff's coefficient.
$J$	Mechanical equivalent of heat.
$K$	Equilibrium constant.
$K_e, K_p$	Equilibrium constant, when molar concentrations and partial pressures respectively are employed.
$k$	Velocity coefficient of reaction.
$L$	Latent heat per mole.
$l$	Length; latent heat per gram.
$M$	Molecular weight.
$M[\alpha]$	Molecular rotatory power.
$M[\omega]$	Molecular magnetic rotatory power.
$m$	Mass.
$N$	Avogadro's constant (Loschmidt's number) or number of molecules in 1 gram-molecule.
$n$	Refractive index.

*List of Symbols, Arranged Alphabetically—(continued).*

Symbol.	Name of quantity.
$n_+, n_-$	Transport number of cation and of anion.
$n_r$	Refractive index (alternative symbol).
$P$	Pressure.
$p$	Pressure.
$p_c, p_r$	Critical pressure : reduced pressure.
$Q$	Quantity of heat; quantity of electricity.
$R$	Gas constant per mole; electrical resistance.
$R_G, R_L$	Molecular refractive power, according to Gladstone and Dale, and to Lorentz and Lorenz respectively.
$r$	Radius.
$r_G, r_L$	Specific refractive power according to Gladstone and Dale, and to Lorentz and Lorenz respectively.
$S$	Entropy.
$T$	Absolute temperature.
$T_c$	Critical temperature (on the absolute scale).
$T_r$	Reduced temperature (absolute).
$T_{c,1}$	Critical solution temperature (absolute).
$t$	Time; temperature (centigrade).
$t_c$	Critical temperature (centigrade).
$t_{c,1}$	Critical solution temperature (centigrade).
$t_r$	Reduced temperature (centigrade).
$U_+, U_-$	Velocity of kation and of anion in cm./sec. when the potential gradient is 1 volt per cm.
$V$	Volume.
$v$	Volume.
$v_c, v_r$	Critical volume : reduced volume.
$W$	Electrical resistance (alternative symbol).
$w$	Mole fraction.
$\alpha$	Degree of dissociation (electrolytic, thermal, etc.); angle of optical rotation.
$[\alpha]$	Specific rotatory power.
$\gamma$	Surface tension; ratio of specific heats.
$\Delta$	Diffusion coefficient.
$\delta$	Variation.
$\partial$	Partial differential.
$\epsilon$	Electrode potential (alternative symbol); dielectric constant.
$\epsilon_h, \epsilon$	Electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, the potential of which is taken as zero (alternative symbols).
$\phi, \phi_h, \phi^e$	Normal potential, that is, the electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration (alternative symbols).
$\eta$	Viscosity.
$\theta$	Temperature (centigrade), (alternative symbol).
$\kappa$	Specific conductance (conductivity); magnetic susceptibility.
$\Lambda$	Equivalent conductivity.
$\Lambda_{10}, \Lambda_v, \Lambda_\infty$	Equivalent conductivity at different dilutions (volumes in litres containing 1 gram-equivalent).
$\Lambda_+, \Lambda_-$	Equivalent conductivity of cation and of anion.
$\lambda$	Wave-length of light.
$\mu$	Molecular conductivity; magnetic permeability.
$\pi$	Ratio of circumference to diameter.
$\Sigma$	Summation.
$\sigma$	Surface tension (alternative symbol).
$\phi$	Fluidity.
$[\omega]$	Specific magnetic rotation.

### I.—*Stereoisomerism of Disulphoxides and Related Substances. Part V. The Dioxides of 3:5-Dimethylthiolbenzoic Acid.*

By ERNEST VERE BELL and GEORGE MACDONALD BENNETT.

IN Part III (J., 1928, 3189) a number of pairs of diastereoisomeric disulphoxides of the type  $A\cdot SO\cdot B\cdot SO\cdot A$  were described. Of the two isomerides in such cases, one should be an internally compensated substance, the other externally compensated and potentially optically active. Confirmation of this view was not possible in the examples referred to, owing to the absence of any group in the molecule which would allow of a resolution into the optically active antipodes. The isolation of a suitable pair of disulphoxides is now described, one of which is shown to be separable into enantiomorphous forms.

The substance first studied proved to be unsuitable, for although *s*-diphenylthiolethane-*mm'*-dicarboxylic acid,  $C_2H_4(S\cdot C_6H_4\cdot CO_2H)_2$ , when oxidised in the form of its dimethyl ester, yielded a pair of dioxides, of m. p.  $195^\circ$  and  $126\text{--}129^\circ$  respectively, the hydrolysis of the ester dioxides was accompanied by a disruption of the molecule so that the isomeric free acids were not isolated. This reaction, which has not yet been investigated in detail, is reminiscent of the scission of 1:4-disulphones by alkalis (Stuffer, *Ber.*, 1890, 23, 1408, 3226).

Attention was then directed to 3:5-dimethylthiolbenzoic acid, which was synthesised as follows.

Carboxybenzene-3:5-disulphonyl chloride, the method of preparation of which was improved, was reduced in the usual manner, and the resulting 3:5-dithiolbenzoic acid isolated in the form of its disulphide, 3:5-disulphidobenzoic acid. Methylation of the regenerated dithiol yielded the required dimethylthiolbenzoic acid. The product of oxidation of this acid by hydrogen peroxide was separated by fractional crystallisation into the  $\alpha$ -dioxide, m. p.  $251^\circ$  (decomp.), and the  $\beta$ -dioxide, m. p.  $209^\circ$  (decomp.), which were present in approximately equal proportion.

Considerable difficulty was found in effecting a resolution of either of these isomerides into optically active forms, perhaps on account of the weakness of the acid caused by the presence in the molecule of two sulphoxyl groups of definitely basic properties. The salts of these acids with strychnine, cinchonine, quinine, *l*-menthylamine and the active phenylethylamines could not be obtained crystalline, but those with brucine were suitable for study. The brucine salt of the  $\alpha$ -dioxide was recrystallised unchanged, whereas that of the  $\beta$ -isomeride showed a continuous increase of rotatory power when it was fractionally crystallised from chloroform. Owing to lack of material, the process had to be interrupted after seven crystallisations when it was still evidently incomplete. The acid recovered from the salt of highest rotation was 1-3 : 5-dimethylthiolbenzoic acid dioxide of m. p. 200—202° (decomp.) and had  $[\alpha]_D -99.6^\circ$  for a 1.89% aqueous solution.

From the mother-liquors of the separation an acid was recovered having a positive rotation  $[\alpha]_D +9.1^\circ$  in 2% aqueous solution. When this was fractionally crystallised, the mother-liquors furnished a dextrorotatory acid having  $[\alpha]_D +22.7^\circ$  in 2.64% aqueous solution. The purification could not be carried further with the amount of acid available.

Although the optically active acids were thus not isolated in a state of optical purity, the results afford confirmation of the stereochemical relationship of the pairs of disulphoxides under discussion : the  $\alpha$ -dioxide of dimethylthiolbenzoic acid has the *meso*-configuration, the  $\beta$ -dioxide being potentially active.

#### EXPERIMENTAL.

*s*-Diphenylthiolethane-mm'-dicarboxylic Acid.—*m*-Dithiobenzoic acid (92 g.) was reduced by heating with glucose (92 g.) and sodium hydroxide (48 g. in 100 c.c. of water) in alcohol (300 c.c.) under reflux and addition of a further equal amount of alkali during  $\frac{1}{2}$  hour, followed by ethylene dibromide (65 g.). The solution was cooled and acidified, and the *diphenylthiolethane-mm'-dicarboxylic acid* collected, washed, and dried (yield, 86 g.). It separated from boiling acetic acid as a white micro-crystalline powder, m. p. 265° (decomp.), insoluble in most solvents (Found : C, 57.1; H, 4.45.  $C_{16}H_{14}O_4S_2$  requires C, 57.5; H, 4.2%).

Oxidation of the sodium salt with hydrogen peroxide in aqueous solution yielded a product so sparingly soluble that a pure substance could not be isolated.

The acid (48 g.), dissolved in alkali (17.2 g. of potassium hydroxide in 30 c.c. of water), was added to methyl sulphate (37.6 g.) on the steam-bath. The *dimethyl* ester obtained, after crystallising thrice

from methyl alcohol, formed prisms, m. p.  $73^{\circ}$ , soluble in all the ordinary solvents (Found: C, 59.7; H, 5.0.  $C_{18}H_{18}O_4S_2$  requires C, 59.7; H, 5.0%).

*Isomeric Dioxides of Dimethyl Diphenylthioethanedicarboxylate.*—The ester (25 g.) in glacial acetic acid (500 c.c.) was oxidised with hydrogen peroxide (18.4 g. of 25.9%  $H_2O_2$ ). After 48 hours the solution was evaporated, and the residue fractionally crystallised from 50% acetic acid. The less soluble  $\alpha$ -dioxide was readily obtained pure (yield, 10 g.) and the m. p.,  $195^{\circ}$  (decomp.), was unchanged by further crystallisation (Found: C, 54.2; H, 4.9.  $C_{18}H_{18}O_6S_2$  requires C, 54.8; H, 4.6%).

This substance, reduced with zinc dust and hydrochloric acid in acetic acid, yielded the parent disulphide, m. p.  $73^{\circ}$ , as proved by direct comparison and the m. p. of a mixture.

From the mother-liquors of the above crystallisation a much more soluble  $\beta$ -dioxide was isolated; after being recrystallised several times from methyl alcohol, it melted at  $126$ – $129^{\circ}$  (decomp.). Like the  $\alpha$ -isomeride it yielded the parent disulphide by reduction; there can be little doubt that it is a disulphoxide, but by an oversight the specimen was hydrolysed without having been analysed.

Hydrolysis of these dioxides by alcoholic potassium hydroxide caused some profound disruption of the molecule, the crude acid obtained having an equivalent of 113 (in place of the expected 185).

*Disulphonation of Benzoic Acid.*—By the following modification of Barth and Senhofer's method (*Annalen*, 1871, 159, 217) the use of a sealed tube was avoided and the product isolated as sulphonyl chloride. Benzoic acid (120 g.) was heated in an open flask with fuming sulphuric acid (240 c.c. of 40%  $SO_3$ ) and phosphoric oxide (180 g.) at  $200^{\circ}$  for 1 hour and at  $250^{\circ}$  for 2 hours. The mixture was cooled, chlorosulphonic acid (600 c.c.) added, and the temperature raised to and kept at  $150$ – $180^{\circ}$  for 1 hour so that the chlorosulphonic acid boiled without escaping. The liquid when cool was run slowly into ice-water, and the crude disulphonyl chloride filtered off, washed, and dried (average yield in four preparations, 102 g.).

The carboxybenzene-3:5-disulphonyl chloride crystallised from benzene in stout needles, m. p.  $193^{\circ}$  (Found: Cl, 22.0. Calc.: Cl, 22.3%). Hopegartner (*Monatsh.*, 1893, 14, 690) gives m. p.  $183^{\circ}$ .

*Preparation of 3:5-Dimethylthiolbenzoic Acid.*—Carboxybenzene-disulphonyl chloride (120 g.), dissolved in glacial acetic acid (1800 c.c.) in a 10-litre flask, was reduced by the addition of concentrated hydrochloric acid (280 c.c.) and then, in small portions and with vigorous mechanical stirring, zinc dust (72 g.). When all had dissolved, like amounts of acid and zinc dust were added in a

similar manner. The mixture was allowed to become hot during the process (2—3 hours). The solution was warmed on the steam-bath, and ferric chloride (240 g.) added. Precipitation of the disulphide was hastened by dilution with water and the product was collected, washed, and dried at  $100^{\circ}$  (average yield, 66 g.). 3 : 5-Di-sulphidobenzoic acid was thus obtained as a white powder, m. p.  $195-200^{\circ}$  (decomp.), so sparingly soluble in all available solvents that it could not be crystallised. It has no doubt a much higher molecular weight than that indicated by the formula (Found : S, 33.7.  $C_7H_4O_2S_2$  requires S, 34.8%).

Reduction of this disulphidobenzoic acid (46 g.) was effected by heating with glucose (53 g.) and alcohol (250 c.c.) during the gradual addition of sodium hydroxide (50 g. in 100 c.c. of water). The mixture was then cooled, and methyl sulphate (63 g.) carefully added. After several hours the alcohol was removed in steam and the product precipitated by acidification was collected, washed, and dried at  $100^{\circ}$  (yield, 38 g.). 3 : 5-Dimethylthiolbenzoic acid crystallises from ethyl acetate in square or hexagonal-shaped plates, m. p.  $153^{\circ}$  (Found : S, 29.9; equiv., by titration, 214.  $C_9H_{10}O_2S_2$  requires S, 29.9%; equiv., 214). The sodium salt is very readily soluble in water, but crystallises well from ethyl acetate in clusters of radiating needles, m. p.  $283^{\circ}$  (decomp.) (Found : Na, 9.5.  $C_9H_9O_2S_2Na$  requires Na, 9.7%).

*Oxidation of Dimethylthiolbenzoic Acid to a Pair of Dioxides.*—Hydrogen peroxide (132 g. of 25% strength), diluted with acetic acid (350 c.c.), was gradually added to a solution of dimethylthiolbenzoic acid (104 g.) in acetic acid (2420 c.c.). After 12 hours, the solvent was removed in steam, and the solution evaporated and kept in a vacuum over sodium hydroxide. The crude mixture of dioxides (119 g.) was powdered and extracted with boiling 90% aqueous alcohol (480 c.c.). The residue (39 g.),  $\alpha$ -3 : 5-dimethylthiolbenzoic acid dioxide, was recrystallised from 90% alcohol. The substance crystallises from hot water in long prisms, m. p.  $251^{\circ}$  (decomp.) (Found : S, 26.0; equiv., by titration, 245.6.  $C_9H_{10}O_4S_2$  requires S, 26.0%; equiv., 246.2).

The alcoholic extract of the crude dioxides deposited crystals of  $\beta$ -3 : 5-dimethylthiolbenzoic acid dioxide on cooling, which were purified by several crystallisations from ethyl alcohol (yield, 20 g.). The substance crystallises from water in tufts of fine needles, m. p.  $209^{\circ}$  (decomp.), and is much more soluble in ethyl alcohol and water than the  $\alpha$ -isomeride (Found : S, 25.9%; equiv., by titration, 245.3).

*Examination of the  $\alpha$ - and  $\beta$ -Dioxides as to the Possibility of Resolution into Optically Active Components.*— $\alpha$ -3 : 5-Dimethyl-

thiolbenzoic acid dioxide was dissolved with brucine (1 mol.) in hot chloroform, and the *brucine* salt obtained in large plates containing chloroform of crystallisation. The solvent was removed at 100° in a vacuum; the residual powder had m. p. 170—175° (decomp.) (Found: N, 4.5.  $C_{32}H_{36}O_8N_2S_2$  requires N, 4.4%). The salt, which was very soluble in chloroform, was recrystallised twice from this solvent.

A solution of the ammonium salt of this acid, recovered from the brucine salt by the action of aqueous ammonia and repeatedly extracted with chloroform to remove all the alkaloid, was found to be optically inactive.

The *brucine* salt of  $\beta$ -3 : 5-dimethylthiolbenzoic acid dioxide was prepared in chloroform solution, from which it crystallised in large plates containing solvent of crystallisation. The solvent was lost gradually in air and completely at 100° in a vacuum. The dried salt had m. p. 130° (Found: N, 4.7%) and was readily soluble in chloroform, but sparingly soluble in other solvents. The optical rotatory power in chloroform was  $[\alpha]_D -28.4^\circ$  ( $c = 10.3$ ,  $l = 0.5$ ) and became, after successive crystallisations from this solvent ( $c = 10$ ),  $-28.4^\circ$ ,  $-36.5^\circ$ ,  $-41.5^\circ$ ,  $-46.4^\circ$ ,  $-48.7^\circ$ ,  $-50.0^\circ$ ,  $-52.0^\circ$ ,  $-59.7^\circ$ . At this point the salt had m. p. 184° and was not optically pure, but the quantity of material was not sufficient for further fractionation. The salt (3.5 g.) was decomposed by aqueous ammonia and freed from brucine by repeated extraction of the solution with chloroform. The ammonium salt was converted into the barium salt by means of an excess of barium hydroxide, the ammonia driven off, and carbon dioxide passed in to remove the excess of baryta. The solution was filtered, and the exact equivalent of sulphuric acid (determined on a portion) added. After the barium sulphate had been removed, the solution was evaporated to dryness on the water-bath. The 1-3 : 5-dimethylthiolbenzoic acid dioxide thus obtained (1.4 g.) crystallised from 50% alcohol in minute needles with a straight extinction, m. p. 200—202° (decomp.). It was readily soluble in water or alcohol. Its rotatory power in water was  $[\alpha]_D -99.65^\circ$  ( $c = 1.887$ ,  $l = 2$ ,  $\alpha = -3.76^\circ$ ) (Found: S, 26.0.  $C_9H_{10}O_4S_2$  requires S, 25.9%).

From the chloroform mother-liquors a brucine salt was recovered which had m. p. 140° (decomp.) and a rotatory power of  $[\alpha]_D +0.59^\circ$  in chloroform ( $c = 10$ ,  $l = 0.5$ ).

The salt was freed from brucine and, by the method described above, an optically impure acid (9 g.) was recovered which had  $[\alpha]_D +9.09^\circ$  in water ( $c = 1.980$ ,  $l = 2$ ). When this was recrystallised from ethyl alcohol, the more active portions were found in the mother-liquor, and by fractional crystallisation an optically impure

d-3:5-dimethylthiolbenzoic acid dioxide was obtained, m. p. 190—205° (decomp.), having  $[\alpha]_D + 22.7^\circ$  in water ( $c = 2.640$ ,  $l = 0.5$ ). (Found: S, 25.4%).

THE UNIVERSITY, SHEFFIELD.

[Received, November 8th, 1929.]

## II.—*Pellitorine, the Pungent Principle of Anacyclus pyrethrum.*

By JOHN MASSON GULLAND and GERALD UERN HOPTON.

WITH one exception, the pungent acid amides of known constitution which occur in nature are alike in containing an aromatic nucleus either in the basic or in the acidic radical. For example, piperine and chavicine (Ott and Eichler, *Ber.*, 1922, 55, 2653; Ott and Lüdemann, *Ber.*, 1924, 57, 214) are piperides of piperic acid and its geometrical isomeride, chavicic acid, respectively, and capsaicin has been shown to be a decenovanillylamide by Nelson (*J. Amer. Chem. Soc.*, 1919, 41, 1115). This characteristic is shared, moreover, by the synthetical pungent amides, which are either derivatives of benzylamine (chiefly vanillylamine) (Nelson, *ibid.*, p. 2121; Ott and Zimmermann, *Annalen*, 1921, 425, 314; Jones and Pyman, *J.*, 1925, 127, 2588) or piperides of arylated (chiefly phenylated) aliphatic acids (Scholtz, *Ber.*, 1895, 28, 1196; Staudinger and Schneider, *Ber.*, 1923, 56, 699; Staudinger and Müller, *ibid.*, p. 711).

The sole exception to these statements is spilanthol, the pungent principle of para cress, *Spilanthus acmella*, Murr. (*S. oleracea*) (Asahina and Asano, *J. Pharm. Soc. Japan*, 1920, 503), whose dihydro-derivative is *n*-decoisobutylamide (*ibid.*, 1922, 85). It is therefore a matter of considerable interest to record the isolation of a purely aliphatic, pungent acid amide, pellitorine, from *Anacyclus pyrethrum*, DC., a plant native to North Africa and gathered chiefly in Algeria. The root of this plant is used medicinally under the names *Pyrethri radix* and pellitory root to stimulate the activity of the salivary glands, and an alcoholic extract was formerly prescribed for the alleviation of bronchitis. The powdered root resembles snuff in appearance, and when chewed causes a persistent tingling sensation and partial insensibility of the tongue, accompanied by profuse salivation (Brit. Pharmacopœia, 1914, p. 322; Squire's "Companion" to the B.P., 1916, p. 1112).

The pungent constituent of pellitory root was first examined by Buchheim (*Arch. exp. Path. Pharm.*, 1876, 5, 455), who isolated a syrup which slowly solidified to a mass of waxy microscopic needles

of very low melting point. He named this material "pyrethrin" and classified it as an amide allied to piperine. By hydrolysis he obtained an oily acid and a base, of which the sulphate was erroneously stated to exhibit all the properties of piperidine sulphate. Later, Dunstan and Garnett (J., 1895, 67, 100) obtained a brown resin which partly crystallised on long standing. They called this product "pellitorine"\* and stated, without advancing any real experimental support, that on hydrolysis it gave rise to what appeared to be a pyridine derivative possessing basic properties. In the following year, Schneegans (*Pharm. Zeit.*, 1896, 41, 668), having used a more laborious process of extraction, recorded the isolation of a somewhat purer specimen of the active principle, which formed colourless needles, m. p. 45°, but no attempt was made to ascertain the constitution of this material.

During the earlier experiments of the present investigation of pellitorine, the method of extraction used by Schneegans was employed, but later it became evident that the simpler procedure of Dunstan and Garnett was equally efficacious when followed by the complex fractional distillation which has been found essential to free the crystalline principle from neutral oily by-products. Earlier workers have commented on the extreme difficulty of eliminating the latter substances. The syrup obtained by evaporating an alcoholic extract of the dried powdered root † was extracted thoroughly with ether, and the ethereal solution was freed from acidic impurities and evaporated. The residual syrup was distilled under highly reduced pressure (0.2—0.5 mm.), and the distillate was subjected to a series of fractionations which are described in detail in the experimental section. Ultimately fractions were obtained which rapidly crystallised in the receiver, and crystallisation of these from light petroleum yielded colourless feathery needles of pure *pellitorine*, m. p. 72°. Considerable quantities remained in the mother-liquor, from which further amounts were obtained by distillation, crystallisation of the solid distillate, and repetition of the process. The yield of pellitorine obtained from 13 kg. of root was 5 g., or 0.04%, but the actual content is probably of the order of 0.06%. Pellitorine is flavourless, but a milligram causes profuse salivation when placed on the tongue. The pungency

\* We propose to retain this name in preference to the earlier "pyrethrin" in order to avoid possible confusion with the constituents of *Pyrethri flores* ("The Extra Pharmacopœia," 1928, 879), the dried flowers of pyrethrum species which are used in powdered form as insecticides (see Staudinger and Ruzicka, *Helv. Chim. Acta*, 1924, 7, 177, and other recent papers).

† The commercial alcoholic extract is very much less satisfactory for experimental purposes than the product freshly obtained in the laboratory.

value was 20 as compared with piperine (100), and was determined by diluting an alcoholic solution until the effect of placing one drop on a cover-glass on the tip of the tongue was just perceptible.

Pellitorine is optically inactive, neutral in character, and unsaturated, since it rapidly decolorises permanganate solution. Elementary analyses and the determination of its molecular weight showed that the formula is  $C_{14}H_{25}ON$ , and the presence of one oxygen atom and one nitrogen atom, and the physiological analogy with piperine, led to the assumption that pellitorine is an acid amide. This view was confirmed by hydrolysis, which took place extremely slowly in boiling alcoholic potash, but was effected more rapidly by heating with dilute hydrochloric acid in a sealed tube. In this way, a crystalline amine hydrochloride, an oily acid, and an oily neutral fraction were obtained.

The neutral fraction contained nitrogen, but as all attempts to crystallise it were unsuccessful and the amount available was small, its further investigation was abandoned.

The basic fraction was shown to be a primary amine by the nitrous acid reaction, and was identified as *isobutylamine* by comparison of the melting points of the hydrochloride, chloroplatinate, and *p-toluenesulphonyl* derivative with those of authentic specimens, by analysis of the first- and last-named derivatives, and by the determination of the melting point of a mixture with authentic *p-toluenesulphonisobutylamide*.

The acid fraction had the characteristic odour of the higher aliphatic acids, was sparingly soluble in water, to which it imparted an acid reaction, and was unsaturated, since it decolorised permanganate solution. In an attempt to purify it by distillation, a small amount of a clear, pale brown oil was collected at 160–200°/0.5 mm., but most of the acid carbonised. This distillate was acidic and unsaturated, but the molecular weight was 271 when determined by titration, a figure considerably higher than that of pellitorine itself. It seemed probable, therefore, that polymerisation or condensation had occurred during the distillation and that the examination of this material would be of little value in arriving at the constitution of pellitorine.

Since the basic portion of the pellitorine molecule is *isobutylamine*, the acidic component must have the formula  $C_9H_{15}\cdot CO_2H$ , and thus lacks four atoms of hydrogen for saturation. Acetylenic linkages being unknown in nature, this deficiency may be accounted for by the presence either of two double bonds or of an alicyclic ring and one double bond, and the choice between these alternatives was made by estimating the amount of hydrogen absorbed during the catalytic reduction of pellitorine. A methyl-alcoholic solution,

when shaken with palladised charcoal in an atmosphere of hydrogen, absorbed the volume corresponding to four atoms of hydrogen, and reduction then ceased completely. The tetrahydropellitorine thus prepared was therefore acyclic, and being a decoisobutylamide, it was subjected to direct comparison, and found to be identical, with a synthetical specimen of *n*-decoisobutylamide. It follows that pellitorine is the isobutylamide of a *n*-nonadienecarboxylic acid, but the position of the double bonds must for the present remain indefinite.

Three observations may be made as the result of this investigation. Firstly, spilanthol and pellitorine are very closely related, differing only in the presence of an extra double bond in the latter, and it is an interesting but not entirely unexpected fact that the plants which yield them are also related, both being members of the order *Compositæ*. Secondly, one double bond at least is necessary for the pungent character of this molecular structure, since *n*-decoisobutylamide is not pungent whereas the two unsaturated compounds are both pungent. *n*-Decoisobutylamide causes no reaction when placed on the tongue, but, after swallowing, a localised tingling sensation lasting for several minutes is felt on the pillars of the fauces. Thirdly, the suggested identity of pellitorine and piperovatine, the pungent principle of *Piper ovatum* (Dunstan and Garnett, J., 1895, 67, 94), is erroneous, since the latter substance has the formula  $C_{16}H_{21}O_2N$  and melts at  $123^{\circ}$ .

#### EXPERIMENTAL.

*Isolation of Pellitorine.*—Powdered pellitory root (13 kg., in batches of 1.5 kg.) was extracted three times with boiling 95% alcohol, and the combined extracts were evaporated to a thin gum, mixed with clean sand, and extracted repeatedly with boiling ether. During this process the mass was stirred as efficiently as possible, but with each extraction the residue became harder, until finally further working became impossible. The ethereal solution, which contained almost all the pellitorine, was shaken twice with dilute sodium carbonate solution, washed with water, dried with sodium sulphate, and evaporated to small volume. The residue, after being transferred to a Claisen flask and freed from ether under diminished pressure, was distilled at the lowest possible pressure attained by a Hyvac pump. During this operation frothing was extremely troublesome. A pale yellow oil was collected at  $150\text{--}275^{\circ}/0.3\text{ mm.}$ ; extensive decomposition then set in, and a hard varnish remained in the flask and was discarded. The distillate was submitted to two fractionations at 0.3 mm. pressure with the following results :

Fraction C was again distilled: 17% was collected at 170—190°/0.3 mm. and solidified (D); the higher fractions were dark-coloured oils. The solid fractions A, B, and D were combined and crystallised repeatedly from light petroleum (b. p. below 40°) by keeping the clear solutions in a refrigerator for some days and washing the deposited crystals with ice-cold solvent. *Pellitorine* forms colourless needles, m. p. 72° (corr.), b. p. 162—165°/0.3 mm., which dissolve very easily in organic solvents but are sparingly soluble in water [Found in material dried at 80°: C, 75.2, 75.0; H, 11.4, 11.3; N, 6.2; *M* in camphor (Rast), 224.  $C_{14}H_{25}ON$  requires C, 75.3; H, 11.2; N, 6.3%; *M*, 223]. It is insoluble in dilute hydrochloric acid and sodium hydroxide solutions, but forms a very faintly yellow solution in concentrated sulphuric acid. Decomposition takes place when a specimen is exposed to the air for some time.

*Hydrolysis of Pellitorine.—Isolation of isobutylamine.* Pellitorine (1 g.) and 2*N*-hydrochloric acid (20 c.c.) were heated in a sealed tube at 150° for 48 hours. There was no increase in pressure in the cooled tube. The products of four experiments were combined and extracted thoroughly with ether (E, see below), and the clear almost colourless acid solution was evaporated to dryness first on the water-bath and then in a desiccator. The residual crystalline isobutylamine hydrochloride (1.8 g.) formed colourless needles, m. p. 174° (Walden, Ulich, and Laun, *Z. physikal. Chem.*, 1925, 114, 290, give m. p. 175.5°), when precipitated from absolute alcoholic solution by means of ether (Found: C, 43.7; H, 11.0. Calc. for  $C_4H_{11}N.HCl$ : C, 43.8; H, 11.0%). The chloroplatinate formed irregular plates, decomp. 217°, when prepared in alcoholic solution.

*p-Toluenesulphonisobutylamide.* isoButylamine hydrochloride (0.24 g.) obtained from pellitorine, recrystallised *p*-toluenesulphonyl chloride (1.3 g.; 3 mols.), ether (25 c.c.), and 2*N*-sodium hydroxide solution (25 c.c.) were shaken mechanically for 12 hours; the smell of the acid chloride could not then be detected. The ethereal layer was separated, washed with water, dried, and freed from solvent. The residual *p*-toluenesulphonisobutylamide crystallised when cold

and separated from light petroleum (b. p. 60—80°) in colourless rhombs, m. p. 75—76° (Found: C, 58.2; H, 7.6.  $C_{11}H_{17}O_2NS$  requires C, 58.2; H, 7.5%). A specimen prepared in a similar manner from authentic *isobutylamine* formed colourless rhombs, m. p. 75—76° alone or when mixed with the material prepared from *pellitorine*.

*Examination of the ethereal extract E* (see above). The ethereal solution was shaken repeatedly with sodium carbonate solution to remove the acidic contents, and was then washed with water, dried, and evaporated. The neutral oily residue (1.6 g.) distilled at 160—190°/0.5 mm.; the clear distillate, which had an odour not unlike that of peaches, contained nitrogen and did not crystallise when kept in a refrigerator for some days. It was not examined further.

The acidic fraction (1.8 g.), which was liberated as a dark oil from the carbonate solution, was perceptibly purified neither by treatment with charcoal nor by repeated precipitation from alkaline solution, and an attempt was made to distil it. Much carbonisation took place, and the distillate (0.5 g.; b. p. 160—200°/0.5 mm.; mol. wt. 271) failed to crystallise. The acid chloride, prepared by means of phosphorus pentachloride in chloroform solution, yielded an oily anilide and an amide; the latter crystallised from very dilute methyl alcohol in colourless plates, m. p. 35°, which dissolved very readily in organic solvents.

*Tetrahydropellitorine* (*n-Decoisobutylamide*).—A solution of *pellitorine* (0.342 g.) in methyl alcohol (25 c.c.) was run into a suspension of palladised charcoal (from palladous chloride, 0.2 g., and charcoal, 1.5 g.) in methyl alcohol (25 c.c.) which was stirred mechanically in an atmosphere of hydrogen: the absorption of hydrogen (69.6 c.c., corrected to N.T.P.) ceased completely after 3 minutes. The volume of hydrogen required for the addition of 4 atoms of hydrogen to  $C_{14}H_{25}ON$  is 68.2 c.c. The solution was filtered from charcoal, the methyl alcohol distilled, and the residual oil dissolved in ether and dried. Removal of the solvent yielded tetrahydropellitorine as a colourless oil which rapidly crystallised in flat needles, m. p. 35° (corr.), very soluble in organic solvents (Found: C, 74.1; H, 12.7. Calc. for  $C_{14}H_{29}ON$ : C, 74.0; H, 12.8%). This material melted at 36° when mixed with synthetic *n-decoisobutylamide*, m. p. 36°; the necessary decoic acid, m. p. 31°, was obtained by the hydrolysis of a carefully fractionated sample of commercial ethyl decoate, and the amide was obtained by the action of *isobutylamine* on the acid chloride in benzene solution.

## III.—1:3-Dithiolan.

By DAVID T. GIBSON.

THE isolation of 1:3-dithiolan,  $\begin{matrix} \text{CH}_2\cdot\text{S} \\ \text{CH}_2\cdot\text{S} \end{matrix} > \text{CH}_2$ , and of 1:3-dithian, although inferred (Baumann and Walter, *Ber.*, 1893, **26**, 1129; Autenrieth and Wolff, *Ber.*, 1899, **32**, 1375), has not been described. The preparation of ethylene dimercaptan (Meyer, *Ber.*, 1886, **19**, 3263; Fasbender, *Ber.*, 1887, **20**, 461; Frasseti, *Ber.*, 1905, **38**, 491) may be more conveniently effected by an extension of Purgotti's method (*Gazzetta*, 1892, **22**, 416). The condensation of formaldehyde and ethylene dimercaptan actually yields two products, dithiolan and a voluminous solid *polymeride*. Dithiolan could not be obtained by the reduction of ethylene trithiocarbonate (compare Hurtley and Smiles, J., 1926, 1821), but it is directly obtained by distilling a mixture of formaldehyde, sodium ethylene thiosulphate, and hydrochloric acid.

Dithiolan is converted by hydrogen peroxide into a liquid *monoxide*, the green solution of which in sulphuric acid immediately becomes deep red on addition of a drop of anisole. With platinic chloride the monoxide gives an orange-red *compound*,  $(\text{C}_2\text{H}_5\text{S}_2)_2\text{PtCl}_3\cdot\text{H}_2\text{O}$  (compare Tschugaev and Benewolenski, *Z. anorg. Chem.*, 1913, **82**, 420). In presence of hydrochloric acid, one molecule of the monoxide undergoes oxidation at the expense of another, one-half of the material being recovered as dithiolan, and the remainder precipitated as an insoluble amorphous *dioxide* (compare the first oxidation product of tetramethoxythianthren; Fries, Koch, and Stunkenbrock, *Annalen*, 1929, **468**, 166).

1:3-Dithian was obtained by treating trimethylene dibromide with sodium thiosulphate, formaldehyde, and hydrochloric acid.

## EXPERIMENTAL.

*Ethylene Dimercaptan*.—Ethylene dibromide (200 c.c.), water (20 c.c.), sodium thiosulphate (100 g.), and alcohol (100 c.c.) were mechanically shaken for 6 hours at 50–60°. The stiff pasty product was collected, boiled with excess of hydrochloric acid, and distilled in steam, yielding 9 g. of the mercaptan, b. p. 144°. If the hydrolysis is conducted with alkali, no mercaptan is formed.

*Condensation of Ethylene Dimercaptan with Formaldehyde*.—The mercaptan was slowly added to formalin solution, containing a trace of hydrochloric acid, below 25°. The clear solution, when gently warmed, suddenly became turbid with separation of 1:3-dithiolan and its *polymeride*. The former was distilled in steam and purified as described below. The *polymeride*, m. p. 105–110°, after, being

washed with ether, was practically insoluble in any organic solvent; it dissolved with effervescence in nitric acid, giving a red solution [Found : C, 34.1; H, 6.1.  $(C_3H_6S_2)_n$  requires C, 34.0; H, 5.7%].

1 : 3-Dithiolan was more conveniently obtained by treating sodium ethylene thiosulphate, prepared as described above, with a mixture of hydrochloric acid and twice the calculated amount of formalin. Steam distillation furnished a 50–60% yield of the dithiolan, which was purified by refluxing it for several hours with aqueous alkali; it then boiled at  $175^\circ/760$  mm. and  $61^\circ/11$  mm. and had  $d^{20}_D$  1.259,  $n^{15}_D$  1.5975, whence  $[R_L]_D = 29.7$  (calc., 29.8) (compare Le Bas, *Trans. Faraday Soc.*, 1920, **15**, 231) (Found : C, 34.2; H, 5.8;  $M$ , 111.  $C_3H_6S_2$  requires C, 34.0; H, 5.7%;  $M$ , 106). It yielded a mercurichloride, m. p.  $119^\circ$ , on treatment with mercuric chloride, and gave Baumann and Walter's disulphone (*loc. cit.*), m. p.  $224^\circ$ , in 80% yield on oxidation with perhydrol in glacial acetic acid at  $50^\circ$ .

1 : 3-Dithiolan Monoxide.—Perhydrol (9 c.c.) in 20 c.c. of glacial acetic acid was added very slowly to specially purified 1 : 3-dithiolan (10 c.c.) in 20 c.c. of glacial acetic acid. After several days, the solvent was removed below  $40^\circ$ , first at 11 mm. and finally at 1 mm. (neglect to remove every trace of solvent at as low a temperature as possible causes complete decomposition in the subsequent distillation) and the residue was distilled over a trace of magnesium carbonate, giving 8 g. of an oil, b. p.  $115$ – $120^\circ/1$  mm. (Found : C, 30.1; H, 5.3;  $M$ , 118.  $C_3H_6OS_2$  requires C, 29.5; H, 5.0%;  $M$ , 122).

The monoxide is miscible with water, and is decomposed by warm hydrochloric acid into dithiolan (identified by its mercurichloride, m. p.  $119^\circ$ ) and a dioxide; m. p.  $134^\circ$  (Found : C, 26.3, 26.4; H, 4.7, 4.3.  $C_3H_6O_2S_2$  requires C, 26.0; H, 4.4%). It is insoluble in all the usual solvents, including aqueous alkali.

With platinic chloride, an aqueous solution of dithiolan monoxide yields a flocculent precipitate, which may be recrystallised from hot water; m. p.  $146$ – $150^\circ$  (decomp.) [Found : C, 14.0; H, 2.7; Cl, 20.3; Pt, 36.7.  $(C_3H_5S_2)_2PtCl_3 \cdot H_2O$  requires C, 13.6; H, 2.3; Cl, 20.1; Pt, 36.8%].

With methyl iodide, dithiolan monoxide yields a *methiodide*, m. p.  $96^\circ$  (Found : I, 47.7.  $C_4H_9OIS_2$  requires I, 48.1%).

1 : 3-Dithian.—Trimethylene dibromide (30 c.c.), sodium thiosulphate (120 g.), and alcohol (100 c.c.) were shaken at  $60^\circ$  for 2 days. The solid which separated was distilled in steam with formalin and hydrochloric acid, and the distillate extracted with ether. The dithian crystallised readily and melted at  $54^\circ$  (Found : C, 40.1, 40.0; H, 7.1, 6.6.  $C_4H_8S_2$  requires C, 40.0; H, 6.7%). On oxid-

ation with perhydrol in glacial acetic acid, it gave Autenrieth and Wolf's disulphone (*loc. cit.*), m. p. 330°, in almost quantitative yield.

#### IV.—*The Influence of Substituents on the Benzoin Reaction.*

By HERBERT HENRY HODGSON and WOLF ROSENBERG.

THE present investigation in conjunction with the results of Ekecrantz and Ahlqvist (*Arkiv Kemi Min. Geol.*, 1908, 3, No. 13) shows that substituents inhibit the benzoin reaction in varying degrees according to their electronic character. On Lapworth's theory (J., 1903, 84, 1004) that the possibility of the benzoin condensation depends on the mobility of the hydrogen atom \* in the initially formed mandelonitrile (I), (a) a *meta*-directing group (R) will activate this hydrogen \* (II) but deactivate the carbonyl group of the second molecule of the reacting benzaldehyde (III), and (b) when R is *op*-directing, H\* (IV) is deactivated but CO (V) is activated. In case (a) the benzoin condensation of (II) and (III) would appear to depend on the relative activation and deactivation: *e.g.*, when R is NO<sub>2</sub> (strong), it over-activates H\* but renders the CO (III) much less capable of forming the initial cyanohydrin, hence excessive production of nitrobenzoic acid occurs (compare Lapworth and Manske, J., 1928, 2533); when R is Cl (weak), only 5% of *o*-chlorobenzoic acid can be isolated, and benzoin formation ensues. In case (b), although cyanohydrin formation may readily occur, the subsequent benzoin condensation of (IV) and (V) may be inhibited because of the deactivated hydrogen \*: *e.g.*, (1) attempts to produce a benzoin from any monohydroxybenzaldehyde have all failed owing to the presence of anionoid oxygen ( $R = \overset{\ominus}{O}$ ), and (2) although the alkyloxybenzaldehydes all give benzoin, the introduction of a second group as in *p*-benzyloxy-*m*-methoxybenzaldehyde brings about the necessary deactivation and no benzoin is formed.

On the above theory, 2-chloro-3-methoxybenzaldehyde produces a benzoin more readily than does 3-methoxybenzaldehyde owing to a reduction by chlorine of the hydrogen deactivation produced by the methoxyl group (VI). 3-Chloro-2-hydroxybenzaldehyde (80%) and 3-chloro-4-hydroxybenzaldehyde (25%), however, appear to

react only as far as the cyanohydrin stage, and Ekecrantz and Ahlqvist (*loc. cit.*) found that *p*-hydroxybenzaldehyde and vanillin were unreactive towards alcoholic potassium cyanide, the complete internal satisfaction of the electronic demands of the carbonyl group thus being exhibited.

The possibility of the benzooin reaction taking place might also be considered from the standpoint of the influence of groups on the stabilities of the respective hypothetical intermediate benzoin cyanohydrins (VII and VIII) (Lapworth, *loc. cit.*):

(a) When  $\text{R}$  is *meta*-directing (VII), the  $\text{H}^*$  tends to be ionised, formation of hydrogen cyanide thereby being promoted, so that, when  $\text{R}$  is sufficiently strong (*e.g.*,  $\text{NO}_2$ ), the initial formation of mandelonitrile is prevented and no benzooin reaction can occur.

(b) When  $\text{R}$  is *op*-directing (VIII), the hydrogens  $^*$  are deactivated and  $\text{CN}$  is activated. Subsequent reaction can and, so far as the end-products are evidence, does occur in two ways: (1) the formation of a benzooin, and (2) the intermediate formation of the isomeride (IX) of this benzooin, which is hydrolysed, giving a benzyl alcohol and an unstable phenylorthoformic acid (X), the latter changing to a stable benzoic acid (XI); *e.g.*, from *o*- and *p*-anisaldehydes, con-

siderable quantities of *o*- and *p*-anisic acids are produced together with the *o*- and *p*-anisoin.

### EXPERIMENTAL.

**2 : 2'-Dichlorobenzoin.**—Solutions of *o*-chlorobenzaldehyde (5 g.) in alcohol (10 c.c.) and of potassium cyanide (1 g.) in water (4 c.c.) were heated together under reflux on the water-bath for 1 hour and poured into aqueous sodium bicarbonate, which dissolved the *o*-chlorobenzoic acid formed (5%); after 1 hour, the whole was extracted with ether, and the extract shaken with aqueous sodium bisulphite to remove unchanged *o*-chlorobenzaldehyde. (Benzoin and benzils do not easily form hydrazones or sodium bisulphite addition compounds, a fact which has been utilised for the removal of unchanged initial material in the various reactions studied.) The 2 : 2'-dichlorobenzoin (40% yield) was obtained by removal of the ether and extraction of the residue with acetic acid or alcohol, from which it separated in white prisms, m. p. 56—57° (Found : Cl, 25.0.  $C_{14}H_{10}O_2Cl_2$  requires Cl, 25.2%). The final resinous residue (40%) contained nitrogen, presumably as cyanohydrin, but no alcohol corresponding to *o*-chlorobenzoic acid was isolated (compare Ekecrantz and Ahlqvist, *loc. cit.*). The acid may have been formed partly by air oxidation, since the amount increased when the reaction mixture was kept for several days.

An alcoholic solution of 2 : 2'-dichlorobenzoin when treated with aqueous-alcoholic sodium hydroxide gives a brownish-red colour, deeper than that given by unsubstituted benzoin, which deepens on boiling but disappears on shaking (compare Hantzsch and Glover, *Ber.*, 1907, 40, 1520), returns on keeping but disappears again on shaking, and so on.

2 : 2'-Dichlorobenzil was prepared by the usual nitric acid method, but better results were obtained when 2 : 2'-dichlorobenzoin (1 g.), dissolved in glacial acetic acid (10 c.c.), was heated with a slight excess of chromium trioxide on the water-bath for 1 hour. After dilution with water and extraction with ether, the benzil crystallised from benzene in pale yellowish-green prisms, m. p. 128° (Found :

Cl, 25.2.  $C_{14}H_8O_2Cl_2$  requires Cl, 25.4%), which were sparingly soluble in boiling alcohol, ether, and glacial acetic acid.

3 : 3'-*Dimethoxybenzoin* (*m-Anisoin*).—Powdered potassium cyanide (1 g.) was added to a boiling solution of *m*-methoxybenzaldehyde (10 g.) in 50% aqueous alcohol (30 g.). After boiling for 2 hours, the mixture was kept over-night in a freezing mixture, and the oily yellowish-brown solid obtained was removed, freed from oil, and washed with ether; the residue crystallised from alcohol in micro-prisms (2 g.), m. p. 41–42° (Found: C, 70.8; H, 5.7.  $C_{16}H_{16}O_4$  requires C, 70.6; H, 5.9%).

2 : 2'-*Dichloro-3 : 3'-dimethoxybenzoin*, readily obtained by the ordinary method, crystallised from alcohol in prisms, m. p. 133–134° (Found: Cl, 20.6.  $C_{16}H_{14}O_4Cl_2$  requires Cl, 20.8%). The *p*-nitrophenylhydrazone crystallised from glacial acetic acid in yellow needles, m. p. 129° (Found: N, 9.0; Cl, 14.8.  $C_{22}H_{19}O_5N_3Cl_2$  requires N, 8.8; Cl, 14.9%), which gave a reddish-violet colour with aqueous-alcoholic sodium hydroxide.

2 : 2'-*Dichloro-3 : 3'-dimethoxybenzil*, prepared in the same way as 2 : 2'-dichlorobenzil, crystallised from benzene in very pale greenish-yellow prisms, m. p. 200° (Found: Cl, 20.8.  $C_{16}H_{12}O_4Cl_2$  requires Cl, 20.9%).

2 : 2'-*Dichloro-3 : 3'-dimethoxybenzilic acid*, formed by boiling 2 : 2'-dichloro-3 : 3'-dimethoxybenzil (5.5 g.), dissolved in alcohol (11 g.), with a mixture of potassium hydroxide (5.5 g.) and water (11 g.) for 10 minutes, crystallised from water in colourless needles, decomp. 182–185° (Found: Cl, 20.0.  $C_{16}H_{14}O_5Cl_2$  requires Cl, 19.9%).

2-*Chloro-3-methoxybenzoic acid* was prepared by gradually adding a saturated aqueous solution of potassium permanganate to a boiling aqueous suspension of 2-chloro-3-methoxybenzaldehyde until it was no longer decolorised and the aldehydic odour had disappeared. The excess of permanganate was destroyed by sulphur dioxide; the solution on cooling deposited colourless needles, m. p. 161.5° after recrystallisation from water (Found: Cl, 19.1.  $C_8H_7O_3Cl$  requires Cl, 19.0%).

*Approximate Determination of the Reactivities of Various Aldehydes from the Quantities of Resinous Products formed.*—These experiments were undertaken to investigate the combined influence of two groups of opposed electronic effects. In each case the benzoïn reaction mixture was poured into water and acidified with acetic acid, the precipitate dissolved in ether, and the solution washed with aqueous sodium bisulphite to remove unchanged initial material, and dried; the ether was then removed, and the residue weighed.

Benzaldehyde.	Unchanged material (g.).	Reaction product (g.).
3-Hydroxy- .....	4.0	9.5
3-Chloro-2-hydroxy- .....	0.4	2.9
3-Chloro-4-hydroxy- .....	4.5	1.5

From the resinous products, and from the corresponding synthetic cyanohydrins, nothing could be obtained crystalline.

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

## V.—dl- $\beta$ -Phenylisopropylamine and Related Compounds.

By DONALD HOLROYDE HEY.

$\beta$ -PHENYLISOPROPYLAMINE has been obtained by Edeleano (*Ber.*, 1887, 20, 618) by the action of bromine and aqueous potash on phenylisobutyramide and its chloroplatinate also is described. The hydrochloride of the *d*-form was obtained by Jones and Wallis (*J. Amer. Chem. Soc.*, 1926, 48, 180) by the hydrolysis of *d*- $\alpha$ -benzylethylcarbimide with concentrated hydrochloric acid. In the present investigation the racemic base was readily obtained by the reduction of *benzyl methyl ketoxime* by means of sodium amalgam in dilute acetic acid solution. Benzyl methyl ketoxime, previously described as a thick oil by Dollfus (*Ber.*, 1892, 25, 1918; 1893, 26, 1971), has now been obtained in a pure crystalline form, melting at 70°.

The *acetyl* derivative (I) of the base, on treatment with phosphoric oxide in boiling toluene (compare Pictet and Kay, *Ber.*, 1909, 42, 1973), gave 1 : 3-dimethyl-3 : 4-dihydroisoquinoline (II), which was isolated in the form of its *picrate*.

The reduction of *isonitrosopropiophenone* under various conditions gives rise to a variety of products, generally in poor yield (Gudeman, *Ber.*, 1889, 22, 562; Behr-Bregowski, *Ber.*, 1897, 30, 1521; Gabriel, *Ber.*, 1908, 41, 1127; Rabe, *Ber.*, 1912, 45, 2166; Calliess, *Arch. Pharm.*, 1912, 250, 141), but the only instance of its direct

reduction to *dl*- $\beta$ -hydroxy- $\beta$ -phenylisopropylamine (norephedrine),  $\text{OH}\cdot\text{CHPh}\cdot\text{CHMe}\cdot\text{NH}_2$  (compare the reduction of benzil monoxime to  $\beta$ -hydroxy- $\alpha\beta$ -diphenylethylamine; Polonowska, *Ber.*, 1888, **21**, 488), has been reported by Rabe, who obtained the base in small yield by using colloidal palladium. Since the inception of this work, however, Hartung and Munch (*J. Amer. Chem. Soc.*, 1929, **51**, 2262) have obtained  $\beta$ -hydroxy- $\beta$ -phenylisopropylamine (phenylpropanolamine) in good yield from isonitrosopropiophenone by catalytic reduction with palladised charcoal. In the present investigation, although a number of reducing agents were employed under various conditions, the desired result was not effected, since the isonitrosopropiophenone exhibited a very marked stability [compare the relatively facile reduction of benzyl methyl ketoxime (see experimental part) and of propiophenone oxime (Billon, *Compt. rend.*, 1926, **182**, 470)], and much of it was recovered unchanged. The great stability of this oximino-ketone has been the subject of comment by Coles, Manske, and Johnson (*J. Amer. Chem. Soc.*, 1929, **51**, 2269).

Melting points of isonitrosopropiophenone varying from  $108^\circ$  to  $115^\circ$  are recorded in Beilstein's "Handbuch der organischen Chemie." The specimen prepared by Hartung and Munch (*loc. cit.*) and crystallised from toluene, melted at  $106\text{--}106.5^\circ$ , whereas the preparation used in this investigation was crystallised from water, melted at  $114.5^\circ$ , and gave rise to metallic complex formation with iron, cobalt, and copper (compare  $\alpha$ - and  $\beta$ -benzil monoximes, Tschugaev, *Z. anorg. Chem.*, 1905, **46**, 148; Taylor and Ewbank, *J.*, 1926, 2818; Pfeiffer and Richarz, *Ber.*, 1928, **61**, 103).

#### EXPERIMENTAL.

*Benzyl Methyl Ketoxime.*—Solutions of 18 g. of benzyl methyl ketone in 40 c.c. of alcohol and of 10 g. of hydroxylamine hydrochloride in 20 c.c. of water were mixed and, after addition of 6 g. of sodium hydroxide in the minimum quantity of water, heated on a boiling water-bath for  $1\frac{1}{2}$ —2 hours. The solution was then diluted considerably, acidified, and extracted with ether. After being washed with a concentrated solution of calcium chloride and dried, the ether was evaporated; the residual thick red oil, which solidified, after several recrystallisations from light petroleum (b. p.  $60\text{--}80^\circ$ ), gave the *oxime* in white prismatic crystals, m. p.  $70^\circ$  (Found: C, 72.8; H, 7.4; N, 9.5.  $\text{C}_9\text{H}_{11}\text{ON}$  requires C, 72.5; H, 7.4; N, 9.4%).

*Reduction of Benzyl Methyl Ketoxime.*—To a well-stirred solution of 10 g. of benzyl methyl ketoxime in glacial acetic acid, diluted with water, 300 g. of 3% sodium amalgam were gradually added. After 6 hours the solution was made alkaline and extracted with ether and the base was extracted from the ethereal solution with

dilute hydrochloric acid; or alternatively the alkaline solution was steam-distilled, the base being collected in dilute hydrochloric acid. The free base, liberated by the addition of alkali, was extracted with ether and dried over solid caustic potash. Evaporation of the ether left a yellowish oil with an ammoniacal odour, which on distillation gave pure *dl*- $\beta$ -phenylisopropylamine as a colourless oil, b. p.  $205^{\circ}$  (Edeleano, *loc. cit.*, recorded  $203^{\circ}$ ). The base readily combines with carbon dioxide.

The *acetyl* derivative, formed in the usual manner, crystallised from aqueous alcohol in fine white needles. These melted initially at  $64^{\circ}$ , but at  $93^{\circ}$  after being kept for some time in a vacuum (Found: C, 74.7; H, 8.6; N, 8.1.  $C_{11}H_{15}ON$  requires C, 74.6; H, 8.5; N, 7.9%).

The *picrate*, prepared from picric acid and the base in concentrated solution and recrystallised from alcohol, gave yellow transparent prisms, containing one molecule of alcohol, which melted at  $143^{\circ}$  (Found: C, 49.9; H, 5.5; N, 13.8.  $C_{15}H_{16}O_7N_4 \cdot C_2H_5 \cdot OH$  requires C, 49.8; H, 5.4; N, 13.7%).

The *hydrochloride*, prepared from hydrogen chloride and the base in dry ether, was rapidly collected, washed with pure dry ether, and transferred to a desiccator evacuated over solid caustic potash. It is extremely hygroscopic and melts at  $145$ – $147^{\circ}$  (Found: C, 63.3; H, 8.6; N, 8.1; Cl, 20.8.  $C_9H_{13}N \cdot HCl$  requires C, 63.0; H, 8.2; N, 8.2; Cl, 20.7%).

*Action of Phosphoric Oxide on Aceto-dl- $\beta$ -phenylisopropylamide.*—A solution of 2 g. of the acetyl compound in toluene was boiled for 3 hours with 4 g. of phosphoric oxide (compare Pictet and Kay, *loc. cit.*). The solution was then made alkaline, the base extracted with ether, the toluene and ether evaporated, and the small residue of oil converted into picrate in concentrated alcoholic solution. Recrystallisation from alcohol gave 1:3-*dimethyl*-3:4-*dihydroisoquinoline picrate* in yellow fern-like crystals, m. p.  $136^{\circ}$  (Found: C, 52.9; H, 4.4; N, 14.35.  $C_{17}H_{16}O_7N_4$  requires C, 52.6; H, 4.1; N, 14.4%).

*isoNitrosopropiophenone.*—This was prepared from propiophenone and amyl nitrite by Claisen and Manasse's method (*Ber.*, 1889, 22, 529); it crystallised from water in fine needles, m. p.  $114.5^{\circ}$ .

*Complex formation.* (a) *With iron.* When aqueous ferrous sulphate solution was shaken with *isonitrosopropiophenone* and dilute caustic soda solution added, a blue colour was produced which, on shaking with benzene, passed into this solvent.

(b) *With cobalt.* To a solution of 3 g. of *isonitrosopropiophenone* in very dilute alcohol was added an aqueous solution containing 4.5 g. of cobalt acetate. A dense yellowish-brown precipitate

formed almost immediately, which was collected after a while and washed with water, dilute alcohol, and finally with a little ether [Found : Co, 10.9; C, 59.9; H, 4.5; N, 7.8.  $\text{Co}(\text{C}_9\text{H}_8\text{O}_2\text{N})_3$  requires Co, 10.8; C, 59.45; H, 4.4; N, 7.7%].

(c) *With copper*. In a similar way, from 3 g. of copper acetate and 2 g. of isonitrosopropiophenone, a dense dark bluish-green precipitate was obtained, which was washed with water, dilute alcohol, and ether [Found : Cu, 25.9; C, 44.7; H, 3.8; N, 5.75.  $\text{CuOH}(\text{C}_9\text{H}_8\text{O}_2\text{N})$  requires Cu, 26.2; C, 44.5; H, 3.7; N, 5.8%].

The author desires to thank Dr. F. Challenger for his advice and interest in this work.

THE UNIVERSITY, MANCHESTER.

[Received, November 1st, 1929.]

## VI.—*Natural Glucosides. Part I. The Constitution of Phloridzin.*

By FRANCIS RABAN JOHNSON and ALEXANDER ROBERTSON.

THE glucoside phloridzin, which occurs in the bark of apple, pear, plum, and cherry trees, was first isolated in 1835 by De Koninck (*Annalen*, **15**, 75, 258) from the root bark of the apple tree, and was correctly analysed by Stas (*Ann. Chim. Phys.*, 1836, **61**, 367), who found that it was decomposed by mineral acids into phloretin and a sugar which he believed to be glucose. The glucoside was subsequently examined by a number of workers and the empirical formula  $\text{C}_{21}\text{H}_{24}\text{O}_{10} \cdot 2\text{H}_2\text{O}$  was established by Rennie (*J.*, 1887, **51**, 634), who effected the hydrolysis by dilute sulphuric acid with the production of phloretin,  $\text{C}_{15}\text{H}_{14}\text{O}_5$ , and glucose. The latter result was confirmed independently by Fischer (*Ber.*, 1888, **21**, 988) and by Schunck and Marchlewski (*Ber.*, 1893, **26**, 942; *Annalen*, 1894, **278**, 349). A synthesis of phloretin by Fischer and Nouri (*Ber.*, 1917, **50**, 611) definitely established its constitution (compare Zemplén and co-workers, *Ber.*, 1928, **61**, 2486; Rosenmund and Rosenmund, *ibid.*, p. 2608). That the glucose residue of phloridzin is attached to the phloroglucinol nucleus was shown by Cremer and Seuffert (*Ber.*, 1912, **45**, 2565), who, by the action of warm baryta water, obtained phloretic acid and phlorin, phloroglucinol  $\beta$ -glucoside. This glucoside had previously been synthesised by Fischer and Strauss (*Ber.*, 1912, **45**, 2467).

As the result of previous work, phloridzin may be represented by formula (I) or (II), and therefore should, on methylation of the phenolic hydroxyl groups and hydrolysis of the product, give a trimethylphloretin (IV or V). The glucoside was methylated in

acetone solution by means of methyl iodide and anhydrous potassium carbonate, a method which has been shown by Robinson (J., 1928, 1457) to effect the methylation of *O*-benzoylphloroglucinaldehyde. In order to ensure complete alkylation of the phenolic groups, prolonged treatment with an excess of the methylating agents was essential. The product, which gave no evidence of the presence of an unprotected phenolic hydroxyl group, appeared to be partly methylated in the sugar residue and could not be purified. Hydrolysis of the crude material, however, with aqueous methyl-alcoholic sulphuric acid gave 6-hydroxy-2:4:4'-trimethoxy- $\beta$ -phenylpropio-phenone (IV); the filtrates containing the sugar residue were not examined. In a subsequent experiment the alkylation was stopped when a sample of the product no longer gave a ferric chloride reaction: a crystalline hydrate of trimethylphloridzin (III) was isolated which gave the ketone (IV) on hydrolysis. Methylation of phloridzin in a methyl-alcoholic-ethereal solution with diazo-methane and hydrolysis of the product also gave (IV).

The orientation of the ketone (IV) is established by ring closure with sodium acetate and acetic anhydride to the 1:4-benzopyrone (VI). The conclusion that this product is a benzopyrone and not a coumarin is based mainly on the behaviour of analogous ketones under the same conditions (Kostanecki and Różycki, *Ber.*, 1901, 34, 107; Crabtree and Robinson, J., 1918, 113, 859; Robinson and co-workers, J., 1929, 61, 152, which see for further references). Ciamician and Silber (*Ber.*, 1894, 27, 1627; 1895, 28, 1393), however, by acetylating phloretin, obtained a substance which they believed to be a coumarin. In any case ring closure can take place only if there is a hydroxyl group in the *o*-position to carbonyl in the hydroxytrimethoxy- $\beta$ -phenylpropio-phenone obtained by hydrolysis of the methylated glucoside. The constitution of phloridzin is therefore represented by formula (I).

The experimental proof of the constitutions of (VI) and of

Ciamician and Silber's product (*loc. cit.*) will be the subject of a future communication.

The compound (IV) was prepared by an independent method: condensation of phloroglucinol dimethyl ether and  $\beta$ -4-methoxy-phenylpropionitrile by the method of Hoesch produced a mixture of ketimine hydrochlorides which, on hydrolysis and separation, gave (IV) and the *isomeride* (V) in almost equal quantities.

Convenient methods for the preparation of *p*-methoxycinnamic acid (compare Perkin, J., 1877, **31**, 408; Einhorn, *Annalen*, 1883, **243**, 363; Knoevenagel, *Ber.*, 1898, **31**, 2606) and of  $\beta$ -4-methoxy-phenylpropionyl chloride (compare Barger and Walpole, J., 1909, **95**, 1723) are described. Dehydration of  $\beta$ -4-methoxyphenylpropionamide (Barger and Walpole, *loc. cit.*) with thionyl chloride gave the *nitrile*.

#### EXPERIMENTAL.

*Methylation of Phloridzin. Trimethylphloridzin.*—(A) Methyl iodide (14 c.c.) was added to a solution of phloridzin (15 g.) in dry acetone (80 c.c.) containing powdered potassium carbonate (25 g.) in suspension, and the mixture refluxed for 40 hours; a further quantity of iodide (28 c.c.) was added in two portions at intervals of 10 hours. After separation from potassium salts the mixture was acidified with acetic acid and the acetone and the excess of methyl iodide were removed by distillation. The pale straw-coloured viscous residue, which could not be crystallised, was insoluble in cold 10% alkali solution and did not give a ferric chloride reaction. A solution of the product in a mixture of 50% methyl alcohol (120 c.c.) and 15% sulphuric acid (50 c.c.) was refluxed for 20 minutes; on cooling, 6-hydroxy-2:4:4'-trimethoxy- $\beta$ -phenylpropiophenone (IV) separated, which crystallised from alcohol in colourless squat prisms (7.2 g.), melting at 110° [Found: C, 68.5; H, 6.3; OMe, 29.4.  $C_{18}H_{11}O_2(OMe)_3$  requires C, 68.3; H, 6.4; OMe, 29.4%]. This substance is slightly soluble in methyl alcohol and insoluble in warm water and in cold 2% aqueous sodium hydroxide solution. Ferric chloride added to an alcoholic solution gives a wine-red coloration. Acetylation with acetic anhydride and sodium acetate on the steam-bath during 3 hours gave the *acetyl* derivative, which separated from warm methyl alcohol in rhombic prisms, m. p. 62–63° (Found: C, 67.3; H, 6.2.  $C_{20}H_{22}O_6$  requires C, 67.0; H, 6.9%). It is readily soluble in warm alcohol and in ether, and does not give a ferric chloride reaction. Hydrolysis in alcohol with a little concentrated potassium hydroxide solution gave the parent ketone (III).

Phloridzin (10 g.) in acetone (50 c.c.) was methylated during 20

hours with methyl iodide and potassium carbonate. The product, isolated as before, solidified, but separated from warm benzene as an oil which gradually crystallised [Found in material dried at  $110^{\circ}$ : OMe, 20.7.  $C_{21}H_{21}O_7(OMe)_3$  requires OMe, 19.5%]. Repeated crystallisation from warm water (charcoal) gave a *monohydrate* of *trimethylphloridzin* (III) in colourless elongated prisms, m. p.  $63-65^{\circ}$  after softening at  $60^{\circ}$  [Found in material dried at  $110^{\circ}$ : C, 60.2; H, 5.9; OMe, 19.8.  $C_{21}H_{21}O_7(OMe)_3$  requires C, 60.2; H, 6.3; OMe, 19.5%. Found: loss on drying at  $110^{\circ}$ , 7.5. A monohydrate requires loss, 7.0%]. The hydrate is readily soluble in alcohol and does not give a ferric chloride reaction. Hydrolysis gave (IV), m. p. and mixed m. p.  $110^{\circ}$ .

(B) Diazomethane (3.5 g.) in dry ether (400 c.c.) was added to a solution of anhydrous phloridzin (5 g.) in absolute methyl alcohol (70 c.c.). A brisk evolution of nitrogen ensued and after 12 hours the ether and alcohol were removed under diminished pressure. The residual syrup, which was readily soluble in alcohol and in warm water and did not give a ferric chloride reaction, could not be crystallised. The crude product on hydrolysis with aqueous methyl-alcoholic sulphuric acid gave (IV), m. p. and mixed m. p.  $110^{\circ}$  after crystallisation from alcohol.

5 : 7 : 4'-Trimethoxy-3-benzyl-2-methyl-1 : 4-benzopyrone (VI).—A mixture of the ketone (IV) (6.5 g.), acetic anhydride (100 c.c.), and fused sodium acetate (40 g.) was heated at  $180^{\circ}$  for 16 hours. Water (400 c.c.) was then added to the cooled mixture and after 3 days the semi-solid product which had separated was extracted with ether. The *benzopyrone* (VI) remained as an insoluble residue, which crystallised from alcohol (charcoal) in clusters of colourless needles, m. p.  $165-166^{\circ}$  (Found: C, 70.7; H, 6.0.  $C_{20}H_{20}O_5$  requires C, 70.6; H, 5.9%). It is soluble in cold concentrated sulphuric acid to a colourless solution exhibiting a blue fluorescence in the light of a carbon arc, and in warm concentrated hydrochloric acid to a pale straw-coloured solution. An alcoholic solution is non-fluorescent.

The ether-soluble fraction of the reaction mixture consisted mainly of impure acetyltrimethylphlorethin, which, on being refluxed with acetic anhydride and sodium acetate at  $180^{\circ}$  for 18 hours, gave a further quantity of the benzopyrone, m. p.  $165-166^{\circ}$ .

$\beta$ -4-Methoxyphenylpropionamide.—A mixture of anisaldehyde (50 g.), malonic acid (45 g.), pyridine (150 c.c.), and piperidine (0.5 c.c.) was heated on the steam-bath for 9 hours and then under reflux for 2 hours. After dilution with water (400 c.c.) and acidification with concentrated hydrochloric acid (300 c.c.), it deposited *p*-methoxycinnamic acid (47 g.), which crystallised from alcohol in

colourless needles, m. p. 186—187° after sintering to an opaque mass at 169—171°. Reduction with sodium amalgam gave an almost theoretical yield of  $\beta$ -4-methoxyphenylpropionic acid, m. p. 101—103° (Perkin, *loc. cit.*).

$\beta$ -4-Methoxyphenylpropionyl chloride was prepared by warming a mixture of the acid (60 g.) and thionyl chloride (84 c.c.) on the steam-bath until the evolution of hydrogen chloride ceased. The excess of thionyl chloride was removed by distillation, the residual acid chloride dissolved in benzene (120 c.c.), and the solution saturated with ammonia; the amide (32 g.) then separated, m. p. 123—124° after crystallisation from water (compare Barger and Walpole, J., 1909, 95, 1723).

$\beta$ -4-Methoxyphenylpropionitrile.—A mixture of  $\beta$ -4-methoxyphenylpropionamide (31 g.) and thionyl chloride (45 c.c.) was heated under reflux for 1 hour. The excess of thionyl chloride was removed by distillation and an ethereal solution of the residue was washed with dilute sodium carbonate solution and then with water. The dried solution was freed from solvent and the resulting oil, on distillation under diminished pressure, gave the nitrile (16 g.) as a colourless oil, b. p. 172—173°/17 mm. (Found: C, 74.1; H, 7.0; N, 8.6.  $C_{10}H_{11}ON$  requires C, 74.5; H, 6.9; N, 8.7%).

*Condensation of  $\beta$ -4-Methoxyphenylpropionitrile with Phloroglucinol Dimethyl Ether.*—A solution of phloroglucinol dimethyl ether (13.8 g.) and  $\beta$ -4-methoxyphenylpropionitrile (14.5 g.) in dry ether (160 c.c.) was saturated with dry hydrogen chloride at 0° in the presence of anhydrous zinc chloride (7 g.). The mixed ketimine hydrochlorides separated as a semi-solid and after 4 days a further quantity was precipitated on the addition of dry ether (500 c.c.). A suspension of the mixture in water (250 c.c.) was heated on the steam-bath for 15 minutes; on cooling, the product solidified. Ethyl acetate extracted the ketone (IV) (6.5 g.), which crystallised from alcohol in squat prisms, m. p. and mixed m. p. 110° (Found: C, 68.2; H, 6.4%). Acetylation with acetic anhydride and sodium acetate at 100° gave the acetyl derivative, m. p. and mixed m. p. 62—63°. The latter, on being heated with acetic anhydride and sodium acetate at 180° for 18 hours, was converted into the benzopyrone (VI), which separated from warm alcohol in clusters of colourless needles, m. p. and mixed m. p. 165—166°.

The residue insoluble in ethyl acetate consisted of unchanged ketimine hydrochloride and was readily soluble in warm alcohol, from which it separated in colourless prisms on the addition of an excess of ethyl acetate. It was hydrolysed by boiling for 2 hours with water (300 c.c.). A solution of the solid product in cold 2%

aqueous sodium hydroxide (filtered to remove traces of insoluble impurities), on acidification with concentrated hydrochloric acid, gave 4-hydroxy-2:6:4'-trimethoxy- $\beta$ -phenylpropiophenone (V) (8 g.), which, on recrystallisation from 70% methyl alcohol and then from benzene, was obtained in colourless rectangular plates, m. p. 142° (Found: C, 68.2; H, 6.4.  $C_{18}H_{20}O_5$  requires C, 68.4; H, 6.3%). It is more readily soluble in alcohol and in benzene than the isomeric ketone (IV) and does not give a ferric chloride reaction. The acetyl derivative could not be crystallised.

The authors desire to express their thanks to the Chemical Society for a grant which has defrayed a part of the cost of this investigation.

## VII.—The Nitration of Aromatic Thiocyanates.

By FREDERICK CHALLENGER, CONSTANCE HIGGINBOTTOM, and  
ALFRED HUNTINGTON.

THE *o*:*p* ratio for the nitration of phenyl thiocyanate (Challenger and Collins, J., 1924, 125, 1377) has been found to be 1:4. The ratio for phenyl selenocyanate (Challenger and Peters, J., 1928, 1368), which is being determined, may be expected to be greater, since rise in the atomic number of the halogens increases ortho-substitution (Lapworth and Robinson, *Mem. Manchester Lit. Phil. Soc.*, 1927-8, 72, 49; *Ann. Rep.*, 1928, 141).

The preparation and nitration of *o*-chloro-, *o*-bromo-, and *m*-chloro-phenyl thiocyanates are now described. The ortho-compounds yielded almost exclusively 2-chloro(or bromo)-4-nitrophenyl thiocyanates. About 0.1 g. of the 5-nitro-derivative was obtained from 5.4 g. of *o*-chlorophenyl thiocyanate and from 5 g. of the *o*-bromo-compound. The results obtained in this and earlier communications are summarised on p. 27: the yield of mononitro-compound is recorded against the nitro-group, and the position of the nitro-group in the isomeride produced is shown by NO<sub>2</sub> in parentheses.

Both the thiocyano-group and the halogens, owing to their large number of unshared electrons, tend to transfer these to the carbon-sulphur or carbon-halogen linkage in phenyl thiocyanates or halogenobenzenes. A drift of electrons (conjugative effect) is thus set up which activates the *o*- and *p*-positions (Allan, Oxford, Robinson, and Smith, J., 1926, 409). The dissociation constants of

thiocyanoacetic acid (Ostwald, *Z. physikal. Chem.*, 1889, **3**, 179) and of chloro- and bromo-acetic acids are  $2.65 \times 10^{-3}$ ,  $1.55 \times 10^{-3}$ , and  $1.38 \times 10^{-3}$  respectively. Thiocyanogen is therefore analogous to chlorine in attracting electrons more strongly than hydrogen and imposing on the benzene nucleus a positive field (negative general effect) which opposes the *o*:*p*-orienting conjugative effect. It is well known, however, that no meta-substitution has been detected with the halogenobenzenes, nor have we observed it with phenyl thiocyanate.

The results obtained on nitration of *p*-tolyl thiocyanate may be regarded as in agreement with the much greater ortho-directing influence of methyl as compared with that of thiocyanogen; the *o*:*p* ratio for  $\text{CH}_3$  is 58.8 : 36.8 and that of SCN is 20 : 80. Here in the major product the "general effects" of methyl (positive general effect) and of SCN support each other.

In *o*-tolyl thiocyanate, where the *p*-positions with respect to both substituents are unoccupied, the effect of SCN predominates. No vicinal derivatives such as  $\text{C}_6\text{H}_3(\text{NO}_2)(\text{SCN})(\text{CH}_3)[6:1:2]$  were isolated and the *o*-effects of SCN and  $\text{CH}_3$  appear to play a subordinate part. The result appears to be largely determined by the conjugative effect of SCN at position 4. Some substitution occurs to a less extent at 5, the position activated by the methyl group and least inhibited by the general effect of SCN.

With *o*-chloro- and *o*-bromo-phenyl thiocyanates examination shows no trace of vicinal derivatives in the nitration products. The conjugative effect of SCN and the general effect of halogen both tend to favour substitution at position 4, and only traces of

the 5-nitro-compounds are formed. With *m*-chlorophenyl thiocyanate vicinal substitution is again absent and two products are formed by the reinforced conjugative effects of SCN and chlorine at positions 4 and 2 respectively, the 4-nitro-compound predominating.

The most interesting feature of these results is the relation of the effects induced by SCN to those induced by methyl and chlorine. It appears from the nitration of the tolyl thiocyanates that the speeds of substitution induced by the CH<sub>3</sub> and the SCN group are not very different, since in comparing ortho-effects (*p*-tolyl thiocyanate) methyl predominates, and in comparing para-directing effects (*o*-tolyl thiocyanate) SCN predominates. On the other hand, the results for halogenophenyl thiocyanates clearly show that the speeds of substitution *o*- or *p*- to SCN are incomparably greater than those *o*- or *p*- to chlorine or bromine in these molecules. In Holleman's series OH > NH<sub>2</sub> > I > Cl > Br > CH<sub>3</sub>, chlorine is slightly more powerful than methyl (compare Challenger and Collins, *loc. cit.*). Further work is in progress and a study of the physical properties of certain thiocyanates will be made. Attempts to prevent elimination of iodine on nitration of *p*-iodophenyl thiocyanate were unsuccessful (compare Challenger and Collins, *loc. cit.*; Körner, *Gazzetta*, 1875, 4, 385; Mayes and Turner, J., 1928, 691).

Ingold, Smith, and Vass (J., 1927, 1245) showed that the decomposition of substituted aryl iododichlorides to chloriodobenzenes is an intermolecular reaction, the position entered by chlorine being determined not necessarily by the iodine, but by the strongest group present. Attempts to decompose the *dichloride* of *p*-iodophenyl thiocyanate so as to induce nuclear chlorination failed, loss of chlorine and regeneration of the iodothiocyanate usually occurring. In sunlight *pp'*-di-iododiphenyl disulphide was formed. This decomposition possibly proceeds by liberation of cyanogen chloride and formation of the *p*-iodophenyl thiolchloride I·C<sub>6</sub>H<sub>4</sub>·SCl. Thiols of this type yield disulphides with alcohol. It has therefore been impossible to compare the orienting effects of iodine and thiocyanogen.

Our results may be compared with those of Werner (J., 1907, 91, 240, 529), who found that a nitro-group in the *o*- or *p*-position to ICl<sub>2</sub> prevents nuclear chlorination. With a halogen atom in the *p*-position, this effect is slightly less, some nuclear chlorination taking place.

#### EXPERIMENTAL.

*o*-Chlorophenyl Thiocyanate.—*o*-Chloroaniline was diazotised at 0°, added to an aqueous solution of ferric chloride and potassium thiocyanate, and left over-night. The *thiocyanate* was extracted

twice with benzene, distilled in steam, and again extracted with benzene. After three fractionations in a vacuum it was almost colourless, boiled at  $160\text{--}160.5^\circ/42\text{--}47$  mm., and solidified in ice. Yield, 18 g. (53% of the theoretical). It has an unpleasant odour and the vapour attacks the eyes and skin (Found: Cl, 20.7, 21.1; S, 19.1, 19.15.  $\text{C}_7\text{H}_4\text{NClS}$  requires Cl, 20.9; S, 18.9%).

The *o*-bromo-, *p*-iodo-, and *m*-chloro-derivatives of phenyl thiocyanate were similarly prepared (see table below). Extraction with benzene prior to steam distillation removes inorganic salts which may facilitate disulphide formation during treatment with steam.

The irritant effect of *m*-chlorophenyl thiocyanate is much more pronounced than that of the other halogen derivatives.

**2-Chloro-4-nitrophenyl Thiocyanate.**—2-Chloro-4-nitroaniline was obtained by the method of Chattaway, Orton, and Evans (*Ber.*, 1900, **33**, 3061), but hot dilute sulphuric acid was found to be most suitable for hydrolysis of the 2-chloro-4-nitroacetanilide, the free base separating on cooling.

2-Chloro-4-nitroaniline was diazotised at  $-5^\circ$  and treated as described above. The *product*, when crystallised from alcohol, acetone and finally from light petroleum, formed colourless needles, m. p.  $85^\circ$  (Found: N, 13.3.  $\text{C}_7\text{H}_3\text{O}_2\text{N}_2\text{ClS}$  requires N, 13.05%).

The other halogenonitro-thiocyanates were prepared similarly (see table), cuprous thiocyanate being occasionally employed in place of ferric chloride.

2-Chloro-5-nitrophenyl thiocyanate melts at  $107^\circ$  (Found: C, 39.6; H, 1.3.  $\text{C}_7\text{H}_3\text{O}_2\text{N}_2\text{ClS}$  requires C, 39.2; H, 1.4%).

Substituted aniline.	Wt. of base (g.).	$\text{H}_2\text{SO}_4$ (c.c.).	Water (c.c.).	$\text{NaNO}_2$ (g.).	KSCN (g.).	$\text{Cu}_2(\text{SCN})_2$ (g.).	$\text{FeCl}_3$ (g.).	M. p. or b. p. of product.
2-Cl	25.5	40	160	18.7	38.8	—	30	B. p. $160^\circ/42$ mm.
2-Br	30	40	160	18.0	38.0	—	63.6	B. p. $161\text{--}165^\circ/10\text{--}12$ mm.
3-Cl	40	54	200	25.0	60.0	—	30.0	B. p. $135^\circ/12.5$ mm.
4-SCN	5	3.9	86	3.0	9 g. KI	—	—	M. p. $53^\circ*$
2-Cl-5- $\text{NO}_2$	10	60	120	5.0	12.0	—	10.0	$107^\circ$
2-Cl-4- $\text{NO}_2$	1.7	20	40	0.9	1.9	—	1.6	" $85^\circ$
2-Br-5- $\text{NO}_2$	2.5	15	30	1.1	1.5	2.0	—	" $124.5^\circ$
2-Br-4- $\text{NO}_2$	1.0	8	16	0.5	0.6	0.8	—	" $93^\circ$
3-Cl-4- $\text{NO}_2$	6.0	100	100	3.0	6.2	—	5.3	" $59^\circ$
3-Cl-6- $\text{NO}_2$	6.0	100	100	3.0	6.2	—	5.3	" $104.5^\circ$

The product contained SCN in place of the  $\text{NH}_2$  of the original base in every case except that marked \*, where *p*-iodophenyl thiocyanate was formed.

**Nitration of *o*-Chlorophenyl Thiocyanate.**—The thiocyanate (5.4 g.) was slowly added to well-stirred nitric acid (*d* 1.5; 18 c.c.) at  $-6^\circ$ , left for 4 hours at room temperature, and poured on ice. The crude

product, m. p. 76—78°, weighed 6.6 g., i.e., 96% of the amount required for a mononitro-derivative. Fractional crystallisation from alcohol and then from light petroleum gave a main product (A), m. p. 85°, and about 0.01 g. of (B), m. p. 107°.

A and B did not depress the m. p.'s of synthetic specimens of 2-chloro-4-nitrophenyl thiocyanate and of 2-chloro-5-nitrophenyl thiocyanate respectively (Found for A: Cl, 16.6; S, 14.7; N, 13.3. Found for B: N, 13.2.  $C_7H_3O_2N_2ClS$  requires Cl, 16.5; S, 14.9; N, 13.05%).

A was boiled with animal charcoal in alcohol: the solution yielded a small quantity of white crystals (E), m. p. 165°, which were less soluble in alcohol and gave no thiocyanate reaction. Since (A) was previously pure, the formation of sulphide or disulphide was suspected and the behaviour of synthetic 2-chloro-4-nitrophenyl thiocyanate towards charcoal was studied. The production of E was confirmed and shown to be due to the charcoal and not to the alcohol. The charcoal gave an alkaline reaction in water. After being boiled with hydrochloric acid and washed, it was found not to affect the thiocyanate even when boiled for several hours in alcohol. When the thiocyanate was left with 10% sodium hydroxide solution for 7 days and recrystallised from acetone, the same product ( $E_1$ ), m. p. 165, was obtained, as also on treatment with warm alcoholic ammonium sulphide ( $E_2$ ). The m. p. of E was not depressed on admixture with  $E_1$  or  $E_2$ . The method of formation of  $E_2$  shows it to be a disulphide (compare Müller, *Z. farb. Text. Ind.*, 1906, 5, 357), a conclusion confirmed by the formation of diphenyl disulphide, m. p. and mixed m. p. 60°, and of di-*o*-nitrophenyl disulphide from the corresponding thiocyanates and sodium hydroxide. *o*-Nitrophenyl thiocyanate also gave the disulphide when boiled with the contaminated charcoal in alcohol.

*Preparation and Nitration of o-Bromophenyl Thiocyanate.*—(a) The preparative details are given on p. 29. The product formed white needles, m. p. about 24° (Found: S, 14.9, 14.8; Br, 37.65.  $C_7H_4NBrS$  requires S, 14.95; Br, 37.3%). (b) The thiocyanate (5 g.) was added during 45 minutes to nitric acid (*d* 1.5; 18 c.c.) at -5° to -6°, left at room temperature for 15 minutes, and poured on ice. The yield of crude product, m. p. about 83°, was 5.8 g. (97% of the amount required for a mononitro-derivative). Fractional crystallisation from alcohol and from light petroleum gave a main product (C), m. p. 93°, and a trace of (D), m. p. 126°. These did not depress the m.p.'s of synthetic specimens of the 4-nitro- and 5-nitro-2-bromophenyl thiocyanates respectively (Found for C: N, 11.0; Br, 31.0, 30.9. Found for D: N, 11.0.  $C_7H_3O_2N_2BrS$  requires N, 10.8; Br, 30.9%).

**2-Bromo-4-nitrophenyl Thiocyanate.**—2-Bromo-4-nitroaniline was prepared from *o*-bromoacetanilide and nitric acid (*d* 1.5) at  $-5^{\circ}$  to  $-10^{\circ}$ . Having been kept for 30 minutes in the freezing mixture and for  $1\frac{1}{2}$  hours at room temperature, the reaction mixture was treated with ice. The solid obtained, m. p.  $120^{\circ}$ , was fractionally crystallised: the less soluble portion, m. p.  $130^{\circ}$  (Chattaway, Orton, and Evans, *loc. cit.*, give  $129^{\circ}$  as the m. p. of 2-bromo-4-nitroacetanilide), was treated for  $1\frac{1}{2}$  hours with sulphuric acid at  $100^{\circ}$  and poured into water, giving the yellow base, m. p.  $105^{\circ}$  (Hübner, *Ber.*, 1877, 10, 1709, gives m. p.  $104.5^{\circ}$ ). The preparation by this method has not been described.

The *thiocyanate* was prepared as usual (see p. 29). It formed pale yellow crystals, m. p.  $93^{\circ}$ , from light petroleum and gave the thiocyanate reaction (Found: N, 10.9.  $C_7H_3O_2N_2BrS$  requires N, 10.8%).

**2-Bromo-5-nitrophenyl Thiocyanate.**—The corresponding amine was prepared by the method used by Chattaway, Orton, and Evans (*loc. cit.*) for the chloro-derivative, the application of which to the bromo-compound does not appear to be described. The pale yellow *thiocyanate* (see p. 29), after crystallising from alcohol and finally from light petroleum, melted at  $126^{\circ}$  (Found: C, 32.6; H, 1.5.  $C_7H_3O_2N_2BrS$  requires C, 32.4; H, 1.16%).

**Preparation and Nitration of *m*-Chlorophenyl Thiocyanate.**—(a) See p. 29 for preparative details. Shortly after the addition of the *m*-chlorobenzenediazonium chloride to the ferric thiocyanate there was a violent reaction and the temperature rose considerably. This was also observed in a second experiment when the mixture was standing in ice. The pure *thiocyanate* boiled at  $135^{\circ}/12.5$  mm. (Found: N, 8.6.  $C_7H_4NClS$  requires N, 8.3%).

(b) The *thiocyanate* (5 g.) was slowly added to well-stirred nitric acid (*d* 1.5; 15 c.c.) at  $-10^{\circ}$ . After an hour the liquor was left at room temperature for 2 hours and poured on ice. Fractional crystallisation of the washed and dried crude product (5.9 g., m. p.  $44-48^{\circ}$ ) from ethyl alcohol and then from methyl alcohol yielded (F), m. p.  $48-51^{\circ}$ , and (G), m. p.  $104^{\circ}$ . Crystallisation of F did not alter the m. p. Distillation with steam failed to purify it, since the product ceased to give the thiocyanate reaction (Challenger and Peters, *J.*, 1928, 1368) and melted at  $130-135^{\circ}$ . Repetition of the nitration and further crystallisation from light petroleum finally gave a large fraction (H), m. p.  $59^{\circ}$ , and a very small one (K), m. p.  $104-105^{\circ}$ . There was no evidence of any other isomeride. H and K did not depress the m.p.'s of the thiocyanates of the same melting points prepared from 3-chloro-4-nitroaniline and 3-chloro-6-nitroaniline, respectively (Found for H and K: N, 13.2 and 13.1 respectively.  $C_7H_3O_2N_2ClS$  requires N, 13.05%).

*Preparation of the 6- and the 4-Nitro-derivative of m-Chlorophenyl Thiocyanate.*—The corresponding amines were prepared by the method of Mayes and Turner (J., 1928, 693). The 6-nitro-thiocyanate, after crystallising from ethyl alcohol and twice from methyl alcohol, melted at 104–105° (Found : Cl, 16.2, 16.7; N, 13.3; S, 14.6). The 4-nitro-compound, m. p. 59°, was crystallised first from alcohol and then from light petroleum (Found : N, 13.3, 13.2.  $C_7H_3O_2N_2ClS$  requires N, 13.05; Cl, 16.5; S, 14.9%).

*Preparation and Attempted Nitration of p-Iodophenyl Thiocyanate.*—This substance was obtained by Challenger and Collins (*loc. cit.*), but was not analysed. It melts at 53° (Found : I, 48.3; S, 11.9.  $C_7H_4NIS$  requires I, 48.5; S, 12.3%).

*p*-Iodophenyl thiocyanate was attacked neither by nitric acid (*d* 1.41) at  $-10^\circ$  or at  $15^\circ$ , nor, in acetic anhydride solution, by nitric acid (*d* 1.5) at  $0^\circ$ . On slow addition of the thiocyanate (1 g.) to a mixture of sulphuric acid (10 c.c.) and nitric acid (*d* 1.41; 10 c.c.) at  $-14^\circ$ , most of it dissolved, forming a pale brown solution, but iodine did not appear to be liberated. After remaining for 3 hours at  $-10^\circ$  to  $-5^\circ$ , the mixture was poured on ice; a black solid then separated, becoming paler in air and giving only *p*-nitrophenyl thiocyanate, m. p. and mixed m. p.  $133^\circ$ , on fractional crystallisation. The acid liquor contained free iodine. Similar results were obtained with nitric acid (*d* 1.5) at  $-16^\circ$ . With equal volumes of nitric acid (*d* 1.5) and (*d* 1.41) at  $-12^\circ$ , reaction was very slow, but on addition of more acid (*d* 1.5) a black solid separated. The *p*-nitro-derivative was isolated as before.

*Preparation of p-Dichloriodophenyl Thiocyanate.*—The iodothiocyanate in three times its weight of chloroform was cooled in ice and treated with chlorine for about 30 minutes and the pale yellow needles were washed with light petroleum; m. p.  $111^\circ$ . The substance was analysed by Willgerodt's method ("Die Organischen Verbindungen mit mehrwertigem Jod," 1914, p. 22) using potassium iodide and sodium thiosulphate (Found : Cl, 21.4, 21.3.  $C_7H_4NCl_2IS$  requires Cl, 21.4%).

When heated in an open vessel to  $100^\circ$ , the iododichloride evolved chlorine. The solidified residue, m. p.  $49^\circ$ , had m. p.  $51^\circ$  after recrystallisation and did not depress the m. p. of *p*-iodophenyl thiocyanate ( $52-53^\circ$ ). The thiocyanate was also formed in (a) boiling carbon tetrachloride and (b) light petroleum (b. p.  $40-50^\circ$ ); addition of iron filings to (a) did not affect the result. After remaining for 24 hours in ultra-violet light, the iododichloride was completely converted into the thiocyanate. The iododichloride (3 g.), exposed to sunlight in a closed bottle, liquefied after 2 weeks but became solid a few days later. Much pressure developed,

hydrogen chloride was present, and a very pungent odour which may have been that of cyanogen chloride. The yellow solid produced melted at 53°; after recrystallisation from alcohol, it became colourless, melted at 126°, and did not depress the m. p. (126°) of *pp'*-di-iododiphenyl disulphide.

*Preparation of Phenyl Thiocyanate and Quantitative Study of its Nitration.*—Challenger and Collins (*loc. cit.*) prepared phenyl thiocyanate by Gattermann's method (*Ber.*, 1890, **23**, 738), using potassium and cuprous thiocyanates. A better yield is obtained with ferric chloride and potassium thiocyanate (Korczyński, *Bull. Soc. chim.*, 1922, **31**, 1179), although in this and other cases (see p. 31) the evolution of nitrogen tends to lag and then suddenly to become violent. The steam-distilled product was carefully fractionated; b. p. 143—145°/64 mm. (Found: S, 23·4, 23·3. Calc.: S, 23·7%). Phenyl mercaptan and phenyl disulphide, which are possible impurities, contain 29·1 and 29·3% of sulphur respectively).

The *o*-, *m*-, and *p*-nitro-thiocyanates required for thermal analysis were prepared by the diazo-reaction (Müller, *Z. farb. Text. Ind.*, 1906, **5**, 357) by means of copper salts. Steam distillation was impracticable and the thiocyanates were purified by extraction of the solid product with alcohol and decoloration with carefully purified charcoal.

*Nitration of phenyl thiocyanate.* The thiocyanate (10 g.) was slowly added to nitric acid (*d* 1·41; 24 c.c.) and sulphuric acid (27 c.c.) at 0—5°. After 5 g. had been added, a solid separated. After remaining for 5 hours at 0°, the mixture rose to room temperature, but, as the odour of phenyl thiocyanate was still perceptible, another 6 c.c. of each acid were added. After 4 hours, the mixture was poured on ice, thiocyanate odour being absent. The oil-free solid was washed, triturated with cold water, shaken with water for several hours, dried at about 90°, and left in a desiccator. Yield, 12·5 g. (94% of the theoretical yield for a mononitro-derivative). The washings and spent acid were extracted with benzene, but yielded only a small amount of oil with an odour of phenyl thiocyanate. The nitration product was examined for compounds other than *o*- and *p*-nitrophenyl thiocyanates. When fused, it had a very slight odour of phenyl thiocyanate. The smell of this substance is very powerful and only minute traces could have been present. Repeated fractionation failed to detect any *o*- or *p*- or dinitro-derivative of phenyl disulphide which might have been produced by oxidation of the nitro-thiocyanates. These substances are difficultly soluble. A test was made for the presence of 2 : 4-dinitrophenyl thiocyanate. Addition of *o*- or *p*-nitrophenyl thiocyanate to a mixture of acetone and sodium hydroxide gives an orange colour to the acetone layer, the

alkali being coloured pale yellow. A trace of the dinitro-compound colours the mixture almost black and the alkali red. With the nitration mixture the colour was orange-yellow, indicating the absence of the dinitro-derivative.

*Thermal analysis of the nitration mixture.* The setting point (S.P.) of the well-washed and dried nitration mixture was  $121.9^{\circ}$ , results differing by not more than  $0.1^{\circ}$  being obtained on remelting. A second nitration of phenyl thiocyanate gave a product of S.P.  $121.7^{\circ}$ . The eutectic point was difficult to observe but appeared to be about  $95^{\circ}$ . The S.P. of various mixtures of *o*- and *p*-nitrophenyl thiocyanates were then determined by adding increasing quantities of the *o*-derivative to the *p*-compound of S.P.  $131.0^{\circ}$ .

% Ortho- .....	1	2	4	6	10
S.P. ....	$130.3^{\circ}$	$129.5^{\circ}$	$128.5^{\circ}$	$127.6^{\circ}$	$126.1^{\circ}$
% Ortho- .....	15	20	21	30	
S.P. ....	$124.0^{\circ}$	$121.9^{\circ}$	$121.5^{\circ}$	$114.5^{\circ}$	

From these figures the nitration product would appear to contain 20% of *o*-nitrophenyl thiocyanate. The eutectic point of one of the synthetic mixtures was found to be about  $96.5^{\circ}$ , in fairly good agreement with that of the nitration product.

The nitration product being assumed to consist solely of 80% of para- and 20% of ortho-thiocyanate, sufficient *o*-nitrophenyl thiocyanate was added to form a 30% mixture. The S.P. was  $114.9^{\circ}$ , and that of a synthetic mixture is  $114.5^{\circ}$  (see table), the results being therefore in agreement. Further evidence was afforded by examination of mixtures containing *m*-nitrophenyl thiocyanate. A synthetic mixture containing 76.2% of para-, 19.0% of ortho-, and 4.8% of meta- had S.P.  $118.6^{\circ}$ . On addition of 0.2094 g. of *m*-nitrophenyl thiocyanate to 4.1870 g. of the nitration product, the resulting mixture should contain 4.8% of meta-. The observed S.P. was  $118.9^{\circ}$ .

Part of the cost of this investigation was defrayed by a grant from the Research Fund of the Chemical Society, for which the authors desire to express their thanks.

THE UNIVERSITY, MANCHESTER.

VIII.—*The Parachor of Chlorine Dioxide.*

By GEOFFREY HERBERT CHEESMAN.

THE structure of chlorine dioxide,  $\text{ClO}_2$ , has always been the subject of much speculation, and the electronic ideas of valency do not solve the difficulty, for the total electron content (19 outer-sheath electrons)

is an odd number. As usual with inorganic compounds, it is difficult to obtain evidence of structure, but in this case it seemed reasonable to try Sugden's parachor method. Chlorine dioxide, being liquid between  $-59^\circ$

and  $+10^\circ$  under atmospheric pressure, is suitable for surface-tension and density measurements. Through-

out this work the chlorine dioxide-carbon dioxide mixture produced by Bray's method was frozen out and fractionated.

Quantities of liquid up to about 1 c.c. were condensed and fractionated in the simple vacuum apparatus shown in Fig. 1. The material was condensed in A, and warmed to  $0^\circ$ , whereupon all the carbon dioxide passed off. About one-quarter of the liquid was allowed to evaporate away through tap D. The remainder was frozen out, the apparatus pumped out, and two-thirds of the remainder distilled

FIG. 2a.

FIG. 2b.

into B by surrounding the latter with liquid air. From this, one-quarter was again rejected, and the middle portion distilled as before into C. All the material was then frozen in liquid air, and the apparatus evacuated and sealed between C and B. About 0.2–0.4 c.c. was thus obtained.

The purity of the material was followed by vapour-pressure determinations with the mercury manometer and sulphuric acid buffer on the left of the apparatus. Reproducible pressures were obtained

in good agreement with those of King and Partington (J., 1926, 925).

Two sets of density determinations were made, the first by a method of balancing columns, and the second by a pycnometer method. The first method is illustrated by Fig. 2*a*. The inner tube of the apparatus, B, was a uniform capillary, and the material was distilled into the lower portion of A through the side tube C. Suction was gently applied at D, and the heights of the liquid in the capillary and of the water in the U-tube E were measured with a sliding microscope. About 20 readings were taken, and the height of liquid plotted against the height of water. The points lay on a straight line, the gradient of which gave the relative density of the liquid at the temperature of the experiment (0°).

Two experiments on these lines gave rather different results, and hence the second method was tried. The actual pycnometer resembled a small thermometer (Fig. 2*b*) with a mark at A on the capillary stem, and a file scratch at S; it was sealed to the fractionation apparatus at X. Sufficient material was distilled in to fill it nearly to A when at 0°, and then frozen out. The apparatus was evacuated, sealed off at Z, and maintained at 0° till the meniscus remained steady, and the distance below A was measured with the sliding microscope. (Further readings at other temperatures gave the corresponding densities, which it is hoped to communicate later.) The instrument was then weighed, the contents frozen, and the apparatus carefully broken open at S, any small fragments (which were only produced on one occasion) being retained. The contents were allowed to evaporate, the apparatus dried in a vacuum, and reweighed. A previous calibration with mercury gave the volume to the mark A and the volume per mm. of stem below the mark. Hence the density of the liquid could be calculated. The densities (g./c.c. at 0°) obtained by the two methods were as follows, the mean of all five determinations being 1.642.

Balanced-column method: 1.622, 1.645. Pycnometer method: 1.661, 1.639, 1.644.

The surface tension was measured by capillary rise, the mean of seven consistent experiments in different apparatus giving  $\gamma/D = 20.1$ . Combination of this with the density above gives the surface tension as 33.1 dynes/cm. at 0°, and hence the parachor is 98.7 units.

The data of King and Partington (*loc. cit.*) and cryoscopic measurements of Bray (*Z. physikal. Chem.*, 1906, 54, 569) appear to indicate absence of association, and a determination in the present work of the Ramsay-Shields coefficient confirms this. (The experiments upon the surface tension, density, and other properties at lower temperatures will be published later.) The determined parachor

may therefore be compared with the sum of the atomic parachors of the elements, *viz.*, 94.3, leaving a structural parachor of +4.4 units.

On the assumption that all octets are completed, there are eleven possible electron distributions for chlorine dioxide. Of these, three do not yield readily calculable parachors, but are improbable on account of large polarities accumulated on single atoms; five others are unlikely because they give large negative structural constants. The remaining three are shown below :

(I.)	$\begin{array}{c} -\frac{1}{2} \quad +1 \quad -\frac{1}{2} \\ \text{O}=\text{Cl}=\text{O} \\ \boxed{\phantom{000}} \end{array}$	(II.)	$\begin{array}{c} +\frac{1}{2} \quad -\frac{1}{2} \\ \text{Cl}=\text{O}=\text{O} \\ \boxed{\phantom{000}} \end{array}$	(III.)	$\begin{array}{c} -\frac{1}{2} \quad +\frac{1}{2} \\ \text{Cl}-\text{O}\equiv\text{O} \\ \boxed{\phantom{000}} \end{array}$
2 Semipolar double bonds	- 3.2	Semipolar singlet	- 12.4	Semipolar singlet	- 12.4
Non-polar singlet .....	- 11.6	3-Membered ring	+ 17.0	Double bond	+ 23.2
3-Membered ring .....	+ 17.0	Structural const.	+ 4.6	Structural const.	+ 10.8
Structural const. ....	+ 2.2				

On the assumption that formula (I) contains only one integral dipole, the structural parachor amounts to +3.6 units. Formulæ (I) and (II) therefore give the closest agreement with the observed value, and further work is now in hand to adduce other evidence for the structure of the dioxide and other halogen oxides. The structure (II) herein suggested appears somewhat novel, but accords quite well with the known reactions of the oxide.

The work was carried out in the laboratory of Professor Baker, and thanks are due to him for his interest in it.

## IX.—*The Chlorination of Anilides. Part VI. The Rates of N-Chlorination of Acetanilides and Acetobenzylamides and the Effects of Substituents upon Side-chain Reactivity.*

By GWYN WILLIAMS.

IN a previous paper (Orton, Soper, and Williams, J., 1928, 998) a method was described for measuring the rates of reaction of anilides with chlorine in aqueous acetic acid media and Wegscheider's test was applied to show that *N*-chlorination and *C*-chlorination proceed simultaneously, so that, under these conditions, the reactions may be represented thus,

The ratio  $k_N/k_C$  (where  $k_N$  and  $k_C$  are the velocity coefficients for

*N*- and *C*-chlorination respectively) is constant for each anilide throughout the reaction, but varies widely for different anilides, having the values 0.00873, 0.0548, 0.850, 10.40 for acetanilide and *m*-, *p*-, and *o*-chloroacetanilides respectively in 40% acetic acid, whilst *N*-chlorination predominates in nitroacetanilides and acetobenzylamides with almost complete exclusion of simultaneous *C*-chlorination. The object of this paper is to consider the influence of the substituents NO<sub>2</sub>, Cl, and CH<sub>3</sub> upon the rates of these reactions, with special reference to the *N*-chlorination which takes place in 40% acetic acid and aqueous media (Soper, *J. Physical Chem.*, 1927, 31, 1192) but is absent under the conditions prevailing in other investigations of the rates of chlorination of anilides (Orton and King, *J.*, 1911, 99, 1369; Orton and Bradfield, *J.*, 1927, 986). The influence exerted by substituents in the benzene nucleus upon side-chain reactivity is closely allied to the general problem of orientation, and the above substituents have been chosen so as to furnish a contrast in orienting activities, those of NO<sub>2</sub> and CH<sub>3</sub> being opposed, whilst the action of Cl depends upon whether its "tautomeric" or its "inductive" influence has the greater scope.

Table I gives the results for 22 anilides. Each value is the average of three or more experiments\* and the mean deviation from the mean is estimated, in general, at  $\pm 2-3\%$ ; it is often less than this (see Orton, Soper, and Williams, *loc. cit.*) and never more than 5%. Where no value is given for  $k_c$ , nuclear chlorination is too slow in comparison with *N*-chlorination to be distinguished with certainty from accidental loss of chlorine. The figures in parentheses are subject to qualifications discussed in the experimental section.

† Chloroamine equilibrium unsuitably placed.

\* I am indebted to Mr. S. P. Hughes, B.Sc., for help in checking values for three substances.

The electronic theory has recently been applied to the classification of benzene side-chain reactions (*Ann. Reports*, 1927, 1928) and, with certain reservations (see below), it may be used to interpret Table I, which illustrates the effects of substituents upon the speed of *N*-chlorination for a particular set of conditions. To this end, Table II has been constructed so as to investigate (a) how far the effects of substituents are consistent in a number of side-chain reactions; (b) whether, if consistency is found, it is such as to support the electronic schemes; (c) to determine whether *N*-chlorination finds a place in the scheme; (d) to seek analogies in other reactions for certain peculiarities observed in *N*-chlorination.

Table II gives the effects of the substituents  $\text{NO}_2$ ,  $\text{Cl}$ , and  $\text{CH}_3$  upon 36 reactions, the rates for each reaction being calculated relative to that for the unsubstituted compound as unity. Only those reactions are included in which more than one substituent has been investigated.

The electronic theory suggests that it should be possible to group side-chain reactions in two main classes accordingly as they are favoured by accession of electrons to the point of reaction or by recession from that point. The influence of  $\text{CH}_3$  should be in the opposite sense to that of  $\text{NO}_2$  and  $\text{Cl}$  (if its inductive influence is predominant), and superimposed on these general effects there should be alternating effects where the substituent can initiate covalency changes. Table II shows that a general measure of consistency exists in the effects of groups in accelerating or retarding side-chain reactions and that the reactions tabulated fall into two main groups; 19 are in Group A with the nitro-group accelerating and the methyl group retarding, and 12 are in Group B, in which the reverse holds. It has been observed in drawing up the table that other substituents fall into line with those tabulated, the same sharp contrast existing between those which are *op*- and those which are *m*-directing in the usual substitution reactions. Five reactions (Group C) cannot be allotted with certainty to either class.

In the following scheme the alternating effects suggested by theory are compared with those observed :

Group A.			Group B.		
	$-\text{NO}_2 > \text{H} > -\text{CH}_3$ .	Agree- ment.	$-\text{CH}_3 > \text{H} > -\text{NO}_2$ .	Agree- ment.	
For $-\text{NO}_2$	<i>m</i> -<(o) <i>p</i> -	7 out of 9	<i>m</i> ->(o) <i>p</i> -	7 out of 8	
For $-\text{CH}_3$	<i>m</i> ->(o) <i>p</i> -	7 out of 9	<i>m</i> -<(o) <i>p</i> -	8 out of 9	

There are also many instances, not included in Table II, of alternating effects in the expected sense when only one substituent has been investigated. In Group C of Table II, also, the alternating effects for a given substituent are generally as anticipated. It is seen in

TABLE II.

Group A.	<i>o</i> -NO <sub>2</sub>	<i>m</i> -NO <sub>2</sub>	<i>p</i> -NO <sub>2</sub>	<i>o</i> -Cl	<i>m</i> -Cl	<i>p</i> -Cl	H	<i>o</i> -CH <sub>3</sub>	<i>m</i> -CH <sub>3</sub>	<i>p</i> -CH <sub>3</sub>	Medium.

 (38) Benzoyl chlorides and isopropyl alcohol at 25°; ref. as (12) and also Norris and Gregory, *J. Amer. Chem. Soc.*, 1928, **50**, 1813.

the table that the effect of chlorine is in almost all reactions in the same sense as that of the nitro-group, its inductive influence thus predominating. Analysis of the superposed alternating effects shows that here the results are complex. It may be noted that there is little evidence in Table II for the occurrence of "steric hindrance" due to a single ortho-substituent, though there are indications in reactions in which a carbonyl group is involved (24—35; compare Olivier, *Rec. trav. chim.*, 1929, **48**, 227). Another instance is recorded by Pfeiffer, Engelhardt, and Alfuss (*Annalen*, 1928, **467**, 158) in the esterification of benzonitriles.

In considering, now, the place to be taken by the results of Table I, we see that *N*-chlorination of acetobenzylamides falls unequivocally into Group B. With acetanilides, the results are more complex. When the acetamido-group is directly attached to the nucleus it can act as a strong *op*-directing group, and, in fact, with acetanilide, *N*-chlorination comprises less than 1% of the total reaction. The allocation of *N*-chlorination to Group B of Table II suggests that it is a reaction which is facilitated by flux of electrons towards the nitrogen, so that *N*- and *C*-chlorination are competing processes. Factors tending to obstruct the sharing of electrons between the nitrogen atom and the nucleus will assist *N*- as against *C*-chlorination; thus acetobenzylamide is *N*-chlorinated twice as fast as acetanilide, and *C*-chlorinated at a negligible rate. The results show that in the acetanilides, the introduction of chlorine atoms into the nucleus also reduces the preponderance of *C*-chlorination, an effect only partially offset in *m*-chloroacetanilide by the mutual reinforcement of the *op*-directing activities of the two groups. Indeed, in the acetanilides, chlorine in all positions accelerates *N*-chlorination. This may be ascribed in the *o*- and *p*-compounds to a dominant tautomeric influence by the halogen atom, but the result with the *m*-compound is unexpectedly high. At the same time, chlorine retards the reaction with the acetobenzylamides in all positions without alternation, the inductive effect of the halogen atom presumably dominating the situation,

owing to the methylene group's intervening between the nitrogen atom and the nucleus. The nitro-group depresses reactivity in both series, but, somewhat unexpectedly, far more effectively in the acetobenzylamides than in the acetanilides. The high value for *o*-nitroacetanilide is unexpected, as is also the extraordinarily high rate of reaction of aceto-*p*-toluidide. The *p*-methyl group produces no such effect in the acetobenzylamides, but it may be noted that it has marked effects in reactions 3, 11, and 15 of Table II. There seems to be no analogy in Table II for the special effect of the *o*-nitro-group, unless it be in reaction 35, where it appears to upset the normal reaction completely. (For "ortho-effects," compare also van Duin, *Rec. trav. chim.*, 1927, 46, 256; Kindler, *Annalen*, 1928, 464, 278.)

The view that *N*-chlorination is a reaction favoured by factors tending to produce a crowding of electrons at the nitrogen atom is supported by the fact that the rates for acetamide, aceto- $\beta$ -phenylethylamide, acetobenzylamide, and acetanilide lie in a continuous decreasing series; for the phenyl group acts as an "electron sink" towards the nitrogen atom, since (a) these substances are chlorinated or nitrated in positions *op*- to the nitrogen atoms, and (b) the approach of the phenyl group towards the nitrogen atom lowers the basic properties. Since *N*-chlorination cannot proceed by the separation of an anion, it seems probable that the vital stage is the attraction of the positive component of an incipiently ionised chlorine molecule, much as in the process of nuclear chlorination.

*Nuclear Chlorination.*—Table I contains two new results for nuclear chlorination—those for *m*-chloroacetanilide, mentioned above, and for aceto-*m*-toluidide. The latter, as we should expect, is *C*-chlorinated far more rapidly than acetanilide. On the other hand, the high rate of *C*-chlorination of the para-isomeride is another unexpected effect of the *p*-methyl group. This effect has been observed before, as is shown by Table III, which gives the relative values of  $k_c$  in glacial acetic acid (Orton and King, *loc. cit.*), in 40% acetic acid, and also in water (Soper, 1927, *loc. cit.*). The figures in parentheses are the values of  $k_N/k_c$ .

TABLE III.

Medium.	Acetanilide.		<i>o</i> -Cl.	<i>p</i> -Cl.	<i>o</i> -CH <sub>3</sub> .	<i>p</i> -CH <sub>3</sub> .
	Abs.	Rel.				
Glacial acetic ...	40	1	0.0018	0.0053	0.23	1.93
40% Acetic ...	11,000	1 (0.0087)	0.0025 (10.4)	0.0123 (0.85)	0.126 (0.101)	1.68 (0.137)
Water .....	17,000	1 (0.0076)	0.0026 (13.6)	0.0124 (0.91)	—	—

*Limitations of Solvents.*—It is to be noted in Table III that a parallelism in the values of  $k_c$  exists in spite of the change in medium,

and also despite the intrusion of simultaneous *N*-chlorination in the aqueous media. The change in solvent is, however, comparatively slight, and it should also be observed that in all the reactions in Table II, *the solvents are very similar*, only one being non-polar. This fact limits the generality of the conclusions to be drawn from the experiments. The results shown in Tables I and II are based upon experiments in which a standard substance is made to react with a series of compounds having various substituents inserted at positions remote from the point of reaction; a connexion is then traced between the changes in the reaction rate and the influence supposed to be exerted by the inserted groups upon the bond actually concerned in the reaction (*e.g.*, compare Norris, *Z. physikal. Chem.*, 1927, **130**, 662; Norris *et al.*, *J. Amer. Chem. Soc.*, 1925—1929). The electronic theory permits clearer definition since it ascribes the effects of substituents to their varying "electron affinities," which modify electronic configurations at the reacting atom, and external physical evidence (*e.g.*, from electric moments) is sometimes available as to the quality of the electron affinities. Consequently the process is now sometimes inverted, and the mechanism of a reaction is inferred from the effects of substituents on its speed (see above, also *Ann. Reports*, 1927, 1928). But these comparative experiments are usually made with solutions, wherein reaction velocity is notoriously susceptible to the influence of environment, the action of which may be *specific* to each reacting substance (Christiansen, *Z. physikal. Chem.*, 1924, **113**, 35; McCombie, Scarborough, and Smith, J., 1927, 802; Norrish and Smith, J., 1928, 129; Richardson and Soper, J., 1929, 1873). Hence, although identical conditions of solvent, vessel, and temperature are employed, so that the only variable is the constitution of one reactant, yet, owing to variations of environmental influences with constitution, the resulting series of reaction rates may fail to register the effects of substituents upon the point of reaction in the molecule. Little information is available on the effect of changing the medium upon comparative rates of reaction of a series of compounds with a standard substance, but this view is supported by the fact that changes of solvent alter the order of the relative rates of reaction of benzyl chloride and its nitro-derivatives with trimethylamine (McCombie, Scarborough, and Smith, *loc. cit.*), and similar effects were observed in other reactions by Berger (*Rec. trav. chim.*, 1927, **46**, 856), by Menshutkin (*Z. physikal. Chem.*, 1900, **34**, 157), and by Blakey, McCombie, and Scarborough (J., 1928, 2863).

On the other hand, it may happen that for a series of related substances, the effects of environment are sufficiently similar to justify drawing the desired inferences connecting the reaction rates

directly with the influence of constitution upon reactivity (see Bradfield and Jones, J., 1928, 1006, 3073; also Hückel, *Ber.*, 1928, 61, 1517; 1929, 62, 2040). Bearing in mind this possibility, together with (a) the inevitable variation in precision in the different measurements quoted in Table II, and (b) the possibility of unsuspected wall effects in certain cases (Bailey, J., 1928, 1204), the general measure of consistency observed in Table II suggests that the only positive conclusion which can be drawn from the available data is that comparative velocity measurements can be used as indications of the effects of substituents upon the point of reaction in the molecule when an assembly of reactions can be examined. Individual anomalies in particular reactions (such as those observed in *N*-chlorination) may be genuine effects of the substituent upon the position of attack in the molecule, or may, at least in part, be due to the imperfect separation of environmental factors as indicated in the foregoing discussion.

#### EXPERIMENTAL.

*Materials.*—Acetanilides were prepared by acetylation of purified anilines, and repeatedly recrystallised from alcohol or dilute acetic acid. Aceto- $\beta$ -phenylethylamide (from the amine) and acetamide were purified by two distillations at 0.5 mm. Benzylamine and its monochloro- and mononitro-substituted derivatives were made (as hydrochlorides) from the corresponding benzyl chlorides by the method of Ing and Manske (J., 1926, 2348), *m*-chlorobenzyl chloride being prepared by chlorination of *m*-chlorotoluene at its boiling point (Kenner and Witham, J., 1921, 119, 1460). The acetobenzylamides were obtained by acetylation of the benzylamine hydrochlorides by warming with excess of acetic anhydride and sodium acetate. In each case, the excess of acetic anhydride was hydrolysed with water, the solution made alkaline with potassium hydroxide, and the (partly precipitated) acetyl derivative extracted with chloroform and recrystallised several times, usually from alcohol or hot water. The following compounds could not be traced in the literature: Aceto-*p*-chlorobenzylamide, m. p. 109.5°, after crystallisation from hot water until of constant m. p. (Found: Cl, 19.1.  $C_9H_{10}ONCl$  requires Cl, 19.3%); aceto-*m*-chlorobenzylamide, m. p. 38°, purified by distillation at 0.5 mm. (Found: Cl, 19.0%). The low m. p. of the *m*-compound as compared with its isomerides is in accord with the rule for disubstituted benzenes (*Ann. Reports*, 1926, 144). (I am indebted to Messrs. W. O. Jones, B.Sc., and G. I. Davies, B.Sc., for the analyses.)

*p*-Methylbenzylamine was made by reducing *p*-toluonitrile with sodium and alcohol; and the other materials required—reaction

medium, chlorine, etc.—were prepared as described by Orton, Soper, and Williams (*loc. cit.*).

*Velocity Measurements.*—The experimental method employed, the precautions taken, and the control experiments applied were those described previously, alternate portions of the reaction mixture being analysed at known time intervals (*a*) for chlorine by titration with *N*/500-sodium thiosulphate, and (*b*) for chloroamine by removal of chlorine with saturated aqueous *p*-cresol and subsequent titration. The initial concentrations of chlorine and of anilide were of the order 0.0005—0.0010*M* and 0.001—0.005*M* respectively, and, as before, hydrochloric acid was always present in 0.01*M* concentration in order to suppress the hydrolysis of chlorine. In view of the more strongly basic character of the acetobenzylamides as compared with the acetanilides, it was considered advisable to test the effect of hydrogen chloride upon the rate of *N*-chlorination. With 0.01*M*-, 0.05*M*-, and 0.10*M*-hydrochloric acid present, the values of  $k_N$  for acetobenzylamide were respectively 170, 176, and 173, showing that there is no appreciable effect over this range of concentration. The heat of reaction was shown to be negligible.\*

The velocity coefficients were calculated as before from the equations for a bimolecular reaction following two courses simultaneously. The following experiment is typical of the results with benzylamides.

*Expt. 133.* Aceto-*m*-nitrobenzylamide = 0.004109*M*; chlorine = 0.001232*M*; HCl = 0.01*M*; thiosulphate = 0.949  $\times$  *N*/500.

Time (mins.)	0	1.10	3.10	5.00	5.90	8.10	10.20	13.40	15.10
Titre (c.c.) ...	1.44	11.98	4.81	11.90	6.80	11.75	8.62	11.62	9.72

From curves constructed with these figures, we have :

Time.	KI titre.	:NCl titre.	Diff.	Change, %.	$k$ .
0	12.08	1.44	10.64	18.0	—
1.00	12.03	2.73	9.30	28.3	35.3
3.10	11.93	4.81	7.12	45.1	35.0
5.90	11.83	6.80	5.03	61.2	35.4
10.20	11.71	8.62	3.09	76.1	35.2
13.40	11.62	9.38	2.24	82.8	34.5

Mean 35.1

Corrected value for  $k_N$  = 33.5.

In experiments such as the above, in which the fall in potassium iodide titre is slight and may be due partly or wholly to accidental loss of chlorine, no reliance can be placed on the result for  $k_C$ ;  $k_N$  is corrected for the fall of potassium iodide titre. Two methods of calculation are possible, on the assumptions (*a*) that the fall is due entirely to *C*-chlorination; (*b*) that it is due entirely to accidental loss, in which case there is no corresponding consumption of anilide. As, however, the anilide is always present in large excess,

the two methods give results which do not differ greatly: in the above experiment,  $k_N$  as calculated by method (b) lies between 32.9 and 34.4. Method (a) has been used throughout, since *C*-chlorination does actually take place slowly with some of the anilides in question (unpublished work by Dr. B. Jones).

The results in parentheses in Table I are provisional only. That for aceto-*m*-toluidide is the mean of five experiments in which potassium iodide was added to the whole of the reaction mixture at a noted time, less than 0.1 min. after mixing. A trial of the method with acetanilide gave a result  $k_C = 10,400$  compared with the previous value 11,000. The ratio  $k_N/k_C$  was found by a separate experiment (see Orton, Soper, and Williams, *loc. cit.*; method for acetanilide). The value given for acetamide is the mean of three concordant experiments, but certain other experiments suggest that complications may arise in the reaction with this substance. The figure for aceto-*p*-methylbenzylamide is the mean of two experiments only and awaits confirmation.

Measurements were also made with 2:4-dinitroacetanilide. One experiment is shown below. Zero time was about 1 min. after mixing.

*Expt.* 145. 2:4-Dinitroacetanilide = 0.001542*M*; chlorine = 0.000623*M*; HCl = 0.011*M*; thiosulphate =  $0.972 \times N/500$ .

Time (mins.)	0	1.00	1.85	2.75	3.80	4.70	6.40	7.50
Titre (c.c.)	6.30*	2.75	2.86	2.61	6.09*	2.87	2.76	5.81*

The titres marked \* were those with potassium iodide alone; *p*-cresol was used with the others. *N*-Chlorination evidently takes place rapidly until the chloroamine concentration reaches a certain value, after which its titre remains constant, although there is still a large amount of free chlorine left. Moreover, the final chloroamine titre was lowered by increasing the initial hydrogen chloride concentration. It thus appears that the chloroamine equilibrium (Orton and Jones, J., 1909, 95, 1456),  $C_6H_5(NO_2)_2 \cdot NHAc + Cl_2 \rightleftharpoons C_6H_5(NO_2)_2 \cdot NClAc + HCl$ , lies much further to the left in 40% acetic acid than with the other anilides examined. This observation with 2:4-dinitroacetanilide is in accord with the fact recorded by Soper and Smith (J., 1928, 138) that the introduction of a single nitro-group into the benzene nucleus greatly increases the hydrolysis constant of a chloroamine.

I wish to express my sincerest thanks to Professor K. J. P. Orton, F.R.S., and to Dr. F. G. Soper for their most valuable advice and help. It is a pleasure, also, to acknowledge the assistance I have received by discussion with Dr. A. E. Bradfield.

X.—*The Dehydration of Copper Sulphate Pentahydrate.*

By WILLIAM E. GARNER and M. G. TANNER.

MEASUREMENTS of the rates of evaporation of water vapour from salt hydrates have usually been made by placing crystals of the hydrate in an atmosphere of air over a suitable dehydrating agent (compare Rae, J., 1916, 109, 1229; Crowther and Coutts, *Proc. Roy. Soc.*, 1924, 106, 215). Under such conditions, an induction period is frequently observed, due to the slow rate at which centres of dehydration are formed on the surface (Langmuir, *J. Amer. Chem. Soc.*, 1916, 38, 2263). In such cases, the maximum rate of evaporation is not attained until the crystals have undergone considerable decomposition. Removal of the air increases the rate of evaporation, but the induction period is not thereby removed (compare Bružs, *Z. physikal. Chem.*, 1929, B, 3, 434).

The haphazard formation of centres of dehydration on the surfaces of crystals leads to the formation of curved surfaces of evaporation, the areas of which, after a given time, are dependent on the number of centres formed, their position, and their time of origin. The area of the interface from which the water is liberated is thus dependent on chance, and is so uneven that it can neither be measured accurately nor evaluated.

These difficulties can be avoided by employing large single crystals of known area which have been activated by rubbing with the product of the dehydration. For example, a crystal of the pentahydrate of copper sulphate, after being rubbed with the monohydrate and placed in a vacuum, forms innumerable centres all over its surface, and the interface which is ultimately formed between the pentahydrate and the monohydrate consists of a series of planes running parallel to the original surfaces of the crystal. This makes it easy to determine the area of the interface from the dimensions of the crystal and the weight of water which has been lost at any time from the beginning of the dehydration. Thus, values for the rate of evaporation from unit area of interface can be calculated.

For an absolute measurement of rate of evaporation, it is clear that the water molecules must evaporate into a space from which return to the surface is impossible. Such an arrangement cannot readily be obtained in practice, but the rate of return can be made very small by using high vacua and suitably shaped containing vessels. An experimental arrangement is described below, which, as a result of many trials, has been found to be satisfactory for this purpose.

From the temperature coefficient of the rate of evaporation, the

critical increment of the process of evaporation can be obtained. The significance of this energy is uncertain, unless the unit process to which it refers is known. There will be at least three possible rates to take into account—(1) the rate of loss of water at the interface  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ – $\text{CuSO}_4 \cdot x\text{H}_2\text{O}$ , where  $x$  may be 3, 1, or 0, (2) the rate of diffusion of water vapour across the layer of dehydrated substance, which increases in thickness with time, and (3) the rate of evaporation of water from the external surface of the crystal. If (1) is the rate which determines the velocity of evaporation, then  $v/A$ , where  $v$  is the velocity and  $A$  the area of the interface at any time, will be constant throughout the whole process; if (2) is important, then  $v/A$  should decrease as the crystal is dehydrated; and if (3) corresponds to the process measured, then the velocity of evaporation will be independent of the time. Experiment shows that  $v/A$  does not change very markedly with the thickness of the dehydrated layer, so that in the case of the pentahydrate of copper sulphate, the slowest process is the change occurring at the interface between the unchanged and the dehydrated substance.

#### EXPERIMENTAL.

Crystals of the pentahydrate of copper sulphate weighing 0.2–0.5 g. were employed. These were grown slowly from small crystals at room temperature, and during growth, were turned over frequently. In the selection of these crystals, attention was paid to their freedom from defects, and those with numerous facets were rejected. Their thickness was measured by a micrometer screw gauge, and the other dimensions were measured by means of a Zeiss glass scale calibrated in 0.5 mm. The surfaces of these crystals were activated by 15 minutes' rubbing with copper sulphate monohydrate enmeshed in a piece of silk.

The crystals of copper sulphate were suspended singly in the apparatus described below by means of four thin pieces of platinum wire attached to a quartz-fibre spring made after the manner of McBain (*J. Amer. Chem. Soc.*, 1926, 48, 690).<sup>\*</sup> The quartz springs, made by winding on a steel rod, were calibrated by measuring the elongation under known weights, a Wilson travelling microscope being used for this purpose.

*Apparatus.*—Several forms of apparatus were tried, in all of which the water was removed in a high vacuum by pumping the vapour through U-tubes immersed in liquid air. In the earlier forms, the water was pumped off below the crystal by one exit (Apparatus A),

<sup>\*</sup> This balance has been used by Hume and Colvin in a study of the decomposition of potassium hydrogen oxalate hemihydrate (*Proc. Roy. Soc.*, 1929, A, 125, 642).

but in the later types, in order to prevent the return of water molecules to the crystal from above, it was removed by two exits, one above and the other below the crystal (apparatus C; see Fig. 1). The bulb containing the crystal was placed in a constant-temperature oven in the earlier experiments, and surrounded by the vapour from a constant-boiling liquid in the later experiments.

In Fig. 1, A is a Pyrex vessel, 5 cm. in diameter and 15 cm. long, in which the crystal is suspended. It was surrounded by the vapour from C or else by water at a constant temperature. The water vapour was withdrawn through wide tubing 2 cm. in diameter, and *via* the two U-tubes B immersed in liquid air.

FIG. 1.

A Hyvac pump and a mercury condensation pump were used in evacuation, and the pressures read on a McLeod gauge. The rates of evaporation were affected when there was a small leak of air into the apparatus, but no effect was observed if the pressure was kept lower than  $10^{-4}$  cm.

The dehydrated crystals were found to consist of  $\text{CuSO}_4 \cdot \text{H}_2\text{O}$  unless the experiment was unduly prolonged. The rate of loss of water from the monohydrate is very slow: even at  $80^\circ$ , a crystal originally weighing 0.339 g. (see Expt. I) lost only 0.00093 g. per hour after it had been converted into monohydrate.

Partly dehydrated crystals show a core of unchanged hydrate, and the surfaces of this core run parallel to the surfaces of the

original crystal. The thicknesses of the dehydrated substance,  $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ , were practically the same on all faces.\* This simplified the calculation of the change in the area of the interface with time.

*Area of Interface.*—The boundaries of the areas of the faces of the crystal and of the area of its chief cross-section were first drawn on squared paper. On the same diagrams were drawn the boundaries of the faces and cross-section of the core of pentahydrate which remained at various stages in the dehydration: the stages chosen were those corresponding to definite thicknesses of the shell of monohydrate. From these diagrams, the areas of the interface and the volumes of the core for four stages in the process of dehydration were evaluated. This treatment gave the volume of unchanged pentahydrate and the area of interface for each of four values of the thickness of the shell of changed salt. The loss of water and the related values, the changes in length of the quartz spring corresponding to the areas of interface so calculated, are readily obtained from the volumes. The values of the area of interface were then plotted against decrease in length of the quartz spring.

#### *Experimental Results.*

The decrease in the length of spring depends on the weight of the crystal and the sensitivity of the spring; on an average, it was about 0.6 cm. Such a change could be measured to about 1 part in 600 parts. The dehydration was in general followed until the pentahydrate was completely converted into the monohydrate; beyond this point, loss of water was very slow, and the crystal became dark. The decrease in length of spring, calculated from the original weight of the crystal, assuming that dehydration proceeds to monohydrate, was in two cases 0.602 and 0.374 cm. The observed values were 0.604 and 0.370 cm., respectively. Typical curves of length of spring plotted against time are given in Fig. 2. The curve for  $56^\circ$  (Curve II) is curious in that, when 2 mols. of water had been lost, there was a marked decrease in the rate of evaporation (see later).

The following results (Expts. I and II) were obtained with an early form of the apparatus in which water was removed by one exit only. The tables give the dimensions of the crystals, the time in hours,† the decrease in length of the spring ( $x$ ), the change in length of spring *per hour* ( $dx/dt$ ), the area of the interface,  $A$ , and the velocity of dehydration,  $k$ , expressed as g. of water lost *per*

\* These were measured by breaking a partly dehydrated crystal and examining the depth of penetration under the microscope. These depths were the same within 10%.

† The first of the times given for each experiment includes that required to heat the crystal to the temperature of the experiment, and hence has little significance.

minute from unit area of interface. The total elongation given is the change in length of spring at the end of the dehydration to  $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ .

Expt. I. Temp. =  $36.5^\circ$ ; weight = 0.339 g.; area of crystal =  $2.40 \text{ cm}^2$ ; thickness = 0.205 cm.; sensitivity of spring = 6.15 cm./g.; total elongation = 0.60 cm.

$t$ .....	0.75	1.8	2.8	4.0	5.2	6.6	9.7	13.8

FIG. 2.

Dehydration curves for  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ .

The loss of water was measured up to a composition of  $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ , at which the rate of evaporation decreased abruptly to about 0.0002 g. per hour. The extrapolated value for  $k$  at zero time is  $5.8 \times 10^{-5}$ , and its value is practically constant throughout.

Expt. II. Temp. =  $36.5^\circ$ ; weight = 0.216 g.; area of crystal =  $1.96 \text{ cm}^2$ ; thickness = 0.144 cm.; sensitivity = 6.15 cm./g.; total elongation = 0.35 cm.

$t$ .....	1.0	2.2	3.5	5.1	6.9	9.2
$x$ , cm. ....	0.05	0.10	0.15	0.20	0.25	0.30
$dx/dt$ .....	0.044	0.040	0.036	0.030	0.023	0.0175
$A$ , $\text{cm}^2$ .....	1.85	1.72	1.60	1.40	1.25	1.00
$k \times 10^5$ .....	6.4	6.3	6.1	5.4	5.0	4.8

In Expt. II, the crystal was smaller than that in Expt. I, and it had a greater ratio of area to volume. The values of  $k$  decreased with time from  $6.4$  to  $4.8 \times 10^{-5}$  g./min. Similar decreases occurred in Expts. III and IV, and a drift is also observable in Expt. VII.

*Apparatus B.*—The results given in Expt. III were obtained with an apparatus similar to that shown in Fig. 1, except that the constant temperature was obtained by placing the apparatus in an air thermostat. The water was removed both above and below the crystal, without, however, changing the magnitude of  $k$  appreciably.

Expt. III. Temp. =  $36.5^\circ$ ; weight =  $0.282$  g.; area of crystal =  $2.33$  cm.<sup>2</sup>; thickness =  $0.150$  cm.; sensitivity =  $6.91$  cm./g.; total elongation =  $0.57$  cm.

Expt. IV shows a very appreciable fall in the values of  $k$ . In the calculation of the critical increment, it will therefore be necessary to use the value for the velocity coefficient obtained by extrapolation back to zero time. In Expt. V, with a much smaller crystal, the rates per unit area are practically constant.

*Experiments in the Neighbourhood of Room Temperature.*—At this temperature, the rate of evaporation is so slow that the dehydration

was not followed up to the monohydrate stage, so that there is not so large a drift in the values of  $k$ .

Expt. VI. Temp. =  $26.5^{\circ}$ ; weight = 0.266 g.; area of crystal =  $2.10 \text{ cm.}^2$ ; thickness = 0.134 cm.; sensitivity = 6.91 cm./g.

*Results at the Temperature of Boiling Carbon Disulphide,  $46^{\circ}$ .—* Expts. IX, X, and XI were carried out at  $46^{\circ}$ . On account of the rapidity of the change, no measurements could be made of the rate in the very early stages of the dehydration. At this temperature, the values of  $k$  do not decrease with time in the manner found with some of the experiments at  $36^{\circ}$ . There was, however, evidence of an induction period. Only the early part of Expt. XI was satisfactory.

Expt. IX. Temp. =  $46.25^{\circ}$ ; weight = 0.263 g.; area of crystal =  $2.49 \text{ cm.}^2$ ; thickness = 0.111 cm.; sensitivity = 10.52 cm./g.; total elongation = 0.85 cm.

*Results at the Temperature of Boiling Acetone,  $56^{\circ}$ .*—At this temperature also, the dehydration proceeds at a constant rate per unit area of interface, but there is a curious difference between the dehydration at this temperature and that at lower temperatures (see Fig. 2). A break occurs on the dehydration curve at the composition  $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$ , and if the crystal is broken at this stage, there is no core of pentahydrate. The interface thus moves into the crystal at a relatively faster rate than is the case for experiments at lower temperatures, since only 2 mols. of water are lost instead of 4. The dehydration of  $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$  proceeds slowly, and after partial dehydration to  $\text{CuSO}_4 \cdot \text{H}_2\text{O}$ , the crystal shows a more amorphous structure than when it has been dehydrated to  $\text{CuSO}_4 \cdot \text{H}_2\text{O}$  directly. In the latter case, the pseudomorph breaks along the old cleavage planes of the crystal, but crystals dehydrated at  $56^{\circ}$  do not show this feature when broken.

Expt. XII. Temp. =  $56.0^{\circ}$ ; weight = 0.423 g.; area of crystal =  $2.57 \text{ cm.}^2$ ; thickness = 0.180 cm.; sensitivity = 10.52 cm./g.; elongation at break = 0.65 cm.

$k \times 10^5$ .....	16.1	15.5	17.3	17.6

The dehydration of  $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$  occurs at the following rates : For Expt. XII, 0.0022 g./hour; for XIII, 0.0019 g./hour; and for XIV, 0.0021 g./hour.

*Temperature Coefficient of the Dehydration.*—The following table gives the rates of evaporation per unit area. Where the rates show a drift, the value for zero time has been taken, but where there is evidence of an induction period, this has been ignored in the evaluation of  $k$ .

Temp. ....	20.5°	21.5°	26.5°	35.1°	36.5°	46.0°	56.0°
$k \times 10^5$ ...	2.55	3.0	3.5	5.8	5.8	9.4	16.8
				6.3	6.4	9.7	18.4
					6.8	11.1	18.4

FIG. 3.

The values of  $\log k$  are plotted against the reciprocal of absolute temperature ( $1/T$ ) in Fig. 3, and the values at 56.0° lie on the same straight line as those for the other temperatures. The value for the critical increment is 10,300 \* calories, and the value of  $\mu$  calculated from this is 2.77, which corresponds to one of the vibration frequencies of the water molecule.

#### Discussion.

Any detailed discussion of the results can have but little value until further hydrates have been studied. The main features which

\* This critical increment is very much smaller than that found by Topley and Hume (*Proc. Roy. Soc.*, 1928, A, 120, 211) for the decomposition of  $\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$ .

are of interest may, however, be examined. It is rather surprising that the rate of evaporation is so little affected by the thickness of the dehydrated salt. Experiment shows that there is a constant unidirectional streaming of molecules from unit area of the interface  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ – $\text{CuSO}_4 \cdot \text{H}_2\text{O}$  to the surface of the crystal. The structure of the material through which the molecules escape can only be guessed. Its nearest analogue is probably that of the structure of amorphous carbon. The molecules probably escape through capillary passages, the diameter of which is of the same order as that of the molecular diameter of water. Thus the movement occurs within the range of the attractive forces of the molecules forming the capillaries, and will thus correspond to that which occurs in an adsorbed gas film. There will be a pressure gradient in the adsorbed film which lies between the interface and the surface of the crystal. This is necessarily the case, since the molecules after leaving the interface expand from regions of small to regions of greater volume. The rate of return of water molecules to the interface will depend on the pressure exerted by the water molecules at the interface, just as in the case of a three-dimensional system, and this rate will be negligible only if the pressure in the neighbourhood of the interface is negligible. It is unlikely that this is the case when the interface is covered by a layer of dehydrated substance, so that the constancy of the values of  $k$  may mean that the pressure in the neighbourhood of the interface is constant at constant temperature and independent of the thickness of layer of dehydrated salt. Thus the values of  $k$  so far obtained may not be the true rates, and hence the temperature coefficient may not give the true critical increment of the dehydration process. Evidence for this view must be sought in measurements of the rate of evaporation in the very early stages of the dehydration of the crystal, when the dehydrated layer is thin, and such measurements can be accurately made only at low temperatures. The curves obtained for  $20^\circ$  (compare curve IV, Fig. 2) are practically linear, but if the linear portion of the curves be extrapolated back to  $t = 0$ , they do not pass through the origin. The rate of dehydration over the first hour is much larger than the steady rate reached subsequently.

The change in the nature of the dehydration phenomena which occurs between  $46^\circ$  and  $56^\circ$  also provides an indication that the constant rates are not true rates. At  $56^\circ$  the dehydration product is the trihydrate, whereas at  $46^\circ$  it is the monohydrate. This behaviour can be explained in terms of the pressure of the water molecules in the surface gas film of the dehydrated layers. As the temperature rises, this pressure increases until it may become greater than the equilibrium pressure of water over the trihydrate.

Since at  $56^{\circ}$ , this hydrate is not dehydrated until the whole of the pentahydrate has disappeared, it is evident that the surface pressures in the dehydrated layers must be greater than the dissociation pressure of the trihydrate. If such pressures prevail, then the possibility of return of water molecules to the interface is always present.

The slow rates of dehydration of the monohydrate and the trihydrate are also of interest. The trihydrate on dehydration does not give a visible interface similar to that obtained when the pentahydrate is dehydrated. Evaporation appears to proceed from the whole of the internal surface of the pseudomorph. The movement of the water molecules may therefore be restricted by the production of discontinuities in the internal surface of the dehydrated substance.

#### *Summary.*

The rates of dehydration of single crystals of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  have been measured in a vacuum over a range of temperatures from  $20^{\circ}$  to  $56^{\circ}$ . Crystals of known weight and area were activated by rubbing with the powder of the monohydrate. Such crystals after partial dehydration gave a core of pentahydrate, the surfaces of which ran parallel to the original surfaces of the crystal. The rate of loss of water divided by the area of the interface between the pentahydrate and the dehydrated product was practically constant for the higher temperatures, but in some experiments at the lower temperatures, the velocity coefficient decreased as dehydration proceeded.

Below  $46^{\circ}$  the dehydrated product was the monohydrate, which remains in the form of a pseudomorph which loses water very slowly. At  $56^{\circ}$ , the first product of the dehydration is the trihydrate, which does not decompose until all of the pentahydrate has disappeared. The trihydrate then slowly gives up its water at a constant rate.

A straight line is obtained by plotting  $\log k$  against the reciprocal of the absolute temperature,  $k$  being the velocity coefficient per unit area of interface. The critical increment of the process is 10,300 calories, and  $\mu = 2.77$ , which corresponds to one of the vibration frequencies of the water molecule.

It is concluded that the rates measured may not be the true rates of evaporation, and that the critical increment may not be the true value for the unit process which occurs at the interface.

Our thanks are due to Imperial Chemical Industries Ltd. for a grant for the purchase of apparatus.

## XI.—*Low-temperature Oxidation. Part II. The Ignition of Some Hydrocarbons in Oxygen.*

By JOHN STANLEY LEWIS.

It is now generally recognised that paraffin hydrocarbons react readily with oxygen at comparatively low temperatures. The temperatures at which rapid oxidation sets in during the slow heating of mixtures of hydrocarbons and oxygen in glass bulbs have been investigated by the author, and some of the conditions noted (J., 1927, 1555; 1929, 759). In the pressure-temperature curves, peculiar increases of pressure occurred at points termed "critical inflexion temperatures" (*C.I.T.*). The slope of the curve above the point of inflexion was influenced by factors such as the rate of heating and the concentration of oxygen and hydrocarbon. This is accounted for by a variation in the velocity of the reactions; increase in concentration caused a more rapid rise in pressure, but on the other hand, a faster rate of heating permitted less time for chemical action to proceed.

The above experiments in slow heating of oxygen-hydrocarbon mixtures occasionally resulted in explosions, and since these occurred at temperatures near the *C.I.T.*, it was surmised that the chemical actions pertaining to the *C.I.T.* were closely connected with explosion or self-ignition temperatures of these mixtures, the main difference being one of velocity. The following work is an investigation of this relationship.

The various methods in use for the measurement of ignition temperatures give discordant results to such an extent that it has become necessary to introduce the qualifying term "relative ignition temperatures" (Mason and Wheeler, J., 1922, 121, 2079), for comparable values can only be obtained when important governing factors (*e.g.*, material and surface area of the igniting vessel, volume of the chamber, concentration of reacting gases, pressure, etc.) are maintained constant. The current methods can be classified as (*a*) crucible method, (*b*) dynamic tube method, (*c*) bomb method, and (*d*) adiabatic compression of the mixture. The gradual heating of mixtures until explosion occurs does not appear to have been described. It is not suggested that the following method, though simple in design, can supersede any of the foregoing methods, but the results help to illustrate many well-established facts connected with ignition temperatures and the difficulties of obtaining even relative values.

## EXPERIMENTAL.

The apparatus consisted simply of a cylindrical bulb (of 125 or 225 c.c. capacity) of good soda glass fitted with a piece of glass tubing  $3\frac{1}{2}$ " long, the end of which was corrugated to enable a piece of rubber pressure tubing 4" long to be firmly attached; the open end of the latter was closed by a stout clip before the mixture in the bulb was heated. The bulb was cleaned with chromic acid and water and dried in a hot air oven by a current of dry air. In an experiment, the cooled bulb was filled with oxygen, and the desired quantity of hydrocarbon was introduced in a small tube drawn off at one end to a sealed capillary, the rubber tubing then being closed with the clip. The capillary was broken when required by shaking the bulb. For experiments of a comparative nature, it is sufficient to measure out the hydrocarbon with a capillary pipette. A bulb of specified dimensions, and filled at atmospheric pressure, being used in a series of experiments, the mass of oxygen remains practically constant.

The conditions requisite for the exploding of the hydrocarbon-oxygen mixtures by progressive heating are (a) sufficiently rapid rise in temperature, (b) adequate concentration of oxygen, and (c) a concentration of hydrocarbon above a certain minimum. At the temperature of explosion the rubber tubing is burst, and occasionally the bulb itself is shattered. The bulbs were therefore enclosed in a copper-gauze cage, and the observer was protected by a plate-glass shield. The explosion temperature is governed by many factors, of which the following have been studied.

*Concentration.*—Other conditions remaining constant, an increase in concentration of a paraffin hydrocarbon tends to lower the explosion temperature until a minimum is obtained. For dilute mixtures, results were only reproducible to within  $3^{\circ}$  or  $4^{\circ}$  owing to difficulty in adjusting the rate of heating, and as a mean of a large number of experiments the curves in Fig. 1 were drawn; the minimum temperature, however, is correct to within  $1^{\circ}$ . The curves exhibit certain points of interest.

(a) For a particular rate of heating, a minimum concentration is necessary to obtain an explosive action, and more dilute mixtures will not explode. This minimum increases rapidly with rise of molecular weight in the case of paraffins. Thus, with a 225 c.c. bulb and a rate of heating of just under  $1^{\circ}$  per min., concentrations of hexane below 10% failed to explode, but extensive oxidation had occurred, as revealed by analysis and by the fact that when the experiment was repeated with a mercury manometer attachment, the pressure-temperature curve showed a well-defined *C.I.T.* at

234—235°. Therefore, it is assumed that, although rapid oxidation had set in at this temperature, the conditions were not such as to give rise to ignition. For octane a concentration of at least 33% was necessary for explosion, whereas all concentrations of *isodecane* (*diisooamyl*) failed to ignite unless a greater rate of heating was employed.

The foregoing affords a rough measure of the ease of oxidation of these hydrocarbons, and, in general, it seems that the minimum

FIG. 1.

percentage for ignition by this method increases with the instability towards oxygen. This applies also to unsaturated hydrocarbons, which will not explode except at high concentrations and rapid rates of heating, the hexylene minimum being much higher than that for amylene.

(b) The character of the explosion is controlled by the concentration of the original mixture. With rich mixtures a minimum explosion temperature obtains, but in the case of paraffin hydrocarbons the explosion is a mild one with a low note, often an absence of flame, and no carbon deposit—just sufficient pressure has been

suddenly generated to burst the rubber tubing. The residual gases in the bulb contain traces of carbon monoxide and dioxide, and the liquid condensed on the walls gives aldehydic reactions. It must be emphasised that the mixture is well outside the usual explosive range of hydrocarbons and in the neighbourhood of equimolecular concentrations. With a reduction in the hydrocarbon content, the violence of the explosion seems to increase until a maximum is reached when the ratio approaches that necessary for complete combustion. In such cases the explosions were sufficiently intense at times to shatter the glass bulb and were always accompanied by flame.

(c) The fall of the curves to the minimum is not without significance. The lighter members of the series are more resistant to, or react more slowly with, oxygen; they can be heated well above the minimum ignition temperature, especially in dilute mixtures, and are less liable to pre-ignition in internal-combustion engines.

*Rate of Heating.*—A more rapid rate of heating tends to raise the ignition temperature. The chemical reactions occurring at the C.I.T. are comparatively slow, and in the case of dilute mixtures may be insufficient to give rise to explosion. It will therefore be a simple matter to "superheat," as it were, the mixture to a temperature above the ignition point obtained by a slower rate of heating, thereby accelerating the chemical action and causing an explosion which is far more violent than with the slower speed. An increase in the hydrocarbon ratio has an opposing effect because it increases the velocity of the reaction and tends to lower the explosion point. It will therefore be more difficult to "superheat" rich mixtures above the ignition temperature. These facts are illustrated in Fig. 1, where the variations of ignition temperatures are given for two widely different rates of heating and for various concentrations.

The olefins, however, do not show this great rise of ignition temperature with speed of heating, and, moreover, because they are more readily oxidised, their minimum concentration for ignition is much higher than that of the corresponding paraffin. Thus, for all conditions tried with amylene, the explosion temperatures only varied between  $240^{\circ}$  and  $244^{\circ}$ , but even with rich mixtures violent explosions were obtained.

A combination of the two factors already mentioned, *viz.*, a high concentration of hydrocarbon and a slow rate of heating, must tend towards a minimum explosion temperature. These minima can be taken as relative ignition temperatures for many of the hydrocarbons, and Table I contains some results obtained by this method. They are of interest in that they are much lower than the ignition temperatures recorded in the literature, which have been obtained by

other methods, and also because they approximate to the *C.I.T.*'s of these hydrocarbons.

TABLE I.

Hydrocarbon.	Minimum ignition temp.	<i>C.I.T.</i>
<i>n</i> -Pentane .....	255—257°	255°
<i>n</i> -Hexane .....	232—233	230
<i>n</i> -Heptane .....	218—220	209
<i>n</i> -Octane .....	203—204	197
<i>iso</i> Decane (Diisoamyl) .....	210	—
Amylene .....	241—242	240
Trimethylethylene .....	243—244	—
Methylethylethylene .....	251—252	—
Hexylene .....	229—230	—

The lowest ignition temperature obtained for *isodecane* (210°) is higher than that of octane (204°). In order to bring about the explosion of *isodecane*, which is very readily oxidised at 200°, it is essential that a high concentration be used and a rapid rate of heating, about 4—5° per min., otherwise the experiment fails. A strict comparison, therefore, can only be made where equimolecular concentrations are subjected to the same rate of heating. Two bulbs containing octane and *isodecane* of about equal concentrations were very rapidly heated in the same bath with sufficient speed to explode them: the former ignited at 217° and the latter at 211°.

Presumably there is no distinction between the *C.I.T.* of a mixture and the explosion temperature, except one of degree. The curves of Brunner and Rideal (J., 1928, 1162) for hexane-oxygen, maintained at constant temperatures below the *C.I.T.*, terminate in a rapid rise in pressure. An examination of the curves (*a*), (*b*), and (*c*) (*ibid.*, p. 1166) reveals the fact that the slope at the *C.I.T.* is more inclined to the vertical, and the angle with the vertical increases with the lowering of temperature. This is as one would expect, since the chemical changes involved decrease in velocity with lowered temperature. It might be reasoned that these changes can be accelerated by concentration, and thus explosive reactions might be obtained below the *C.I.T.* by keeping the gases at a constant temperature. A 50% hexane mixture in a 225 c.c. bulb was maintained at a temperature just below the *C.I.T.* At 228° an explosion resulted, but lower temperatures failed to cause ignition. A weaker mixture, with 35% hexane and immersed in the same bath, also failed to explode. It may happen that the 50% mixture would explode at a still lower temperature if initially compressed, but it is not possible to attempt this in glass bulbs.

*Catalytic Actions.*—Many investigations have been carried out upon the influence of surface and of positive and negative catalysts on ignition temperatures, but the results are frequently conflicting.

In comparison with metallic surfaces, it is usually stated that glass and silica surfaces have a very low activity on the oxidation of hydrocarbons, so that the result with a plain glass surface will be taken as a zero. This problem of catalytic action is so complex that the following experiments must be regarded as qualitative and introductory. The oxidation of these hydrocarbons proceeds in stages, and it is clear from what follows that the course of the reactions and the nature of the final products are dependent on the surface in contact with the reacting gases.

(a) *Powdered glass.* The ignition point of paraffins is raised in all cases, the amount depending on the rate of heating and the concentration, but variation in the weight of glass between 0.2 and 1.0 g. had little effect. In one set of experiments, the ignition point of octane was raised from 204° to 218° and that of hexane from 232° to 257°, but the differences diminish greatly with rich mixtures and slower temperature rise. On the other hand, the ignition temperature of amylene underwent little change in the presence of powdered glass, but the violence of the explosion was considerably decreased. Powdered pumice behaves similarly.

(b) *Charcoal.* The action of this catalyst is noteworthy in that it affects paraffins and olefins in opposite directions, and the extent varies with the nature of the charcoal. The ignition temperature of paraffins was *raised*, whilst that of amylene was *lowered considerably*; with wood charcoal (0.5 g.) which has been powdered, sieved (60 mesh), and strongly heated in a covered crucible, and with the same rate of heating, 40% mixtures of the various hydrocarbons gave the following results :

Hydrocarbon .....	$C_8H_{18}$	$C_7H_{16}$	$C_6H_{14}$	$C_5H_{10}$
Blank expt. ....	205°	220°	233°	240°
Charcoal present .....	220	249	254	210

Amylene appears to vary more widely with different charcoals, and explosions at 200°, 210°, and 227° were obtained with three samples. Decolorising charcoal failed to cause an explosion under any conditions of concentration and rate of heating, although the hydrocarbon was considerably oxidised.

(c) *Metals.* Metals may have no effect on the ignition point, or may raise the temperature or even inhibit explosion in some instances, according to the metal employed, extent and condition of the surface, concentration of hydrocarbon, and the speed of heating.

(i) *Silver.* In one set of experiments the silver was deposited on the inside of the bulb, and in another set a strip of the metal was enclosed. The explosion temperatures were raised considerably in every case; thus, octane gave 204° (blank), 212° (silver coating), and 214° (silver strip).

(ii) Platinum. The results were much as those for silver. Octane gave 205° (blank), 218° (strip), and 212° (coating), whilst hexane gave 232° (blank) and 249° (strip).

(iii) Tin, Zinc, and Aluminium. There was no appreciable rise in explosion temperatures with  $4'' \times \frac{1}{8}''$  strips of metal with freshly cleaned surfaces. All hydrocarbons in the presence of any one of them detonated within 0—2° of the blank. The metallic surfaces remained bright, and light yellow liquids condensed in the bulb on cooling.

(iv) Lead. The temperature of ignition is considerably raised and explosion may even be inhibited. A  $4'' \times \frac{1}{8}''$  strip of the metal was heated with 50% octane-oxygen at a rate of about 2° per min. No ignition occurred up to 275°, and examination of the bulb after cooling showed that the surface of the metal had been attacked, yielding a loose greyish powder easily rubbed off; a dark brown viscous gum collected on the bottom of the bulb, but the walls remained clear. When opened under water, the bulb became about three-quarters filled with liquid, and qualitative examination denoted the presence of carbon dioxide and monoxide, a trace of oxygen, and a small remainder of combustible gases that burned with a non-luminous flame.

(v) Copper. This metal also prevented the ignition of octane, but the appearance of the bulb was very different from that in which lead had been heated. A brownish skin was deposited over the whole surface of the glass, and the copper was only tarnished if it had not had a preliminary cleaning, but was blackened by a film of oxide if the surface had been freshly scraped. Opening the bulb under water gave a residue of gas appreciably more than in the experiments with lead, but it was qualitatively similar.

The effect of these two metals diminishes with decrease in molecular weight of the hydrocarbon, and the ignition temperature of pentane was raised only 2° and that of hexane 7° by approximately the same sized strips of metal.

(vi) Iron. A 50% octane mixture was slowly heated with a strip of steel: a violent explosion occurred at 207°, shattering the glass bulb. This was the first instance of such an event with this hydrocarbon, for under all other conditions the bulb remained intact. The surface of the steel remained bright.

The results obtained in the foregoing experiments may be discounted because the metals are coated with oxide films at the temperature of explosions. As will be suggested later, the lag is a far more satisfactory measurement than the ignition temperature, and experiments are now in progress on the effect of metal surfaces and metallic oxides on the time of lag.

(d) *Lead tetraethyl*. The minimum explosion temperature was raised in every case, sometimes as much as  $40^{\circ}$ , depending on the concentration of lead tetraethyl (up to a maximum effect), the rate of heating, and the surface area of the glass in contact with the gases. The last factor was illustrated by heating 50% hexane-oxygen mixtures in a bulb with various proportions of powdered glass and lead tetraethyl, the rate of heating being the same in each experiment. In presence of 1 g. of powdered glass, the ignition temperature with a 0.9% lead tetraethyl solution in hexane was  $260^{\circ}$ , and for 0.2 g. of the glass it was  $274^{\circ}$ . Again, a 0.25% solution of the lead compound raised the ignition temperature of hexane to  $269^{\circ}$  in the presence of 0.1 g. of powdered glass, but only to  $240^{\circ}$  with 1.0 g. It is apparent that the ratio of lead tetraethyl to powdered glass is a controlling factor in the rise of ignition temperature, the latter tending to inhibit the action of the lead compound.

The effect of increasing concentration of lead tetraethyl on the explosion temperature of octane is shown in the following results.

PbEt <sub>4</sub> , % .....	0	1	2	3	4	5
Explosion temp. ....	$204^{\circ}$	$230^{\circ}$	$232^{\circ}$	$238^{\circ}$	$239^{\circ}$	$238^{\circ}$

*Volume of Bulb*.—Two bulbs of 125 c.c. and 225 c.c. capacity were filled with oxygen-hydrocarbon mixtures of as nearly as possible the same composition. They were connected by a piece of pressure tubing and heated in the same bath to about  $160^{\circ}$ , so that equalisation of pressure (and possibly also of concentration) was effected; they were then separated by clamping the tubing at two points and cutting the rubber between the clamps. Both bulbs exploded within a few seconds of each other on further heating.

*Concentration of Oxygen*.—It is usually stated that the ignition temperature as determined by the usual method is lower in oxygen than in air, but it must be stressed that other variables are introduced: when determinations are made with air, the oxygen, on account of its lower concentration, may be consumed before explosion is possible; with pure oxygen, a higher concentration of hydrocarbon can be introduced, thereby reducing the explosion temperature to a minimum. When air was substituted for oxygen in the glass bulbs, the hydrocarbons could not be ignited by rapid heating in a bath, although this can be done when the rate of heating is much greater, as in the crucible methods, etc., or when the mixture is suddenly heated in a tube or bomb initially at a high temperature. An atmosphere of 50% oxygen-nitrogen failed to ignite a given weight of hexane heated at a rate of  $3^{\circ}$  per min., whereas with 75% oxygen content in the bulb originally, explosion took place at  $247^{\circ}$ . On repeating the latter experiment and comparing it with a bulb

containing pure oxygen and the same weight of hexane as a check, the latter exploded at 245°. Many such experiments with paraffins indicated that increase in oxygen content tends to lower the ignition temperature, but the effect is small compared with that of the hydrocarbon. Amylene, however, showed practically no change of ignition temperature when exploded in various concentrations of oxygen. The presence of nitrogen in the lowered concentrations may have some effect, but this has not been investigated. By making a fine slit in the rubber tubing attached to the bulbs, the pressure inside is maintained at atmospheric pressure, but the concentration of both reactants is diminished, and this would be expected to raise the ignition temperature. This was found to be the case, except that a more rapid heating is necessary to cause explosion; thus, hexane exploded at 256°. These results were more comparable with those obtained by the crucible method, and some experiments of the latter kind were carried out in test tubes, the effect of the same factors being investigated.

*Test-tube Experiments.*—*Air.* The tubes were almost wholly immersed in an oil-bath at the required temperature, and drops of the liquid were allowed to fall into them from a capillary tube, the quantity being varied until lowest ignition was obtained. Experiments with *closed* and *open* mouths proved that the former gave much lower ignition temperatures with air and oxygen. Thus, in a 7" × 1" test-tube the minimum ignition temperature in air for octane was 225–226°, and 214° when a tightly fitting lid was applied—the mouth of the test-tube was ground down to a level surface and the lid smeared with plasticine to make it air-tight. Various numbers of drops of octane were introduced at decreasing temperatures until no signs of ignition or rapid oxidation occurred. Between each trial the residual gases in the tube were blown out and any signs of carbon deposit removed. Ether was found to ignite at 183–184° by such a method in a 7" × 1" tube. For the final tests, it is essential that freshly cleaned tubes be used each time in order to obtain the lowest ignition point.

These experiments are noteworthy since they emphasise the facts that there is no line of demarcation between the rapid oxidation temperature and the ignition point, and that the time of lag can be much longer than is generally supposed. At temperatures well above the ignition point, the lag is comparatively short, and the flame and characteristic sound of explosion well defined, but as the temperature is lowered these become less definite and the time for their appearance much longer. By using the covered-tube method, the author obtained lags of over 500 secs. on many occasions with rich mixtures of hydrocarbons dropped into oxygen. Under such

conditions no explosion sound can be heard, but a slight puff which pushes up the lid slowly, and furthermore, there is no apparent flame.

The diameter of the test tube is also an important factor, although beyond 7" the length had no appreciable effect. With the 7" tubes, the ignition point was at first lowered with increased diameter but was subsequently raised with still wider tubes, although the concentration of hydrocarbon was increased proportionately, thus :

Diameter.	Ignition temp. in air for	
	octane.	hexane.
0.75	221°	271°
1.00	214	265
1.25	216	268
1.50	219	269

*Oxygen.* Ignition temperatures in oxygen are lower than in air; thus, for a 7"  $\times$  1" tube, the following results were obtained.

Hydrocarbon .....	$C_5H_{12}$	$C_6H_{14}$	$C_7H_{16}$	$C_8H_{18}$	$C_9H_{20}$
Temp. in air .....	305°	265°	247°	214°	—
„ oxygen .....	295°	248°	235°	207°	270°

*Powdered glass and pumice.* The ignition temperature is raised, depending on the weight of powder, up to a maximum on the molecular weight of the hydrocarbon (or, more correctly, its ease of oxidation). Thus, the increase for the same weight of pumice is more for octane than for hexane.

*Charcoal.* The temperature of paraffin hydrocarbon ignition in oxygen is raised; thus in 7"  $\times$  1" tubes, 0.2 g. of charcoal required a temperature of 221° to ignite octane and 254° for hexane. Amylene exploded in oxygen alone at 270°, but at 268° in the presence of charcoal. The concentration of amylene required to bring about explosion is always much higher than that of paraffins.

*Metals.* These may be classified as (a) those having little effect, such as aluminium, tin, and zinc (see above), and (b) those promoting oxidation and raising the ignition temperature, such as platinum, copper, and lead, the effect being greater the lower the molecular weight. Interesting results were obtained with a copper test-tube 6"  $\times$  1", the inner surface of which had been cleaned and polished. The ignition temperature of octane in air was 223° at first, but after repeated experiments the readings were much higher, and even in oxygen the hydrocarbon would not ignite at 225° after such treatment. It is evident that deposits interfere with successive results, and the surface must be renewed for each experiment. When this was done, the original value of 223° was obtained.

*Lead tetraethyl.* As in the previous experiments, the temperature of ignition was raised in all cases, e.g., hexane in air to 283° by a

1% concentration of the lead compound, the lag being nearly 300 seconds. The addition of powdered glass or pumice reduces the ignition temperatures and the lag. The latter at 278° was 250 secs. for 0.2 g. of powdered pumice, but ignitions were obtained as low as 273° with 1.0 g. of pumice.

### *Discussion.*

Mason and Wheeler (*loc. cit.*) have pointed out that when such mixtures as have been used in the foregoing experiments are gradually heated, the rate of combination of oxygen and hydrocarbon increases; and so the heat evolved by the reaction raises the temperature of the products and unburnt gases above that of the external source of heat. There will be a tendency for the rate of reaction to increase until the whole of the hydrocarbon or oxygen is consumed. When, however, the initial temperature imparted to the walls of the vessel is sufficiently high, the rate of reaction will become so rapid as to produce flame. This statement is only partially true, and the above observations apply to experiments in which oxygen-methane mixtures were allowed to enter an evacuated silica bulb maintained at a comparatively high temperature, so that the mixture is heated much more rapidly than in the present experiments. The heat of the reaction at this high temperature cannot be dissipated as quickly and will undoubtedly be utilised in raising the temperature of the contained gases and hence the velocity of their reaction, which will become explosive. It is incorrect, however, to state that oxygen-hydrocarbon mixtures react with gradually increasing velocity with rise of temperature as suggested above, because the author (*loc. cit.*) has shown that there is a definite transition from slow chemical action to rapid action at a temperature which has been termed the *C.I.T.*, and Brunner and Rideal (*loc. cit.*) have proved that for hexane-oxygen mixtures this rapid change may take place at still lower temperatures when the mixtures are maintained at constant temperatures for lengthy intervals. The transition from very slow oxidation to explosion is still far more abrupt when anti-oxidants are added, such as lead tetraethyl, which reduces the reaction considerably almost up to the temperature of explosion. Moreover, neither the "lag" interval nor the catalytic effects of promoters and inhibitors of oxidation receive a satisfactory explanation from the above statement.

In order to account for such facts as the last, the theory of chain mechanism has recently been applied to the combustion of hydrocarbons, notably by Egerton and Gates (*J. Inst. Pet. Tech.*, 1927, 281; *Nature*, 1928, 121, 10) and also by Brunner and Rideal for hexane (*loc. cit.*). The latter workers have measured the amounts

of peroxides or "moloxydes" of hexane during the period of autoxidation, but the author believes that these peroxides are produced from the unsaturated hydrocarbon initially formed by primary dehydrogenation (see Part I; J., 1929, 759). Further, the fall in pressure noted by these authors for hexane-oxygen at 210° is not definitely proved to be a measure of the moloxyde formation. Similar experiments have been repeated with silica and glass bulbs and the pressure drop in the former is appreciably less, indicating greater surface action with glass. The amount of gummy residue was larger in the glass bulb, and this would suggest that the fall in pressure is chiefly due to the formation of condensation products. In the case of unsaturated hydrocarbons, this fall of pressure is much more pronounced (see Part I) and leads to the conclusion that the chemical change involved is the same, although the velocity differs, being much greater for amylene. The primary dehydrogenation would therefore be a comparatively slow reaction, especially at first (see Part I), and probably takes place in the gaseous phase. This would account, in part at least, for the fact that metallic lead has no inhibiting action whilst lead tetraethyl vapour is particularly effective at this stage of the oxidation, if one could assume (in spite of some adverse opinions) that the vapour of lead resulting from the decomposition of the tetraethyl is the active component. It is also significant that this anti-oxygen does not inhibit the oxidation of amylene to the same extent as that of pentane.

The successive stages in the combustion of paraffin hydrocarbons suggested by the author are: (a) primary dehydrogenation resulting in unsaturated hydrocarbons, (b) combination of the latter with oxygen to produce unstable peroxides, (c) decomposition of the peroxides *per se* to aldehydes, etc., which are further oxidised to water and oxides of carbon if the mixtures are rich in oxygen. The velocities of these step reactions probably vary widely in themselves and still more so in the presence of catalysts. According to the chain-reaction mechanism, then, when hydrocarbon-oxygen mixtures are slowly heated, as in the experiments of the author and of Brunner and Rideal, or during the "lag" interval present in the determination of auto-ignition temperatures, there will be an increase every moment of the active centres present due to one cause or another, and after a certain lapse of time, which may extend to several minutes as shown in the experimental part (autoxidation), they may be present in such concentration as to give rise to rapid pressure increase without flame or even to explosion. The reaction is exothermic, and when approximately equimolecular concentrations are used, the products are chiefly aldehydic, acid, or gummy, with very small proportions of the oxides of carbon and water. If there

is present a large excess of oxygen, the oxidation becomes far more violent and complete, owing to the liberation of heat in this initial reaction, which raises the temperature of the whole system and brings about the further oxidation of the peroxide decomposition products.

An increase in concentration of hydrocarbon tends to reduce the auto-ignition temperature (see Mason and Wheeler, J., 1924, 125, 1869), whereas the oxygen concentration produces a much smaller effect. These authors attribute this phenomenon to the fact that the component with the greater "stopping power" for radiant energy such as will "activate" it, increases the rate of reaction with the concentration. Or, according to the chain mechanism, the increase of hydrocarbon molecules is said to augment the number of chains formed in unit time and hence the number of active centres. The oxygen concentration lowers the ignition to a much smaller extent, as pointed out above. Moore (*J. Inst. Pet. Tech.*, 1919, 186) added 70% of carbon dioxide to the oxygen, and, using a platinum crucible method, found an inappreciable difference in the ignition temperature of kerosene. White and Price (J., 1919, 115, 1462) and Mason and Wheeler (*loc. cit.*), using two different methods, obtained appreciable changes with variations in the air/fuel ratio; they did not actually study the effect of oxygen concentration, since the mass of fuel was not maintained constant. The auto-ignition temperature, then, is a function of the concentration of hydrocarbon and, to a much smaller extent, of oxygen. If either or both of these are consumed during the pre-flame period, no ignition obtains. Insufficient active centres have been produced, or, in other words, the accumulation of peroxides has been too slow and one or the other of the reactants has disappeared before ignition occurs. Hence it will be necessary to raise the temperature of the mixture of similar composition in order to accelerate the formation of active centres in unit time, i.e., the autoxidation, and thus produce an explosion. The lag has been decreased. It should follow from the above view that the ignition temperature of a given mixture will be lowered by an increase in pressure, but very little work has been done on this subject. There is a possibility that the effect of increased concentration by pressure would be nullified at a lower temperature by the reduction in the rate of formation of reactive centres, so much so that these would be deactivated before explosion could occur; this would to a certain extent reduce the effect of increased pressure.

The effect on the ignition temperature of various materials has received much consideration but results are at variance (Moore; White and Price, *loc. cit.*; Egerton and Gates, *J. Inst. Pet. Tech.*,

1927, 244); for paraffin hydrocarbons, however, the author proves that some metals, such as aluminium, tin, nickel, and zinc, have little if any effect upon the explosion temperature, whereas others, such as silver, iron, platinum, copper, and lead, raise the temperature of ignition and may even prevent the explosion. It is suggested that this is brought about by the removal of the peroxides on the surface of these metals, yielding aldehydes or their polymerised products (gums), the exact nature of the decomposition being determined by the temperature and the nature of the metal employed. An increase in the number of chains broken in unit time may be said to have been taking place on the metallic surfaces. The same result is brought about by an increase in the surface of the glass in contact with the gas, which will account for the rise in explosion temperature occasioned by the presence of powdered glass and pumice, or the etching of the internal surface of the vessel. The action of carbon on the paraffins and olefins is noteworthy. Towards the former it acts similarly to powdered glass and pumice in raising the ignition point. The powdered charcoal is a strong absorbent; it is also reputed to be a destroyer of peroxides, and since these are readily formed by olefins, the rate of oxidation and the heat evolution may be so rapid as to give rise to local ignition, which will account for the low ignition point of amylene at a charcoal surface.

In the glass-bulb experiments, the difference in the ignition temperatures with change of volume from 125 c.c. of 225 c.c. was inappreciable probably owing to the high concentrations of oxygen and hydrocarbon. In closed glass tubes of various diameters, White and Price (*loc. cit.*) found that the temperature decreased at first and then increased with increasing diameter of the tube. The test-tube method indicated a similar result, but it is apparent that when narrow test-tubes are used the initial concentration of the reactants will be small and one or the other will be consumed before the desired concentration of active centres is attained.

The results with lead tetraethyl confirm those of Egerton and Gates (*J. Inst. Pet. Tech.*, 1927, 244) and of Weerman (*ibid.*, p. 300), but if, as the former point out, anti-knocks do influence the ignition temperatures, it will not follow that the converse is true, *viz.*, that substances which raise the ignition temperatures of a fuel are anti-knocks (compare the action of carbon). The action of the above inhibitor in the presence of powdered glass or pumice is noteworthy. It has been shown that an increase in the surface thus produced tends to reduce the inhibitory action of the lead tetraethyl, probably owing to an increase in the rate of oxidation. It must be emphasised that the rises of ignition temperatures brought about by this reagent

are entirely different from the foregoing. Lead tetraethyl is a negative catalyst, or anti-oxygen, and delays or inhibits even the initial stage of oxidation, so that very little change occurs in the hydrocarbon at temperatures somewhat higher than the normal ignition point. On the other hand, lead and copper, powdered glass and pumice are promoters of oxidation by surface action and bring about the rise of temperature by a removal of a fraction of the products in one stage of the oxidation which give rise to the explosion.

The spontaneous ignition temperatures are not related to the detonation characteristics of a fuel; thus, the unsaturated hydrocarbons with less knocking tendencies have lower explosion temperatures than the corresponding paraffins. Brown and Watkins (*J. Ind. Eng. Chem.*, 1927, **19**, 368) found that the ratio of the maximum rate of rise of pressure to the ignition temperature (absolute) gives a number which rises directly as the knocking quality of the fuel or inversely as Ricardo's "highest useful compression ratio" (*H.U.C.R.*). The estimated *H.U.C.R.*'s of paraffins and aromatics agree fairly well with those practically determined, but no figures are given for unsaturated hydrocarbons. Since these have correspondingly lower ignition temperatures, it should follow that their maximum rate of rise of pressure is less than that of the corresponding paraffin, and the testing of this point would help to elucidate the problem. In order that fairly accurate results may be obtained for the above ratio, it is essential that the data for auto-ignition be fairly trustworthy. Oftentimes discrepancies are found in the published results, *e.g.*, octane having a higher ignition temperature than heptane, and heptane than hexane. A similar result is shown for decane and octane above, but this is readily explained by the greater oxidisability of decane which is consumed at low temperatures on the surface of the glass, or, in terms of chain mechanism, the deactivation exceeds the rate of chain formation at the lower temperatures, so that it is difficult to make it explode by slow heating. A strict comparison with octane can only be made with equimolecular concentrations of hydrocarbons, equal area and nature of surface, and equal rate of heating. Under such conditions, octane has been shown to ignite before decane, although the rate of heating required for the latter to explode is so rapid that the ignition temperature of octane is somewhat raised above its minimum. The anomalous results obtained by the crucible methods can be explained in a similar manner: the droplets may not have yielded equimolecular concentrations, the rates of heating at the two temperatures are not the same, and at the temperature at which one might expect ignition, the hydrocarbon has been completely removed by flameless or surface combustion, especially when

platinum has been used and the drops have been small. Hence, one unhesitatingly concludes that the method of determining the relative ignitabilities by the measurement of the duration of the pre-flame period or "lag" at a temperature higher than the ignition temperature is to be preferred to the "crucible" experiments. Some of the paraffins have been compared by Mason and Wheeler (J., 1924, 125, 1873) by this method.

The view is prevalent that fuel droplets ignite more easily than the vapour, and this is attributed to the accumulation of peroxides in the liquid drops (Callendar, *Engineering*, 1927, 147). Since extremely low ignition temperatures can be obtained when the concentration of the hydrocarbon and oxygen is high, it is reasonable to suppose that the ignition of the droplets in the above experiments has been favoured by the richness of the vapour-oxygen atmosphere surrounding each liquid particle, thereby bringing about the conditions for the minimum ignition temperature. No significance can be attached to the fact that, when a fuel is sprayed or vaporised through a heated tube, the spray gives rise to a profusion of peroxides whilst the vaporised mixture shows little effect. If peroxides are produced in one stage of the oxidation, this will probably be at the surface of the droplets where they would be absorbed by the comparatively cool liquid and thus preserved. On the other hand, when vapour only is present, the peroxides would eventually come in contact with the heated walls of the tube, with resultant decomposition.

#### *Summary.*

A simple preliminary apparatus has been used to find the conditions and temperature of ignition of mixtures of some hydrocarbons and oxygen, and a mechanism of the reactions has been considered.

Spontaneous ignition temperatures, as determined by the usual methods, are raised by materials, such as lead tetraethyl, which inhibit oxidation or reduce autoxidation, in that they diminish the number of fresh chains formed in unit time, whereas promoters of oxidation by surface action raise the temperature of ignition by removing one of the intermediate products, presumably peroxides, or alternatively, according to the chain mechanism theory, they increase the rate of deactivation.

The disturbing factors in the determination of relative ignition temperatures are so numerous that the measurement of the "lag" in the case of equimolecular concentrations at some point above the ignition temperature is to be preferred as a measure of the ignitabilities of hydrocarbons.

The explosion of hydrocarbons takes place in two stages : (a) the

explosion of the products of autoxidation (peroxides or chain reactions, in which approximately equal number of molecules of oxygen and hydrocarbon participate), and (b) the combustion of the products of stage (a) in excess of oxygen to oxides of carbon and water.

## XII.—*The Hydrides of Boron.*

By BERTRAM DILLON STEELE and JAMES EDWARD MILLS.

THE investigations of Stock and his collaborators (*Ber.*, 1912 *et seq.*) have definitely shown the existence of a series of boron hydrides of a composition which is unexpected in view of the position of boron in the periodic classification and of the existence of trivalent alkyl compounds. The conclusions of Jones and Taylor (*J.*, 1879, **35**, 41; 1881, **39**, 213), Sabatier (*Compt. rend.*, 1891, **112**, 866), and Ramsay and Hatfield (*P.*, 1901, **17**, 152) as to the existence of  $\text{BH}_3$  are without sufficient experimental foundation, yet a doubt remains that the existence of the simpler hydrides might be established if the field of investigation were widened. All previous investigators have used magnesium boride, except Hoffmann (*Chem.-Ztg.*, 1911, **35**, 265), who showed that commercial iron and manganese borides, on reaction with acids, give boron hydrides, which he did not identify. In the case of carbon, different metallic carbides yield different types of hydrocarbons, and it was suspected that other metallic borides might not yield the same hydrides. The suspicion, however, has not been substantiated.

Wöhler and Deville (*Ann. Chim. Phys.*, 1858, **52**, 63), using high temperatures, prepared borides of aluminium which are practically unreactive with acids, but, by using a method similar to that of Stock and Massenez (*Ber.*, 1912, **45**, 3543) for the preparation of magnesium boride, we have prepared an aluminium boride which reacted with acids to give hydrogen containing boron hydride. The same method, with special precautions, led to the preparation of a cerium boride which reacted similarly. In both cases the yield of boron hydride is small, this being particularly so with the aluminium compound. The identity of our boron hydrides with those formed from magnesium boride has been definitely established in the case of gaseous  $\text{B}_4\text{H}_{10}$ , and although the results in the case of the liquid hydrides are not absolutely decisive, the indications are that they are also the same, namely,  $\text{B}_5\text{H}_9$  and  $\text{B}_6\text{H}_{10}$ .

## EXPERIMENTAL.

*Preparation of the Aluminium Boride.*—Fine aluminium powder (3 parts) and finely powdered boron oxide (1 part) were intimately mixed and fused in small quantities (8–10 g.) in an iron crucible over a large Meker burner. After 3–5 minutes' heating, a bright glow spread through the mass, and at this point the crucible was removed and quickly cooled by plunging its lower portion into water. The product was a greyish, very friable mass.

FIG. 1.

*Preparation of the Cerium Boride.*—Cerium metal powder ( $2\frac{1}{4}$  parts) and powdered boron oxide (1 part) were mixed, and very small quantities fused in a fairly rapid stream of hydrogen. (If large portions were used or if the stream of hydrogen was not rapid, reaction was so vigorous as to melt the bottom of the crucible.) The product, a hard black mass, was powdered in a percussion mortar.

*Generating Apparatus.*—For the decomposition of the boride, phosphoric acid ( $d\ 1.4$ ) at  $75^\circ$  was used. It appears to give better yields than hydrochloric acid, and although some phosphine is formed, this is more readily removed in fractionation than the hydrogen sulphide which results from the use of sulphuric acid.

The acid was placed in a 6-litre flask, and the aluminium or cerium boride in A (Fig. 1), which was closed at the top by a mercury seal through which passed a glass rod with a tapered grinding fitting into a constriction at B. By depressing this rod slightly, and either slowly revolving it or tapping A, the powder could be introduced into the acid at a suitable rate. D was a double-surface water-cooled condenser, and  $C_1$  a condenser immersed in liquid ammonia. The liquid ammonia and finally phosphoric oxide remove water.  $C_2$  was the main condenser immersed in liquid air, and containing cotton wool to prevent any boron hydride passing through as a fume or mist.  $C_3$  was another liquid-air condenser, without cotton wool, and connected to a closed U-tube manometer. The issuing hydrogen bubbled out through mercury at E. The whole was connected to the mercury pump. Owing to the hardening action of the boron hydride on tap lubricant, taps were discarded in favour of either U-tube arrangements with greaseless gas valves (see Stock, *Ber.*, 1914, 47, 3109), or simply U-tubes 80 cm. in length with mercury traps at the top, connected to a mercury reservoir. The positions of these tap substitutes are at  $U_1$ ,  $U_2$ , and  $U_3$ . In case a larger quantity of gas than could be obtained from one charge of A was required,  $U_2$  would be shut when the powder was exhausted, and the air pumped out through  $U_1$  when fresh powder was introduced.

The boron hydride condensed in  $C_2$ , except some of the higher-boiling product, which condensed in the liquid ammonia. In no case did the issuing hydrogen burn with a green flame. When all the gas had been generated,  $U_2$  was shut, the hydrogen pumped out, and the condensate transferred to the condenser without cotton wool, any boron hydride in the liquid ammonia being transferred also. A constriction at L was then sealed off,  $U_3$  shut, and the glass tubing to the right of it cut and joined to the fractionating and analysing apparatus shown in Fig. 2, all the air being then pumped out.

*Fractionation and Analysis.*—By blowing liquid air through pentane in a Dewar vessel, a range of temperature up to  $-120^\circ$  could be attained, the temperature being measured by a standardised pentane thermometer. Fractionation was carried out at selected temperatures, the pressure shown by the manometer being read;  $U_3$  was opened for a short interval, thus allowing passage to  $C_4$  in liquid air, then closed again, and the manometer re-read, the process being repeated if necessary. The fraction thus removed and condensed in  $C_4$  was then analysed without interfering with the residue of the yield,  $U_3$  being kept shut and  $C_3$  replaced in liquid air. The liquid air was removed from  $C_4$ , and the fraction allowed to vaporise

into the density bulb. Since we were dealing with small quantities, we condensed all the fraction in  $C_5$  by liquid air, shut  $U_4$  and  $U_5$ , and then removed the liquid air. The pressure was read on the manometer, the tap to the density bulb shut, and the small amount of gas in the connecting tubes pumped out and collected. When the bulb was replaced after weighing and the air pumped out, the tap to the bulb was opened and the gas condensed by liquid air in  $C_7$ , where it was reweighed. By removing the liquid air from under  $C_7$  the gas was allowed to stream through a quartz tube  $Q$ , which was heated to redness. Unless the passage of the gas is very slow, decomposition is not complete.  $C_6$  was kept in liquid air to collect undecomposed gas. The hydrogen was pumped out and its volume measured. Any undecomposed gas was then transferred by liquid

FIG. 2.

air back to  $C_7$ , and the process repeated. Any solid boron hydride formed in the cooler part of the tube was decomposed by strong heating. Entire decomposition was assured. The deposited boron was estimated both by direct weighing and by titration as boric acid after oxidation by nitric acid. A further study of the composition was afforded by reaction with strong alkali solution, and then decomposition of any hypoborate formed by addition of excess of sulphuric acid; for this purpose, in the case of  $B_4H_{10}$  an amount was pumped out and its volume measured, and in the case of the higher-boiling fractions an amount in  $C_7$  was weighed. The reaction is  $B_xH_y + 3xH_2O = xH_3BO_3 + \frac{1}{2}(3x + y)H_2$ .

The results leave no doubt as to the formation of  $B_4H_{10}$  from both the aluminium and the cerium compound. The results given by the liquid fractions are not quite so definite, but indicate  $B_5H_9$  and  $B_6H_{10}$ .

Silicon hydrides, phosphine, and carbon dioxide are formed from the aluminium compound and phosphoric acid. Phosphine and carbon dioxide, but no silicon hydrides, are formed from the cerium compound.

*Results from Cerium Boride.*—280 G. of the boride and 4 litres of phosphoric acid were used. The earlier fractions proved on analysis to be mixtures of phosphine and carbon dioxide, with no trace of boron hydride. The hydride was first detected in a fraction at  $-90^{\circ}/<1$  mm. The fraction taken at  $-80^{\circ}$  with a constant vapour pressure (about 1 mm.) gave the following results:

Volume = 12—15 c.c.

- (a) Molecular weight, 52.5 (Calc. for  $B_4H_{10}$ , 54).
- (b) Decomposition by water: 1 vol.  $\rightarrow$  10.7 vols. (Calc., 11 vols.).
- (c) Decomposition by heat: 4.5 c.c. (at 765 mm. and  $22^{\circ}$ ) gave 22.3 c.c. of hydrogen (Calc., 22.5 c.c.) and a deposit of boron—(1) by weight = 8.5 mg., (2) by titration = 8.2 mg. (Calc., 8.3 mg.).

The next fractionation, carried out at the temperature of liquid ammonia ( $-33^{\circ}$ ), gave 35 mg. of a liquid; the residue (about 10 mg.) was not analysed.

(a) Decomposition by water: 6.4 mg. gave 26.8 c.c.  $H_2$  at N.T.P. (Calc.: For  $B_6H_{10}$ , 26.1 c.c.; for  $B_5H_9$ , 26.6 c.c.; for  $B_4H_{10}$ , 28.9 c.c.).

(b) Decomposition by heat: 28.7 mg. gave 24.6 mg. of boron and 45.5 c.c. or 4.1 mg. of hydrogen (Calc.: For  $B_4H_{10}$ , 23.4 mg. B, 5.3 mg.  $H_2$ ; for  $B_5H_9$ , 24.7 mg. B, 4.0 mg.  $H_2$ ; for  $B_6H_{10}$ , 24.9 mg. B, 3.8 mg.  $H_2$ ).

This fraction probably contained some  $B_4H_{10}$ , and the analyses are probably those of a mixture of  $B_4H_{10}$ ,  $B_5H_9$ , and  $B_6H_{10}$ —the  $B_4H_{10}$  in small amount.

*Results from Aluminium Boride.*—800 G. of the boride were used. Early fractions contained no boron hydride. The fraction (about 15 c.c.) at b.p.  $-80^{\circ}/1$  mm. gave:

- (a) Molecular weight, 55.05.
- (b) Decomposition by water: 1 vol.  $\rightarrow$  10.8 vols. of  $H_2$ .
- (c) „ „ heat: 1 vol.  $\rightarrow$  5.05 vols. of  $H_2$ .

The next fraction was taken at  $-60^{\circ}$ . It was too small to be analysed, but probably contained the last of the  $B_4H_{10}$ .

Two fractions were taken at  $-33^{\circ}$ ; the first (10 mg.) was lost, but the second (20 mg.) gave a result agreeing very closely with

$B_6H_{10}$  : 10.45 mg. gave 15.4 c.c.  $H_2$  at *N.T.P.* and 9.0 mg. B (calc. for  $B_6H_{10}$  : 15.2 c.c.  $H_2$ , 9.1 mg. B).

In conclusion, the authors wish to express their thanks to the Trustees of the Commonwealth Science and Industry Endowment Fund for a grant which helped to defray the expenses of the research.

### XIII.—*Acid and Salt Effects in Catalysed Reactions.* *Part XXIII. The Catalytic Activity of Acid Salts with Reference to the Catalytic Effects produced by Potassium Hydrogen Oxalate in the Acetone-Iodine Reaction.*

By HARRY MEDFORTH DAWSON and JESSE EYRE SMITH.

IN two previous papers (Dawson, Hoskins, and Smith, J., 1929, 1884; Dawson and Smith, *ibid.*, p. 2530) an account has been given of the catalytic effects associated with oxalic acid in the first and second stages of ionisation. The experimental work relates to the effects produced by mixtures of acid and salt represented respectively by  $cH_2C_2O_4 + xKHC_2O_4$  and  $cKHC_2O_4 + xK_2C_2O_4$ , where  $c$  is constant and  $x$  is variable, and further, to the influence of inert salts on the primary and secondary ionisation of oxalic acid. The relations disclosed by these observations permit us to proceed to the detailed consideration of the catalytic properties of solutions of the binoxalate.

The interesting problem presented by the catalytic activity of the acid salts of polybasic acids does not appear to have been subjected to systematic investigation, and the results of the present enquiry indicate that their behaviour cannot be explained in terms of any form of the simple hydrogen-ion theory.

The hydrogen-ion concentration of solutions of an acid salt of the type MHA is given by

$$[H^+] = \sqrt{K_1 K_2 [HA'] / (K_1 + [HA'])}$$

where  $K_1$  and  $K_2$  are the mass-law constants for the first and second stages of dissociation of the acid  $H_2A$ . This reduces to  $[H^+] = \sqrt{K_1 K_2}$  if the concentration ( $c$ ) of the acid salt is large compared with  $K_1$ , and to  $[H^+] = \sqrt{K_2(c - [H^*])}$  if  $c$  is small in comparison with  $K_1$ . If  $K_2$  is small the latter expression becomes  $[H^+] = \sqrt{K_2 c}$ . In so far as the hydrogen ion is responsible for the catalytic effects in the

solutions of an acid salt, it may therefore be anticipated that the connexion between the reaction velocity and the concentration of the acid salt will depend on the relative magnitudes of  $c$  and  $K_1$ .

The restricted solubility of the binoxalates imposes a rather low upper limit to the range of concentration of the solutions which may be used for the study of the catalytic effects. In pure aqueous solution, the range extends from about  $c = 0.01$  to  $c = 0.3$  mol. per

FIG. 1.

Plot of reaction velocity against concentration. The full curve represents the experimental data and shows the deviations from linearity at low concentrations. The dotted curves show the variation of the partial velocities  $v_h$ ,  $v_{H_2Ox}$ , and  $v_{HOx}$ .

litre, and since the mean value of  $K_1$  for this series of solutions may be taken as 0.08, it follows that  $c$  is less than  $K_1$  for the less concentrated, and greater than  $K_1$  for the more concentrated solutions of the series. This circumstance has a direct bearing on the relations which are shown by the measured reaction velocities.

The observations were made at  $25^\circ$  with an acetone concentration of 20.0 c.c. per litre, and the usual procedure was followed in determining the initial velocity. By plotting this against the concen-

tration, it is found (see Fig. 1) that the velocity varies almost linearly with the concentration when  $c > 0.1$ , but that at lower concentrations  $dv/dc$  increases as  $c$  diminishes.

In accordance with previous results, the specific reaction velocity may be represented by the equation

$$v = k_h[H'] + k_{H_2Ox}[H_2Ox] + k_{HOx'}[HOx'] + k_{Ox''}[Ox''] \quad (1)$$

in which the concentrations of the various catalytic entities are given by

$$[H'] = \sqrt{K_1 K_2 [HOx'] / (K_1 + [HOx'])}, [H_2Ox] = [H'] [HOx'] / K_1, \\ [HOx'] = c - [H'] - 2[H_2Ox], \text{ and } [Ox''] = [H'] + [H_2Ox].$$

The magnitude of the ionisation constants and of the catalytic coefficients varies with the nature and concentration of the ionic environment and such variations must be taken into account as far as possible in the application of equation (1).

Since the binoxalate ion is neither catalytically nor chemically inert, it is not possible to determine the inert-salt effects peculiar to an atmosphere of potassium and binoxalate ions by the methods which are permissible in the case of solutions of salts which are both chemically and catalytically inert. In these circumstances it has been assumed that the values of  $K_1$  and  $K_2$  for the binoxalate solutions are the same as for the corresponding solutions of potassium chloride. For the latter it has been shown (*loc. cit.*) by experiments relating to the first and second stages of ionisation that the values are given by

$$\log K_1 = 2.756 + 0.42\sqrt{x} - 0.275x$$

and

$$\log K_2 = 5.857 + 0.81\sqrt{x} - 0.39x,$$

in which  $x$ , the total salt concentration, corresponds in the present paper with the molar concentration ( $c$ ) of the binoxalate.

With regard to the variations in the catalytic coefficients, it may be recalled that the available evidence would seem to show that the hydrogen ion is considerably more susceptible than other catalytic entities to changes in environment. The effects in question are specific in the sense that they depend on the nature of the ions in the solution, and as already pointed out, they cannot be determined for a solution of potassium binoxalate. Since, however, the maximum salt concentration in our experiments is only 0.3 mol. per litre, it is permissible as a first approximation to assume that  $k_h$  is not affected by the presence of the binoxalate. In support of this procedure, it may be noted that the catalytic effect due to the hydrogen ion in the more concentrated solutions is only a small fraction of the total effect. The reaction velocities recorded in

Table I are therefore based on the following values for the various catalytic coefficients, *viz.*,  $k_h = 465 \times 10^{-6}$ ,  $k_{H_2Ox} = 210 \times 10^{-6}$ ,  $k_{HOx} = 13.0 \times 10^{-6}$ , and  $k_{Ox''} = 1 \times 10^{-6}$ . The first column gives the concentration of the binoxalate; the second, third, fourth, and fifth give the partial velocities due to the hydrogen ion, the undissociated oxalic acid, the binoxalate ion, and the oxalate ion respectively; the sixth shows the calculated, and the seventh the observed velocity.

TABLE I.

Catalytic activity of aqueous solutions of potassium hydrogen oxalate.

0.30	1.43	2.22	3.59	0.014	7.25	6.90

The autocatalytic effect of the hydriodic acid produced in the reaction sets a lower limit to the concentration of the binoxalate solutions for which the reaction velocity can be measured with accuracy. Within the available range of concentrations it is clear from the table that equation (1) affords a satisfactory account of the measured velocities. The systematic divergence at the higher concentrations suggests that the increase in  $K_1$  and  $K_2$  may not be so great for the binoxalate as for the corresponding chloride.

By plotting the partial velocities against the concentration of the acid salt, it is found that  $v_{HOx}$  is a linear function of  $c$ , and  $v_{H_2Ox}$  very nearly so when  $c$  is greater than 0.1, whilst  $v_h$  tends towards a maximum value. These relations are consistent with the fact that the experimental  $v$ - $c$  curve is approximately linear for  $c > 0.1$ . The slope of this linear portion of the curve corresponds with  $dv/dc = 20 \times 10^{-6}$ , and when extrapolated to  $c = 0$ , the line in question is found to cut the zero ordinate at about  $v = 0.8 \times 10^{-6}$ , which, it may be noted, is nearly three times as great as the velocity at the smallest concentration. In connexion with this very considerable initial velocity which seems to be indicated by the linear portion of the experimental  $v$ - $c$  curve, it may be recalled that the hydrogen-ion concentration approximates to the value  $[H'] = \sqrt{K_1 K_2}$  when  $c$  becomes large in comparison with  $K_1$ . If this value of  $[H']$  is

combined with the stoicheiometric equation  $c = [\text{H}_2\text{Ox}] + [\text{HOx}'] + [\text{Ox}']$  and the mass-action expressions

$$K_1 = [\text{H}'][\text{HOx}']/[\text{H}_2\text{Ox}] \text{ and } K_2 = [\text{H}'][\text{Ox}']/[\text{HOx}']$$

we obtain

$$[\text{H}_2\text{Ox}] = c[\text{H}']^2/([\text{H}']^2 + K_1[\text{H}'] + K_1K_2) = c\sqrt{K_2}/(\sqrt{K_1} + 2\sqrt{K_2})$$

$$[\text{HOx}'] = cK_1[\text{H}']/([\text{H}']^2 + K_1[\text{H}'] + K_1K_2) = c\sqrt{K_1}/(\sqrt{K_1} + 2\sqrt{K_2})$$

and

$$[\text{Ox}'] = cK_1K_2/([\text{H}']^2 + K_1[\text{H}'] + K_1K_2) = c\sqrt{K_2}/(\sqrt{K_1} + 2\sqrt{K_2})$$

Putting  $\sqrt{K_2}/(\sqrt{K_1} + 2\sqrt{K_2}) = \gamma$  and  $\sqrt{K_1}/(\sqrt{K_1} + 2\sqrt{K_2}) = \delta$ , and substituting the values of  $[\text{H}']$ ,  $[\text{H}_2\text{Ox}]$ ,  $[\text{HOx}']$ , and  $[\text{Ox}']$  in equation (1), the latter becomes

$$v = k_h\sqrt{K_1K_2} + \{(k_{\text{H}_2\text{Ox}} + k_{\text{Ox}'})\gamma + k_{\text{HOx}'}\delta\}c. \quad (2)$$

according to which, apart from variations in  $K_1$  and  $K_2$ , the  $v$ - $c$  curve should be a straight line the slope of which is given by the value of  $(k_{\text{H}_2\text{Ox}} + k_{\text{Ox}'})\gamma + k_{\text{HOx}'}\delta$ . Since  $\gamma$  and  $\delta$  are not greatly affected by the variations in  $K_1$  and  $K_2$ , the slope may be determined with some precision. If, for instance, we utilise the values of  $K_1$  and  $K_2$  which correspond with  $c = 0.2$ , namely,  $K_1 = 7.8 \times 10^{-2}$  and  $K_2 = 14 \times 10^{-5}$ , then  $\gamma = 0.039$  and  $\delta = 0.93$ , and for  $(k_{\text{H}_2\text{Ox}} + k_{\text{Ox}'})\gamma + k_{\text{HOx}'}\delta$  we obtain  $20.3 \times 10^{-6}$ , which agrees closely with the slope of the linear portion of the experimental curve.

The term  $k_h\sqrt{K_1K_2}$  in the above velocity equation obviously corresponds with the initial velocity which is indicated when the approximately linear  $v$ - $c$  curve is extrapolated to  $c = 0$ . This curve is actually slightly concave to the  $c$  axis, which means that the slope of the tangent decreases and therefore that the intercept on the zero concentration ordinate increases as the value of  $c$  increases. This may be due in part to the circumstance that the hydrogen-ion concentration has not reached the value represented by  $\sqrt{K_1K_2}$  within the range of the concentrations actually used, but it is also quite probably attributable in part to the increase in  $K_1$  and  $K_2$  which occurs when the concentration increases. In any case, the velocity measurements are not accurate enough to permit of the determination of the variation of the intercept with the concentration of the binoxalate, and it must suffice to record the fact that linear extrapolation of the velocities for the higher concentrations leads to a velocity for  $c = 0$  which corresponds fairly closely with the magnitude  $k_h\sqrt{K_1K_2}$ .

To provide further support for the conclusions suggested by the data recorded in Table I, a parallel series of measurements has been made with solutions in which the ionic strength was kept constant at  $\mu = 0.3$  by the addition of potassium chloride. This series is represented by  $c\text{KHC}_2\text{O}_4 + (0.3 - c)\text{KCl}$ . In the application of equation (1) to these solutions, the constant values taken for  $K_1$  and  $K_2$  are those corresponding with  $0.3M$ -potassium chloride, and the value of  $k_h$  is assumed to be determined by the potassium chloride content of the solutions. The arrangement of Table II, in which the results are recorded, is exactly similar to Table I.

TABLE II.

Catalytic activity of potassium hydrogen oxalate in solutions of constant ionic strength ( $\mu = 0.3$ ).

0.15	1.34	0.99	1.79	0.008	4.13	4.08
0.20	1.39	1.39	2.39	0.010	5.18	4.99
0.25	1.42	1.80	2.98	0.012	6.21	5.94
0.30	1.43	2.22	3.59	0.014	7.25	6.90

The  $v$ - $c$  curve corresponding to the second series of observations is of the same general character as the curve for the chloride-free solutions and need not be discussed in detail. There is, of course, no suggestion that constancy of ionic strength affords conditions of ionic environment which entitle the results in Table II to be regarded as strictly comparable. The combined results for the two series afford, however, considerable justification for the belief that inert-salt effects, in so far as they have not been allowed for, are of very minor significance, and that equation (1) provides a satisfactory basis for the interpretation of the experimental data.

Both sets of observations show that the connexion between the reaction velocity and the concentration of the acid salt varies with the latter. The connexion is approximately linear for the more concentrated solutions of the series. The hydrogen-ion concentration of these solutions varies within very narrow limits and the observed catalytic effects are mainly due to the binoxalate ion and the undissociated oxalic acid, the concentrations of which vary linearly with the total concentration of the acid salt. In the more dilute solutions, on the other hand, the dominant catalyst is the hydrogen ion, and as the concentration falls there is a gradual

approach to a condition in which the reaction velocity is essentially determined by the hydrogen-ion concentration.

The results show conclusively that the catalytic activity of acid salts is in large measure due to the catalytic action of the acid ion ( $\text{HA}'$ ) and of the undissociated acid ( $\text{H}_2\text{A}$ ).

#### XIV.—*The Routine Preparation of Conductivity Water. Part II.*

By JOHN M. STUART and FRANK WORMWELL.

NEARLY five years' experience in the preparation of large quantities of conductivity water has shown the desirability of certain modifications in the still previously described (J., 1927, 2156). After about two years' work, minute cracks developed where the narrowed portion of tube ( $d$  in Fig. 1 of that paper) joined the main condensing column, and, later, this column became constricted where it is held by a retort clamp just above the lower jacket.

A modified design (Figs. 1 and 2 of present paper) has now been adopted. The tin condensing column C is placed vertically above the tinned-copper steam-trap to which it is connected by a copper tube A, tinned inside and flanged at each end. The top copper flange D is tin-soldered to the lower flanged end of this condensing column, the weight of which is carried on the steam trap B, Fig. 2. The joints of this, shown at S in Fig. 2, are silver-soldered. The trap itself is carried on vertical steel rods arranged as in the earlier still; the only clamp required is one to steady the top of the condensing column.

The condensed water collects in a circular trough T, formed between a short length of tin tube and the inner wall of the condensing column; from this it flows along a short horizontal water-jacketed tin tube H, where it meets a stream of purified air from the tube K; thence it passes through a glass condenser, the outlet of which is formed into a horizontal T-piece, the lower tube of which is connected to the conductivity measuring cell. The arrangement permits a thermometer to be placed vertically in the water in the conductivity cell itself; this is desirable, for the temperature varies between about  $17^\circ$  and  $25^\circ$ , with appreciable effect on the conductivity.

In the main condensing column there is a piece of pure sheet tin bent so as to break up the main column of steam rising straight up from the trap, and ensure its thorough mixture with the

stream of purified air from tube H. This tin was introduced when the still had only been run for a few days, the conductivity of the water being then about  $0.15 \times 10^{-6}$  mho. Shortly afterwards a steady decrease in conductivity occurred, which may, however, have been the usual improvement due to the gradual washing out of impurities from a newly erected still.

All soldered joints in the condensing column are made with pure tin. Before finally fixing the condensing column in position it

FIG. 1.

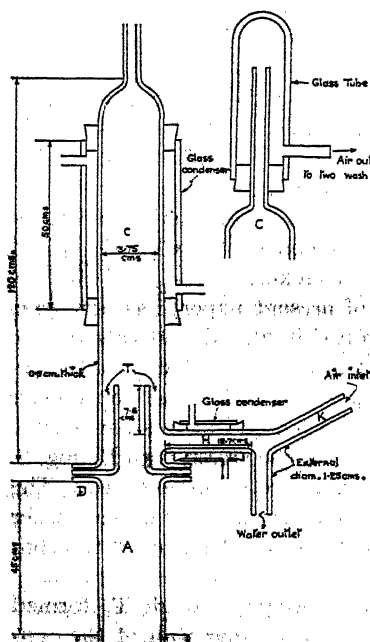

FIG. 2.

should be washed out with carbon tetrachloride and thoroughly steamed. The Weiland air-purification train originally used and illustrated in Fig. 1 of the earlier paper was found to be inconvenient for continuous use owing to sticking taps. The form of train now used consists of four columns, 3 cm. in diameter and 45 cm. high, containing glass beads and joined together by short lengths of rubber tubing so that they can be separated for refilling, thus rendering taps unnecessary. The presence of rubber in the air train does not appear to affect the conductivity of the water.

A typical day's run with the still is recorded below. The temper-

ature is that of the water in the cell, and  $\kappa$  is its conductivity in gemmhos, corrected to 18°.

Time.	Temp.	$\kappa$ .	Time.	Temp.	$\kappa$ .	Time.	Temp.	$\kappa$ .
11.40 a.m.	20.6°	0.090	1.10 p.m.	22.1°	0.057	3.05 p.m.	20.5°	0.058
11.47	20.9	0.067	1.28	21.6	0.055	3.27	20.5	0.060
12.05 p.m.	21.4	0.064	1.43	21.5	0.055	3.50	20.1	0.062
12.22	21.9	0.057	2.03	20.4	0.056	4.10	21.4	0.062
12.40	21.1	0.057	2.22	21.3	0.058	4.30	21.6	0.063
12.57	21.8	0.057	2.43	21.3	0.058			

Total volume of conductivity water collected from 11.40 a.m. to 4.30 p.m. = 4555 c.c.

Total volume of water rejected at trap = 2300 c.c.

The conductivities so far obtained are much the same as those of the older still when both are run simultaneously, but the latter occasionally gives very low values, *e.g.*, 0.047 at 18°. Probably, after a few months' use, the new still will give similar results—the best hitherto is  $\kappa = 0.053$  at 18°.

The advantages claimed for the modified design are low cost, great strength and compactness, ease of erection and working, and durability. The actual still occupies a bench length of 110 cm. or, including the air-purification train, 2 m. It quickly gives good-quality water which, at its best is rather better than that from such stills as that of Bencovitch and Hotchkiss (*J. Physical Chem.*, 1925, 29, 705).

The authors wish to thank Mr. R. May for advice on the construction of the still, and Professor G. T. Morgan for permission to publish the results.

## XV.—*The Interaction of Butyl Chloral Hydrate and 2:4-Dihalogen-substituted Phenylhydrazines.*

By FREDERICK DANIEL CHATTAWAY and HARRY IRVING.

WHEN butyl chloral hydrate reacts with phenylhydrazine, the hydrazone initially formed decomposes almost at once with such violence that the course of the reaction cannot easily be followed. When, however, a 2:4-dihalogen-substituted phenylhydrazine is used, the decomposition proceeds more quietly and the final products can be isolated. As in the reactions between the halogen-substituted phenylhydrazines and ordinary chloral (Chattaway and Bennett, 1927, 2850; Chattaway and Daldy, J., 1928, 2756), these final

products differ according to the nature of the solvent in which the reaction takes place.

The first product of the interaction of butyl chloral hydrate and 2 : 4-dichlorophenylhydrazine hydrochloride in aqueous solution is a viscous crimson mass which cannot be obtained in a condition suitable for analysis, since, from the moment of its formation, whether alone or in contact with a solvent, it continually evolves hydrogen chloride, yielding finally a well-crystallised substance of the composition  $C_{10}H_8N_2Cl_4$ . This appears to have been formed from a molecule of butyl chloral and a molecule of 2 : 4-dichlorophenylhydrazine by the elimination of a molecule of water and a molecule of hydrogen chloride :

When strongly reduced, it yields 2 : 4-dichloroaniline; the halogen atom eliminated in the reaction must therefore have been one of those in the butyl chloral residue. Its pale yellow colour indicates that, unlike the compound formed in the corresponding reaction of ordinary chloral, it has no azo-linkage in its molecule. It is unsaturated and combines directly with two atoms of bromine to give a colourless *dibromo*-addition compound,  $C_{10}H_8N_2Cl_4Br_2$ . With acetic anhydride it yields a colourless *monoacetyl* derivative, pointing to the presence of a single imino-group in the molecule. This acetyl derivative is still unsaturated and gives on careful chlorination a colourless dichloro-addition compound of the composition  $C_{10}H_7N_2Cl_4(CO \cdot CH_3)Cl_2$ .

These reactions appear to show that it is  $\alpha\beta$ -*dichlorocrotonaldehyde*-2 : 4-*dichlorophenylhydrazone* (III) formed by the elimination of hydrogen chloride from the unstable butyl chloral 2 : 4-dichlorophenylhydrazone (I) which is without doubt formed initially.

As in the analogous reactions between halogen-substituted phenylhydrazines and chloral (see above), or dichloroacetaldehyde (Chattaway and Farinholt, this vol., p. 94), it seems probable that butyl chloral 2 : 4-dichlorophenylhydrazone also loses hydrogen chloride in a reversible manner to give a crimson azobutylene derivative of the constitution  $C_6H_3Cl_2 \cdot N \cdot N \cdot CH : CCl \cdot CHClMe$ , 2 : 4-dichlorobenzeneazo- $\beta\gamma$ -dichloro- $\Delta^a$ -butylene (II).

In virtue of its azo-structure this compound would be intensely red and, although it is not formed to an extent large enough to permit of its isolation, it nevertheless gives a deep crimson azo-colour to the viscid mass obtained in the early stage of the condensation.

The course of the reaction where  $X = C_6H_3Cl_2(2 : 4)$  may be represented as follows :

Although  $\alpha\beta$ -dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone (III) combines readily with two atoms of bromine at the ordinary temperature and without further substitution, a similar addition compound with chlorine cannot be obtained, since simultaneous substitution always takes place. The final product of the chlorination is  $\alpha\alpha\beta\beta\omega$ -pentachlorobutaldehyde-2:4:6-trichlorophenylhydrazone (IV), in which two atoms of chlorine have added on to the double bond, a third has entered the nucleus, and a fourth has displaced the methine hydrogen atom:

When butyl chloral hydrate and 2:4-dichlorophenylhydrazine hydrochloride react in alcohol or acetic acid, the reaction pursues a different course and a well-crystallised yellow compound (V) of the composition  $\text{C}_{10}\text{H}_9\text{ON}_2\text{Cl}_3$  is ultimately obtained. This appears to have been derived from butyl chloral 2:4-dichlorophenylhydrazone (I) by replacement of two atoms of chlorine by an atom of oxygen. When strongly reduced, it yields 2:4-dichloroaniline; the halogen atoms lost in the decomposition must therefore have been in the butyl chloral residue. Its yellow colour indicates that there is no azo-group in the molecule, and the presence of an imino-group is established by the formation of a colourless monobenzoyl derivative,  $\text{C}_{10}\text{H}_8\text{ON}_2\text{Cl}_3(\text{CO} \cdot \text{C}_6\text{H}_5)$ .

It must therefore have the structure  $\beta$ -chloro- $\alpha$ -ketobutaldehyde-2:4-dichlorophenylhydrazone (V). When heated with a substituted phenylhydrazine in any alcoholic solution, it yields a sparingly soluble osazone (VI) in which the ketonic oxygen has been replaced by a hydrazine residue, and also the one remaining chlorine atom in the aldehyde residue has been simultaneously replaced by an alkoxy-group:

When the reaction between butyl chloral hydrate and 2:4-dichlorophenylhydrazine hydrochloride is carried out in methyl

alcohol, the latter reaction takes place so readily that the ketonic hydrazone (V) and the sparingly soluble methoxyl-osazone (VI) are formed together, but they may be separated by fractional crystallisation.

#### EXPERIMENTAL.

*The Action of 2:4-Dichlorophenylhydrazine Hydrochloride on Butyl Chloral Hydrate in Water: Formation of  $\alpha\beta$ -Dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone (III).*—To 20 g. (1 mol.) of 2:4-dichlorophenylhydrazine hydrochloride dissolved in 1000 c.c. of water at 75° acidified with 5 c.c. of concentrated hydrochloric acid, was added a solution of 18 g. (1 mol.) of butyl chloral hydrate and 13 g. of sodium acetate in 250 c.c. of water, also at 75°. The liquid immediately became turbid owing to the separation of yellow oily droplets, which turned first pink and then red, finally coalescing to form a viscous crimson mass. When cold, the supernatant liquid was decanted and the red viscous material was extracted with chloroform, in which it was readily soluble. The chloroform solution, after drying over calcium chloride, was kept at the ordinary temperature in an open dish for 4 days until the evolution of hydrogen chloride, which had been continuous from the first, had apparently ceased.

The chloroform had then evaporated, leaving a semi-crystalline mass. The crystals were separated, washed free from viscous material with light petroleum, and recrystallised repeatedly from boiling alcohol (animal charcoal).

*$\alpha\beta$ -Dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone* crystallises from boiling alcohol or acetic acid, in which it is readily soluble, in pale yellow, long, slender, flattened prisms, m. p. 112° (Found: C, 40.5; H, 3.0; N, 9.4; Cl, 47.7.  $C_{10}H_8N_2Cl_4$  requires C, 40.3; H, 2.7; N, 9.4; Cl, 47.65%).

*Reduction of  $\alpha\beta$ -Dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone.*—5 g. of the hydrazone were dissolved in 20 c.c. of glacial acetic acid and boiled with excess of granulated tin and 20 c.c. of concentrated hydrochloric acid. When the pale yellow colour had completely disappeared (1 hour), the hot solution was made alkaline with aqueous caustic soda and steam-distilled. 2:4-Dichloroaniline (1 g.) in the distillate was identified by conversion into its acetyl derivative, which, alone or mixed with an authentic specimen, melted at 145.5°.

*The Action of Bromine upon  $\alpha\beta$ -Dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone.*—When bromine (1 mol.), dissolved in a few c.c. of glacial acetic acid, was added to a cold saturated solution of the hydrazone in glacial acetic acid,  $\alpha\beta$ -dichloro- $\alpha\beta$ -dibromocrotonaldehyde-2:4-dichlorophenylhydrazone separated. It dissolved

readily in hot glacial acetic acid, from which it separated in colourless compact prisms, m. p. 126—127° (decomp.) (Found: Cl, 31.3; Br, 35.3.  $C_{10}H_8N_2Cl_4Br_2$  requires Cl, 31.0; Br, 34.9%).

*Action of Chlorine upon  $\alpha\beta$ -Dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone.*—A rapid stream of chlorine was passed into a suspension of 6.5 g. of the hydrazone in 20 c.c. of glacial acetic acid. The temperature rose somewhat, hydrogen chloride was freely evolved, and the solid dissolved, giving an almost colourless solution. When no further change appeared to be taking place ( $\frac{1}{2}$  hour), the solution was set aside for 24 hours, during which  $\alpha\alpha\beta\beta\omega$ -pentachlorobutaldehyde-2:4:6-trichlorophenylhydrazone (IV) (7.6 g.) slowly separated. It crystallised from boiling acetic acid or alcohol, in which it was readily soluble, in very slender, colourless prisms, m. p. 84—85° (Found: Cl, 64.7.  $C_{10}H_6N_2Cl_8$  requires Cl, 64.8%).

*Reduction of  $\alpha\alpha\beta\beta\omega$ -Pentachlorobutaldehyde-2:4:6-trichlorophenylhydrazone.*—2 G. of the octachloro-compound were reduced by boiling in acetic acid solution with tin and hydrochloric acid. 2:4:6-Trichloroaniline, separated from the solution, made alkaline, by steam distillation, was identified by conversion into its acetyl derivative, m. p. 208—209°.

*Acetylation of  $\alpha\alpha\beta\beta\omega$ -Pentachlorobutaldehyde-2:4:6-trichlorophenylhydrazone.*—A solution of the hydrazone in acetic anhydride containing a drop of concentrated sulphuric acid was boiled for several minutes. On cooling,  $\alpha\alpha\beta\beta\omega$ -pentachlorobutaldehyde-N-acetyl-2:4:6-trichlorophenylhydrazone separated. It crystallised from boiling acetic acid, in which it was readily soluble, in colourless rhombic plates, m. p. 108—109° (Found: Cl, 58.85.  $C_{12}H_8ON_2Cl_8$  requires Cl, 59.1%).

*The Action of Acetic Anhydride upon  $\alpha\beta$ -Dichlorocrotonaldehyde-2:4-dichlorophenylhydrazone.*—When warmed with acetic anhydride containing a drop of concentrated sulphuric acid, the hydrazone reacted with evolution of heat to give a clear brown solution, from which  $\alpha\beta$ -dichlorocrotonaldehyde-N-acetyl-2:4-dichlorophenylhydrazone separated on cooling. It crystallised from boiling alcohol or acetic acid, in which it was easily soluble, in six-sided prisms, m. p. 122.5° (Found: C, 42.2; H, 3.5; N, 8.5; Cl, 41.6; *M*, cryoscopic in benzene, 329, 333.  $C_{12}H_{10}ON_2Cl_4$  requires C, 42.4; H, 3.0; N, 8.2; Cl, 41.7%; *M*, 340).

*Action of Chlorine upon  $\alpha\beta$ -Dichlorocrotonaldehyde-N-acetyl-2:4-dichlorophenylhydrazone.*—A slow stream of chlorine was passed into a suspension of 2 g. of the acetylhydrazone in 10 c.c. of glacial acetic acid, cooled to prevent any marked rise in temperature. The clear solution obtained was set aside for 4 hours. On cautious

addition of water,  $\alpha\beta\beta$ -tetrachlorobutaldehyde-N-acetyl-2 : 4-dichlorophenylhydrazone separated; this was moderately easily soluble in boiling alcohol, from which it separated in colourless compact prisms, m. p.  $97-98^\circ$  (Found : Cl, 51.7.  $C_{12}H_{10}ON_2Cl_6$  requires Cl, 51.8%).

*The Action of 2 : 4-Dichlorophenylhydrazine Hydrochloride upon Butyl Chloral Hydrate in Ethyl Alcohol : Formation of  $\beta$ -Chloro- $\alpha$ -ketobutaldehyde-2 : 4-dichlorophenylhydrazone (V).*—20 G. of 2 : 4-dichlorophenylhydrazine hydrochloride (1 mol.), 18 g. of butyl chloral hydrate (1 mol.), and 150 c.c. of ethyl alcohol were gently warmed together. As the reactants dissolved, a bright red colour was developed and, when the boiling point of the alcohol was reached, a vigorous reaction set in, hydrogen chloride was freely evolved, and the alcohol continued to boil for some time without further heating. The bright red colour gradually disappeared and the solution became pale yellow.

Half the alcohol was then distilled off and the concentrated solution left to cool; the yellow crystals thus obtained, after being washed with a little cold ligroin, separated from boiling alcohol, in which they readily dissolved, in pale yellow, very slender, hair-like prisms, m. p.  $129^\circ$  (Found : C, 43.2; H, 3.3; N, 10.3; Cl, 38.0.  $C_{10}H_9ON_2Cl_3$  requires C, 42.9; H, 3.3; N, 10.0; Cl, 38.0%).

$\beta$ -Chloro- $\alpha$ -ketobutaldehyde-2 : 4-dichlorophenylhydrazone was also formed when the reaction was carried out in acetic acid solution, the evolution of hydrogen chloride being naturally more marked in this case.

*The Action of Benzoyl Chloride upon  $\beta$ -Chloro- $\alpha$ -ketobutaldehyde-2 : 4-dichlorophenylhydrazone.*—4 G. of benzoyl chloride (1 mol. + excess) were added to 2 g. of the hydrazone dissolved in 6 g. of pyridine. After 30 hours, the deep orange-coloured reaction mixture was poured into dilute hydrochloric acid and the oily layer which separated was washed with aqueous alkali to remove excess of benzoyl chloride. When digested with a few c.c. of warm alcohol, the oil solidified to a mass of crystals.  $\beta$ -Chloro- $\alpha$ -ketobutaldehyde-N-benzoyl-2 : 4-dichlorophenylhydrazone crystallises from boiling alcohol, in which it is sparingly soluble, in small, colourless, compact prisms, m. p.  $166.5^\circ$  (Found : Cl, 28.0.  $C_{17}H_{13}O_2N_2Cl_3$  requires Cl, 27.75%).

*The Interaction of 2 : 4-Dichlorophenylhydrazine Hydrochloride with  $\beta$ -Chloro- $\alpha$ -ketobutaldehyde-2 : 4-dichlorophenylhydrazone in Methyl Alcohol : Formation of  $\alpha$ -Keto- $\beta$ -methoxybutaldehyde-2 : 4-dichlorophenylosazone (VI).*—2 G. (1 mol.) of the hydrazone and 1.5 g. of 2 : 4-dichlorophenylhydrazine hydrochloride (1 mol.) in 20 c.c. of methyl alcohol were boiled for about 5 minutes and cooled. The osazone obtained was readily soluble in boiling pyridine, from which

it separated in compact, bright yellow prisms, m. p.  $196^{\circ}$  (decomp.). It is very sparingly soluble in boiling alcohol, but may be recrystallised from boiling benzene [Found: C, 46.8; H, 3.8; N, 12.9; Cl, 32.95; OMe, by Hewitt and Moore's modification (J., 1902, 84, 318) of Zeisel's method, 7.1.  $C_{16}H_{13}N_4Cl_4(OMe)$  requires C, 47.0; H, 3.7; N, 12.9; Cl, 32.7; OMe, 7.15%].

The corresponding *ethoxy-osazone*, similarly prepared in ethyl-alcoholic solution, crystallised from boiling alcohol, in which it was sparingly soluble, in dull yellow, irregular plates, m. p.  $162^{\circ}$  (decomp.) [Found: Cl, 31.5; OEt, 8.9.  $C_{16}H_{13}N_4Cl_4(OEt)$  requires Cl, 31.65; OEt, 9.95%].

*The Interaction of 2 : 4-Dichlorophenylhydrazine Hydrochloride and Butyl Chloral Hydrate in Methyl Alcohol.*—When a powdered mixture of 20 g. of 2 : 4-dichlorophenylhydrazine hydrochloride (1 mol.) and 18 g. of butyl chloral hydrate (1 mol.) suspended in 50 c.c. of methyl alcohol was treated in the way described for the reaction in ethyl alcohol (p. 92), the same phenomena were observed as in that case; when cold, the reaction mixture had almost solidified to a pulp of crystals. These were separated and extracted with 50 c.c. of boiling ethyl alcohol, a quantity (A) remaining undissolved. The solution, on cooling, deposited yellow needle-like crystals which, after repeated crystallisation from alcohol, melted at  $129^{\circ}$  (8 g.), alone or mixed with  $\beta$ -chloro- $\alpha$ -ketobutaldehyde-2 : 4-dichlorophenylhydrazone (Found: Cl, 37.9. Calc.: Cl, 38.0%).

The material (A), after being extracted twice more with 50 c.c. of boiling ethyl alcohol, left a yellow crystalline residue sparingly soluble in most of the common organic solvents; this separated from boiling pyridine, in which it was moderately easily soluble, in bright yellow, compact prisms (9 g.), m. p.  $196^{\circ}$  (decomp.), identical with the methoxy-osazone described above (Found: Cl, 32.7. Calc.: Cl, 32.7%).

Similar series of reactions were carried out with 2-chloro-4-bromophenylhydrazine and 2 : 4-dibromophenylhydrazine, the following compounds, all crystallised from alcohol, being prepared:—

$\alpha\beta$ -Dichloro- $\alpha\beta$ -dibromobutaldehyde-2 : 4-dibromophenylhydrazone, slender, hair-like, dull yellow prisms, m. p.  $119.5^{\circ}$  (Found: C, 30.7; H, 2.3; N, 7.3; Cl, 18.3; Br, 41.3.  $C_{10}H_8N_2Cl_2Br_2$  requires C, 31.0; H, 2.1; N, 7.2; Cl, 18.3; Br, 41.3%).

$\alpha\beta$ -Dichloro- $\alpha\beta$ -dibromobutaldehyde-2 : 4-dibromophenylhydrazone, colourless compact prisms, m. p.  $132$ — $133^{\circ}$  (decomp.) (Found: Cl, 13.1; Br, 58.7.  $C_{10}H_8N_2Cl_2Br_4$  requires Cl, 13.0; Br, 58.5%).

$\alpha\beta$ -Dichloro- $\alpha\beta$ -dibromobutaldehyde-N-acetyl-2 : 4-dibromophenylhydrazone, colourless, compact, rhombic plates, m. p.  $141^{\circ}$  (Found: Cl, 16.5; Br, 37.3.  $C_{12}H_{10}ON_2Cl_2Br_2$  requires Cl, 16.5; Br, 37.3%).

$\alpha\beta$ -Dichlorocrotonaldehyde-2-chloro-4-bromophenylhydrazone, slender, pale yellow prisms, m. p.  $118^\circ$  (Found: C, 35.2; H, 2.3; N, 8.2; Cl, 31.0; Br, 23.3.  $C_{10}H_8N_2Cl_3Br$  requires C, 35.0; H, 2.35; N, 8.2; Cl, 31.1; Br, 23.3%).

$\alpha\beta$ -Dichlorocrotonaldehyde-N-acetyl-2-chloro-4-bromophenylhydrazone, colourless plates, m. p.  $134^\circ$  (Found: C, 37.8; H, 2.65; N, 7.3; Cl, 27.75; Br, 20.85.  $C_{12}H_{10}ON_2Cl_3Br$  requires C, 37.5; H, 2.6; N, 7.3; Cl, 27.7; Br, 20.8%).

$\beta$ -Chloro- $\alpha$ -ketobutaldehyde-2-chloro-4-bromophenylhydrazone, very slender, lemon-yellow prisms, m. p.  $135^\circ$  (Found: C, 37.1; H, 2.9; N, 8.6; Cl, 21.9; Br, 24.7.  $C_{10}H_9ON_2Cl_2Br$  requires C, 37.05; H, 2.8; N, 8.65; Cl, 21.9; Br, 24.7%).

$\beta$ -Chloro- $\alpha$ -ketobutaldehyde-2:4-dibromophenylhydrazone, very slender, pale yellow prisms, m. p.  $143.5^\circ$  (Found: Cl, 9.7; Br, 43.6.  $C_{10}H_9ON_2ClBr_2$  requires Cl, 9.6; Br, 43.4%).

$\beta$ -Chloro- $\alpha$ -ketobutaldehyde-N-benzoyl-2:4-dibromophenylhydrazone, colourless compact prisms, m. p.  $183.5^\circ$  (Found: Cl, 7.5; Br, 33.75.  $C_{17}H_{13}O_2N_2ClBr_2$  requires Cl, 7.5; Br, 33.8%).

$\alpha$ -Keto- $\beta$ -methoxybutaldehyde-2:4-dibromophenylsazone, bright yellow prisms, m. p.  $194^\circ$  (decomp.), from pyridine or alcohol (Found: C, 33.8; H, 2.8; N, 9.2; Br, 52.3.  $C_{17}H_{16}ON_2Br_2$  requires C, 33.3; H, 2.6; N, 9.2; Br, 52.25%).

$\alpha$ -Keto- $\beta$ -ethoxybutaldehyde-2:4-dibromophenylsazone, yellow, six-sided plates, m. p.  $177^\circ$  (decomp.) (Found: Br, 50.6.  $C_{18}H_{18}ON_2Br_2$  requires Br, 50.8%).

Part of the earlier work described in this paper was carried out in association with Mr. John Cripps Brashaw of Trinity College.

THE QUEEN'S COLLEGE, OXFORD.

## XVI.—The Formation of Glyoxalosazones by the Interaction of Dichloroacetaldehyde and Aryl Hydrazines.

By FREDERICK DANIEL CHATTAWAY and LARKIN HUNDLEY  
FARINHOLT.

WHEN chloral reacts with aryl hydrazines (Chattaway and Bennett, J., 1927, 2850; Chattaway and Daldy, J., 1928, 2756), pale yellow hydrazones are first formed. These are extremely unstable and lose hydrogen chloride very easily, brilliant crimson azo-derivatives of  $\alpha\alpha$ -dichloroethylene being obtained. This loss of hydrogen chloride, however, is a reversible reaction and if the acid is not removed and if the reaction is carried out in alcoholic solution, the trichloromethyl group of the original hydrazone is hydrolysed and

a hydrazone of a glyoxylic ester is produced. The equilibrium being thus destroyed, the red colour at first produced disappears as the azo- $\alpha\alpha$ -dichloroethylene reverts to the original hydrazone :

A similar series of reactions occurs when dichloroacetaldehyde reacts with aryl hydrazines. Hydrazones are at first normally produced which quickly lose hydrogen chloride with the production of a brilliant crimson colour.

This crimson colour is undoubtedly due to the formation of azo-derivatives of  $\alpha$ -monochloroethylene. These, however, are too unstable to allow of their isolation in a pure state and, the reactions by which they are produced being reversible, the crimson colour rapidly disappears on heating and osazones of glyoxal separate, since the dichloromethyl group of the parent hydrazones is very reactive and condenses with another molecule of the aryl hydrazine, either directly or after hydrolysis : thus, where R is  $\text{C}_6\text{H}_5$ , 4- $\text{C}_6\text{H}_4\text{Cl}(\text{Br})$ , 2 : 4- $\text{C}_6\text{H}_3\text{Cl}_2(\text{Br}_2)$ , or 2 : 4 : 6- $\text{C}_6\text{H}_2\text{Cl}_3(\text{Br}_3)$ ,

In this connexion it may be recalled that  $\alpha\alpha$ -dichloro-5-carboxy-2-hydroxyacetophenone similarly yields an osazone with phenylhydrazine (Chattaway and Calvet, J., 1927, 687).

The glyoxalosazones are pale yellow, well-crystallised compounds, for the most part sparingly soluble in ordinary organic solvents. They melt at a high temperature, usually with decomposition, and are easily chlorinated and brominated. They also form well-crystallised diacetyl derivatives,  $\text{R}\cdot\text{N}\cdot\text{Ac}\cdot\text{N}\cdot\text{CH}\cdot\text{CH}\cdot\text{N}\cdot\text{N}\cdot\text{Ac}\cdot\text{R}$ .

The action of chlorine on the unsubstituted glyoxaldiphenylosazone, on glyoxaldi-*p*-chlorophenylosazone, and on glyoxaldi-2 : 4-dichlorophenylosazone yields the same product,  $\omega\omega'$ -dichloroglyoxaldi-2 : 4-dichlorophenylosazone,

Direct halogenation does not introduce a third chlorine atom into the benzene nucleus.  $\omega\omega'$ -Dichloroglyoxaldi-2 : 4 : 6-trichlorophenylosazone, however, is readily formed by the action of chlorine on glyoxaldi-2 : 4 : 6-trichlorophenylosazone.

Bromine acts in an exactly analogous manner, being substituted for hydrogen in the benzene nuclei and replacing the two  $\omega\omega'$ -hydrogen atoms.

The  $\omega\omega'$ -substituted halogen atoms in these compounds are remarkably unreactive. The  $\omega\omega'$ -halogenated osazones can be recovered unchanged even after refluxing with alcoholic ammonia for some hours. They are also not readily reduced by tin or zinc in hydrochloric or acetic acid.

The glyoxalosazones, when the  $\omega\omega'$ -positions are occupied by halogen atoms, are not acetylated when heated with acetic anhydride, tarry products being obtained; nor can chlorine or bromine be substituted for hydrogen in the  $\omega\omega'$ -positions in the diacetylosazones, even on heating in glacial acetic acid for several hours, the initial material being recovered.

#### EXPERIMENTAL.

*Action of Phenylhydrazine upon Dichloroacetaldehyde.*—As the same results were obtained whether dichloroacetaldehyde alcoholate or dichloroacetaldehyde itself was used, the former was always employed, since it is very troublesome to isolate the aldehyde.

To 150 c.c. of acetic acid were added 15.9 g. of dichloroacetaldehyde alcoholate (1 mol.) and 21 g. of phenylhydrazine (2 mols.). On being gently warmed, the solution developed a crimson colour which, as the temperature was raised to about  $70^\circ$ , disappeared and glyoxal-diphenylosazone separated. This compound crystallised from boiling alcohol, in which it was moderately easily soluble, in clusters of pale yellow, rhombic plates, m. p.  $169-171^\circ$  (compare Oddo and Cusmano, *Gazzetta*, 1911, **41**, ii, 251).

*Action of p-Chlorophenylhydrazine Hydrochloride upon Dichloroacetaldehyde Alcoholate.*—To 150 c.c. of acetic acid were added 16 g. of dichloroacetaldehyde alcoholate (1 mol.), 36 g. of p-chlorophenylhydrazine hydrochloride (2 mols.), and 20 g. of anhydrous sodium acetate. On warming, a brilliant crimson colour developed which on further heating disappeared and glyoxaldi-p-chlorophenylosazone separated. It crystallised from boiling alcohol or acetic acid, in both of which it was sparingly soluble, in pale yellow, quadrilateral plates, m. p.  $227^\circ$  (decomp.) (Found: Cl, 22.9.  $C_{14}H_{12}N_4Cl_2$  requires Cl, 23.1%).

The other glyoxalosazones described in this paper were prepared in a similar manner, a deep crimson colour in each case appearing, and disappearing as the heating proceeded and the yellow osazone separated.

*Glyoxaldi-2:4-dichlorophenylosazone* crystallises from boiling acetic acid, in which it is very sparingly soluble, in clusters of pale

yellow needles, m. p. 253—254° (decomp.) (Found: Cl, 37.5; C, 44.8; H, 2.6; N, 14.9.  $C_{14}H_{10}N_4Cl_4$  requires Cl, 37.7; C, 44.7; H, 2.7; N, 14.9%).

*Glyoxaldi-2 : 4 : 6-trichlorophenylosazone* crystallises from acetic acid or alcohol, in both of which it is moderately easily soluble, in clusters of very pale yellow needles, m. p. 189° (Found: Cl, 47.8.  $C_{14}H_8N_4Cl_6$  requires Cl, 47.8%).

*Glyoxaldi-p-bromophenylosazone* separates from either acetic acid or alcohol, in both of which it is sparingly soluble, in pale yellow, quadrilateral plates, m. p. 215° (decomp.) (Found: Br, 40.2.  $C_{14}H_{12}N_4Br_2$  requires Br, 40.4%).

*Glyoxaldi-2 : 4-dibromophenylosazone* crystallises from boiling acetic acid, in which it is very sparingly soluble, in pale yellow, fine needles which darken at about 237° and melt with decomposition at 243° (Found: Br, 57.4.  $C_{14}H_{10}N_4Br_4$  requires Br, 57.7%).

*Glyoxaldi-2 : 4 : 6-tribromophenylosazone* separates from acetic acid, in which it is sparingly soluble, in faintly yellow, quadrilateral plates, m. p. 226—228° (decomp.) (Found: Br, 67.25.  $C_{14}H_8N_4Br_6$  requires Br, 67.4%).

All the glyoxalosazones were easily acetylated when heated with acetic anhydride containing a drop of sulphuric acid. The diacetyl derivatives are all colourless, and were crystallised from acetic acid.

Diacetylglyoxaldiphenylosazone forms quadrilateral plates, m. p. about 360° (decomp.); *diacetylglyoxaldi-p-chlorophenylosazone*, six-sided prisms, m. p. about 330° (decomp.) (Found: Cl, 18.0.  $C_{18}H_{16}O_2N_4Cl_2$  requires Cl, 18.1%); *diacetylglyoxaldi-2 : 4-dichlorophenylosazone*, compact six-sided prisms, m. p. 291—292° (decomp.) (Found: Cl, 30.6.  $C_{18}H_{14}O_2N_4Cl_4$  requires Cl, 30.8%); *diacetylglyoxaldi-2 : 4 : 6-trichlorophenylosazone*, flattened prisms, m. p. about 370° (decomp.) (Found: Cl, 40.0.  $C_{18}H_{12}O_2N_4Cl_6$  requires Cl, 40.2%); *diacetylglyoxaldi-p-bromophenylosazone*, six-sided prisms, m. p. about 340° (decomp.) (Found: Br, 33.4.  $C_{18}H_{16}O_2N_4Br_2$  requires Br, 33.3%); *diacetylglyoxaldi-2 : 4-dichlorophenylosazone*, slender six-sided prisms, m. p. 300° (decomp.) (Found: Br, 50.1.  $C_{18}H_{14}O_2N_4Br_2$  requires Br, 50.1%); and *diacetylglyoxaldi-2 : 4 : 6-tribromophenylosazone*, clusters of needles, m. p. about 365° (decomp.) (Found: Br, 60.3.  $C_{18}H_{12}O_2N_4Br_6$  requires Br, 60.3%).

*Action of Chlorine upon Glyoxaldiphenyl-, Glyoxaldi-p-chlorophenyl-, and Glyoxaldi-2 : 4-dichlorophenylosazones.*—When any one of these osazones was suspended in glacial acetic acid, and a rapid stream of chlorine passed in to saturation, hydrogen chloride was liberated, the suspended osazone dissolved, and *os'-dichloroglyoxaldi-2 : 4-dichlorophenylosazone* separated as a greenish-yellow solid. It crystallised from benzene in pale yellow, fine needles, m. p. 240—

251° (decomp.; after darkening at about 240°) (Found: Cl, 47.6.  $C_{14}H_8N_4Cl_6$  requires Cl, 47.8%).

$\omega\omega'$ -Dichloroglyoxaldi-2:4:6-trichlorophenylosazone was similarly formed by the action of chlorine upon glyoxaldi-2:4:6-trichlorophenylosazone. It is sparingly soluble in boiling acetic acid but much more readily soluble in boiling benzene, from which it crystallises in clusters of very pale yellow, fine needles, m. p. 229—231° (decomp.) (Found: Cl, 55.1.  $C_{14}H_6N_4Cl_8$  requires Cl, 55.2%).

$\omega\omega'$ -Dibromoglyoxaldi-2:4-dibromophenylosazone crystallises from benzene, in which it is moderately easily soluble, in clusters of long, fine, pale yellow needles, m. p. 205° (decomp.) (Found: Br, 67.15.  $C_{14}H_8N_4Br_6$  requires Br, 67.4%);  $\omega\omega'$ -dibromoglyoxaldi-2:4:6-tribromophenylosazone in long, fine, pale yellow needles, m. p. 230° (decomp.) (Found: Br, 73.3.  $C_{14}H_6N_4Br_8$  requires Br, 73.5%);  $\omega\omega'$ -dibromoglyoxaldi-2:4-dichlorophenylosazone in pale yellow needles, m. p. 270—273° (decomp.) (Found: Br, 29.8.  $C_{14}H_8N_4Cl_4Br_2$  requires Br, 29.9%); and  $\omega\omega'$ -dichloroglyoxaldi-2:4:6-tribromophenylosazone in very pale yellow, slender needles, m. p. 257° (decomp.) (Found: Cl, 8.9.  $C_{14}H_6N_4Br_6Cl_2$  requires Cl, 9.1%).  $\omega\omega'$ -Dibromoglyoxaldi-2:4:6-trichlorophenylosazone crystallises from glacial acetic acid in clusters of fine, almost colourless needles, m. p. 246° (decomp.) (Found: Br, 26.8.  $C_{14}H_6N_4Cl_6Br_2$  requires Br, 26.5%).

## XVII.—2-Thiol-4(5)- $\beta$ -aminoethylglyoxaline (2-Thiol-histamine).

By FRANK LEE PYMAN.

IN view of the physiological activity of histamine, and of the natural occurrence of ergothioneine, the synthesis of 2-thiolhistamine appeared to be of interest. This has now been effected by using as the starting material,  $\alpha\delta$ -dibenzamido- $\beta$ -ketobutane (I) which Windaus, Dörries, and Jensen (*Ber.*, 1921, 54, 2745) prepared from the tribenzamidobutene resulting from the benzylation of histamine. When  $\alpha\delta$ -dibenzamido- $\beta$ -ketobutane was hydrolysed with

alcoholic hydrochloric acid at 150°,  $\alpha\delta$ -diamino- $\beta$ -ketobutane dihydrochloride (II) was obtained, and on condensation of this with 1 mol.

of sodium thiocyanate 2-thiolhistamine (III) resulted. Its constitution follows from the results of analysis combined with the fact that it yields histamine on oxidation.

Dr. Dale, Sec. R.S., and Mr. J. H. Gaddum, M.A., of the National Institute for Medical Research, to whom the author wishes to express his thanks, found that 50 mg. of 2-thiolhistamine hydrochloride produced a smaller fall in the blood pressure of a cat under ether than 0.001 mg. of histamine when injected intravenously, and also that 50 mg. of 2-thiolhistamine hydrochloride appeared to have no effect upon a 20 g. mouse when injected subcutaneously. Mr. W. A. Broom, B.Sc., of Boots' Pharmacological Department found that 2-thiolhistamine hydrochloride had only one/two-thousandth part of the activity of histamine in causing contraction of the isolated uterus of a virgin guinea-pig, and did not reduce the blood sugar of the rabbit when injected subcutaneously. It appears, therefore, that the substance has no significant histamine-like action.

#### EXPERIMENTAL.

$\alpha\delta$ -Dibenzamido- $\beta$ -ketobutane was prepared by the method of Windaus, Dörries, and Jensen (*loc. cit.*), the yield being 80 to 90% of the theoretical. It melts at 158–159° (corr.) and is not easily soluble in alcohol, requiring about 7 parts by weight of boiling alcohol for solution, and being much less soluble in cold alcohol. Windaus, Dörries, and Jensen give m. p. 151° and state that the substance is easily soluble in alcohol.

$\alpha\delta$ -Diamino- $\beta$ -ketobutane.— $\alpha\delta$ -Dibenzamido- $\beta$ -ketobutane (10 g.), alcohol (50 c.c.), and concentrated hydrochloric acid (50 c.c.) were heated under pressure for 2 hours at 150°. The solution was evaporated to low bulk, extracted with ether to remove benzoic acid, digested with charcoal, filtered, concentrated to low bulk, and mixed with alcohol;  $\alpha\delta$ -diamino- $\beta$ -ketobutane dihydrochloride then crystallised, and further crops were obtained on concentration, the total yield being 73% of the theoretical. This salt crystallises from water in colourless diamond-shaped plates, m. p. 221° (decomp.; corr.). It is anhydrous and is very easily soluble in water, but sparingly soluble in alcohol (Found: C, 27.5; H, 7.4; Cl, 40.3.  $C_4H_{10}ON_2 \cdot 2HCl$  requires C, 27.4; H, 6.9; Cl, 40.5%). On the addition of cold saturated aqueous picric acid it gives a sparingly soluble picrate, crystallising from water in long, yellow, prismatic needles, m. p. 212° (decomp.; corr.).

2-Thiol-4(5)- $\beta$ -aminoethylglyoxaline.— $\alpha\delta$ -Diamino- $\beta$ -ketobutane dihydrochloride (7.0 g.) and sodium thiocyanate (3.24 g.) were dissolved in 20 c.c. of water. The solution was evaporated to a syrup and heated for another hour at 100°, and just enough water was

added to dissolve the sodium chloride which had separated. On keeping, 2-thiolhistamine hydrochloride crystallised; it was purified by recrystallisation from water (yield, 3.7 g. = 52% of the theoretical).

2-Thiol-4(5)- $\beta$ -aminoethylglyoxaline hydrochloride crystallises from water in clusters of colourless prismatic needles, m. p. 248–249° (corr.). It is anhydrous, very easily soluble in water, giving a neutral solution, and almost insoluble in hot absolute alcohol (Found: C, 33.0; H, 6.1; Cl, 19.8; S, 17.9.  $C_5H_9N_3S \cdot HCl$  requires C, 33.4; H, 5.6; Cl, 19.8; S, 17.8%). When cold aqueous solutions of this salt and picric acid are mixed, no immediate precipitate is formed, but a picrate crystallises on keeping in dense, golden, bevelled tablets, m. p. 225° (decomp.; corr.). Aqueous solutions of the hydrochloride give with diazobenzene-*p*-sulphonic acid (a) in the presence of sodium carbonate, an orange colour; (b) under Hunter's conditions (*Biochem. J.*, 1928, 22, 4), in the presence of sodium carbonate and acetate, a yellow solution, which changes to red with a faint purple fluorescence on addition of sodium hydroxide.

*Oxidation.* 2-Thiolhistamine hydrochloride (0.18 g.) was boiled with hydrated ferric chloride (1.6 g.) in water (30 c.c.) for  $\frac{1}{2}$  hour. The solution was partly neutralised with sodium carbonate, mixed with a hot saturated aqueous solution of picric acid (0.46 g.), filtered, and kept. Histamine dipicrate (0.38 g.; yield, 67%) then separated in a pure state, having m. p. 238° (decomp.; corr.) when heated quickly, alone or mixed with an authentic specimen.

### XVIII.—Comparison of Some Physical Constants of Thiocyanate, Azide, and Nitrite Solutions.

By P. GÜNTHER and W. PERSCHKE.

CRANSTON and LIVINGSTONE recently published measurements of physical constants of azide and cyanate solutions which led them to infer that the two anions have the same spatial structure in solution (*J.*, 1926, 501). About the same time, the X-ray investigations of Hendricks and Pauling (*J. Amer. Chem. Soc.*, 1925, 47, 2904) definitely proved that in the crystalline state both these ions consist of atoms arranged in an open chain with very similar spacings, as theoretical considerations had first caused Langmuir (*ibid.*, 1919, 41, 1543) to assume, discarding the old ring formula for the azides.

The correspondence of Cranston and Livingstone's conclusions with these results was probably fortuitous. The physical

characteristics of ionic solutions are in general greatly influenced by solvation of the ions, although this may in turn be dependent on the configuration of the atoms in the ion. It is nevertheless certain that considerable differences between ions can be concealed to a great extent by addition of water molecules. Yet if Cranston and Livingstone's conclusions were right in the case of the azide and cyanate ions, in that similarity in the configuration of the ions may be inferred from similarity in certain physical properties, we should be in possession of a very simple and convenient method for determining the structure of the thiocyanate ion also.

The following reasons may be given for doubting the validity of Cranston and Livingstone's deductions. In view of the fact that the cyanate is readily decomposed by water, a mixture of water and alcohol was employed as a solvent in determining the density and the refractive index. It would thus appear possible that the various ions would show preference in combining with one species of the molecules of the solvent. Moreover, the experiments only extended in the case of the potassium salts to 0.5*N*-solutions, and in the case of the sodium salts to 1.0*N*-solutions, whereas it is just the high concentrations that are of advantage in discovering the differences in the influence exerted by the solute on the character of the solutions.

In view of the possibility of determining the structure of the thiocyanate ion, we have tested the method employed by Cranston and Livingstone by comparing the physical properties of nitrite solutions with those of azide solutions. The nitrite ion differs little from the azide ion in weight, but in the configuration of its atoms it is certainly quite different, for its structure is very probably similar to that of the nitrate ion, which is known—at any rate in the crystalline state—not to have the nitrogen atom placed in a straight line between two oxygen atoms. We should thus expect nitrite solutions to have physical constants very different from those of azide solutions. With some degree of probability the following surmise can be made as to the difference between the structure of the thiocyanate and the cyanate ion, the latter of which is known to be the same as that of the azide ion, at least in the crystalline state. According to the measurements of Hendricks and Pauling, in the potassium cyanate crystal the centres of gravity of the atoms at the two ends of the cyanate chain are 2.32 Å.U. apart; whereas in the potassium azide crystal the corresponding distance between the two extreme nitrogen atoms is 2.34 Å.U. If we calculate the lengths of the cyanate and azide chains from the radii of the nitrogen, oxygen, and carbon atoms, as determined by Goldschmidt from other crystalline compounds of these elements

("Geochemische Verteilungssätze der Elemente," VII, Die Gesetze der Krystallochemie, Oslo, 1926, pp. 26 *et seq.*), we find the length corresponding to the azide chain to be 2.84 Å.U., and in the case of the cyanate chain 2.85 Å.U. The radii of the atoms in the configurations in question are therefore smaller than usual, but the contraction is practically the same in both cases. Computing the length of the thiocyanate chain in the same way, using Goldschmidt's atomic radius of sulphur (1.04 Å.U.), we find 3.2 Å.U., a value some 18% greater than for the cyanate chain. If, on account of the equal contractions in the case of the azide and cyanate ions, we assume the same contraction to take place in the thiocyanate ion, the ratio of the chain lengths above computed would be more or less preserved.

The molecular weights of sodium azide and sodium thiocyanate are 65.0 and 81.1 respectively. Their influence on the density differences of solutions can be calculated for all concentrations.

In our experiments with sodium azide, thiocyanate, and nitrite we were able to work with pure water as solvent and to attain much higher concentrations than the above-named authors. The experiments show that the correct results which Cranston and Livingstone's method gave are hardly more than accidental. No conclusions can be drawn as to the similarity or dissimilarity of the atomic structure of the ions we investigated. We did not compare the densities of the solids, since, according to the crystallographic determination of Hendricks and Pauling, it is hardly possible that sodium thiocyanate can have the same arrangement of ions in the crystal as potassium cyanate; so we left out this comparison, carried out by Cranston and Livingstone, but we introduced another series of experiments, comparing the viscosities of the solutions.

#### EXPERIMENTAL.

*Materials.*—Sodium azide was recrystallised from water by precipitation with alcohol and sodium thiocyanate was recrystallised from alcohol. The sodium nitrite was Kahlbaum-Schering's "purissimum." The purity of the azide was determined by precipitation as silver azide, which was converted into chloride and weighed as such, the analysis being checked by decomposing the azide with titrated sulphuric acid: the percentage varied between 97.0 and 98.2%. The sodium nitrite contained 97.8% of pure salt, and the thiocyanate 98%, as determined by titration with silver nitrate. Impurities certainly had no influence on the validity of the conclusions drawn from the experiments. 3*N*-Solutions of these salts were prepared, and diluted with distilled water as required.

*Densities.*—The following densities were determined with Mohr's specific gravity scales and, in part, checked with a pycnometer.

*Densities of aqueous solutions at 20.1°.*

	<i>M</i> =	3.0.	2.0.	1.0.	0.5.	0.25 (at 16.7°).
NaN <sub>3</sub> .....	1.1137	1.0764	1.0380	1.0184	1.0099	
NaCNS .....	1.1162	1.0786	1.0395	1.0198	1.0101	
NaNO <sub>2</sub> .....	1.1273	1.0857	1.0427	1.0210	—	

The densities of the azide and thiocyanate solutions differ very slightly—by less than 0.3% in the highest concentrations. The influence of the greater molecular weight of the thiocyanate is almost completely compensated for by the marked contraction taking place on dissolution, which amounts to as much as 3.85%. In comparing the azide with the nitrite solutions a discrepancy is observable, which can, however, be ascribed chiefly to the greater molecular weight of the latter substance; it is therefore impossible to draw any conclusions from these observations as to the configuration of the ions.

*Viscosity.*—The viscosities were determined with an Ostwald viscometer :

*Coefficients of viscosity at 20.1° (water = 1).*

	<i>M</i> =	3.0.	2.0.	1.0.	0.5.
NaN <sub>3</sub> .....	1.344	1.179	1.050	1.006	
NaCNS .....	1.254	1.105	1.043	1.005	
NaNO <sub>2</sub> .....	1.281	1.126	1.046	1.006	

Corresponding to differences in the contraction occurring in solution, the azide ion has the greatest influence on the viscosity coefficient and the thiocyanate ion the smallest.

*Refractive Indices.*—The refractive indices were obtained with a Pulfrich refractometer. On account of the differences in density of the solutions, however, it was necessary to compare the values of the specific refractivity, *R*, and for this purpose the densities were redetermined at 25°.

	<i>M</i> =	3.	2.	1.	0.5.
NaCNS .....	1.3831 <sub>9</sub>	1.3669 <sub>9</sub>	1.3500 <sub>2</sub>	1.3413 <sub>1</sub>	
NaN <sub>3</sub> .....	1.3669 <sub>0</sub>	1.3560 <sub>7</sub>	1.3442 <sub>8</sub>	1.3385 <sub>8</sub>	
NaNO <sub>2</sub> .....	1.3542 <sub>4</sub>	1.3475 <sub>8</sub>	1.3404 <sub>9</sub>	1.3365 <sub>8</sub>	

$$R = \frac{n^2 - 1}{n^2 + 2} \cdot \frac{1}{d}$$

	<i>M</i> =	3.	2.	1.	0.5.
NaCNS .....	0.2096	0.2087	0.2074	0.2067	
NaN <sub>3</sub> .....	0.2026	0.2036	0.2049	0.2056	
NaNO <sub>2</sub> .....	0.1930	0.1970	0.2013	0.2036	

The thiocyanate has the greatest and the nitrite ion the smallest influence on the refraction of light.

*Electrical Conductivity.*—The conductivities, which Cranston and Livingstone determined in methyl-alcoholic solution, were measured in a solution of conductivity water. The electrodes consisted of platinised platinum sheet, and in agreement with the results of Briner and Winkler (*J. Chim. physique*, 1923, 20, 201), as against those of Cranston and Livingstone, the platinum coating was found not to decompose the azide solution. The conductivities were unchanged after  $\frac{1}{2}$  hour, 1 hour, and 2 hours, and at the end of a series of experiments no ammonia could be determined in the solution even with the help of Nessler's reagent.

*Molecular conductivities.*

	$M =$	0.5.	0.25.	0.125.	0.063.
NaCNS .....		65.80	75.04	81.92	90.40
NaN <sub>3</sub> .....		65.54	74.84	81.52	90.40
NaNO <sub>2</sub> .....		62.60	72.36	82.88	93.97

The conductivities of thiocyanate and azide agree up to 0.5*M*, even better than those up to 0.1*M* in Cranston and Livingstone's experiments. The conductivity of the nitrite solution differs in magnitude as well as in its dependence on the concentration.

A survey of all the experimental results here given shows that experiments of this kind do not enable us to draw conclusions as to the configuration of atoms in the ion, as Cranston and Livingstone have done.

### XIX.—*The Inhibition of Chemical Reactions. Part III. The Inhibition by Sulphur of the Atmospheric Oxidation of Benzaldehyde.*

By KENNETH CLAUDE BAILEY.

It has long been known that benzaldehyde is oxidised rapidly by oxygen or by air, and it has been shown that the velocity of oxidation may be greatly reduced by the presence of *very* small traces of "anti-oxygens," *i.e.*, negative catalysts which are themselves oxidisable (see Moureu and Dufraisse, *Chem. and Ind.*, 1928, 47, 819, 848, for a summary of many previous papers); for instance, one part of sulphur in 100,000 parts reduces it to about one-third (*idem, ibid.*, p. 822).

The following additional facts are of importance to the understanding of the present research. (1) The reaction is a chain reaction, in which several thousand molecules are oxidised for each

quantum absorbed, as proved by Bäckström (*J. Amer. Chem. Soc.*, 1927, **49**, 1460; *Medd. K. Vetenskapsakad. Nobel-Inst.*, 1927, **6**, 15 and 16), in amplification of Christiansen's theory. (2) In at least some cases of anti-oxygen action the negative catalyst is itself oxidised; this has been clearly proved for the inhibition by alcohols of the oxidation of sodium sulphite (Alyea and Bäckström, *J. Amer. Chem. Soc.*, 1929, **51**, 90). (3) The velocity of oxidation of benzaldehyde is increased by the addition of sand (Reiff, *ibid.*, 1926, **48**, 2893) or pumice (Brunner, *Helv. Chim. Acta*, 1927, **10**, 707). (4) The reaction certainly takes place in stages (Bäckström, *loc. cit.*), and is retarded by intensive drying (Reiff, *loc. cit.*). It has recently been suggested that pure benzaldehyde does not undergo oxidation (Kuhn and Meyer, *Naturwiss.*, 1928, **16**, 1028). (5) Benzoic acid, produced in the reaction, itself acts as a feeble inhibitor.

Most theories of anti-oxygenic action suppose that the negative catalyst detaches oxygen from its preliminary loose combination with the autoxidisable substance (*e.g.*, benzaldehyde), although there is a difference of opinion as to whether the oxygen is eventually liberated again as such (Moureu and Dufraisse, *loc. cit.*), or is fixed by reaction with the negative catalyst, as in the experiments of Alyea and Bäckström. In the latter case, inhibition must depend on the fact that the oxidation of the inhibitor is incapable of setting up or carrying on a chain of further oxidations.

The part of the problem which seems to have been least satisfactorily dealt with is that mentioned in the first paragraph. The explanation of the inhibitory effect of such minute traces must depend to a large extent on a demonstration of the site of reaction.

Moureu and Dufraisse (*loc. cit.*) and Bäckström (*loc. cit.*) believe the reaction to take place homogeneously in the liquid phase. The first two authors suggest that, as very few of the benzaldehyde molecules are at a sufficiently high energy level to react with oxygen, it is possible for a small number of inhibitor molecules to deal with these activated molecules, an explanation which demands for the original complex of benzaldehyde and oxygen the ability to survive  $10^5$  collisions (if the inhibitor is present in the proportion of one part in  $10^5$  parts) without further reacting with a benzaldehyde molecule to give stable benzoic acid. Bäckström depends on the high quantum yield of the reaction for an explanation of the efficiency of the negative catalyst.

The alternative is that offered by Reiff (*loc. cit.*) and Brunner (*loc. cit.*), and accepted by Rideal (*Trans. Faraday Soc.*, 1928, **24**, 571—574), *viz.*, that the reaction takes place, or is initiated, at the surface of the containing vessel, and is inhibited by the negative catalyst, adsorbed in high concentration on this surface. That

reactions are sometimes thus initiated and inhibited is unquestionable, a case in point being the inhibition of esterification by alkaline catalysts, investigated by the writer (J., 1928, 1204, 3256).

Reiff showed that the velocity of oxidation of 10 c.c. of benzaldehyde, standing without being shaken, was doubled by the introduction of 10 c.c. of sand, the activity of which in promoting the reaction would then be approximately equal to that of the original surface of the vessel. He further showed that 5 c.c. of benzaldehyde with 5 c.c. of sand absorbed oxygen  $1\frac{1}{2}$  times as quickly as 10 c.c. of benzaldehyde alone, and that 2 c.c. of benzaldehyde and 5 c.c. of sand absorbed oxygen three times as quickly. This latter result Reiff interpreted as showing that here the oxygen had to diffuse through a much thinner layer of benzaldehyde to reach the sand and the oxidation rate therefore increased. The rate was greatly increased by shaking, and this was attributed to the increased rate of diffusion of oxygen to the active solid surface.

These experiments, however, only *prove* that oxidation can take place on the surface of the sand. It is *assumed* that the velocity in the absence of added sand depends on the walls of the container. It seems unlikely that the smooth walls of a 50-c.c. vessel could have an activity comparable with that of 10 c.c. of finely-divided sand, and scepticism on this point is increased by the fact that almost identical speeds of reaction were obtained by Reiff with vessels of silica, Pyrex glass, and soft glass, and with vessels lined with paraffin wax. The use of dust-free benzaldehyde caused no decrease in the rate of oxidation. These experiments suggest that the velocity of reaction is appreciably affected only by the introduction of a *large* amount of extra surface. Experiments on paraffin-lined vessels and on the effect of sand are described later.

Brunner performed experiments in a shaking machine, and showed that the velocity of oxidation was increased in direct proportion to the amount of powdered pumice added. Here too it is assumed that the original reaction, in the absence of pumice, is due to the walls of the vessel.

The possibility that the reaction takes place in the vapour phase is rejected by Moureu and Dufraisse (*Chem. Reviews*, 1926, 3, 134, 129), who believe that crystals of benzoic acid appear on the upper portion of the vessel only where benzaldehyde has first condensed as a liquid. The appearance of the vessel in some experiments which were carried on for several days by the writer does not accord with this, for fine needle crystals were formed which projected for a considerable distance into the gaseous phase. In any event, however, the amount of reaction in the gaseous phase is small and, although estimations of the benzoic acid on the vessel wall above

the surface of the liquid were made in many cases, the amount, even where the reaction had proceeded until all the oxygen had been absorbed, never exceeded 4% of the total benzoic acid formed.

The evidence offered in the present paper tends to show that the choice lies, not between a reaction initiated at the solid-liquid interface and one taking place homogeneously in the liquid phase, but between the latter and a reaction initiated at the liquid-gas interface and capable of being inhibited there by a catalyst adsorbed preferentially at that interface.

#### EXPERIMENTAL.

The investigation concerns mainly the oxidation of benzaldehyde by atmospheric air, when standing quietly in an unshaken vessel. Experiments were made with pure oxygen also, but the results were of the same general type as when air was used.

In these experiments the benzaldehyde, unless otherwise specified, was Kahlbaum's pure material, freshly distilled in an atmosphere of nitrogen, and stored under that gas. The velocity of reaction was followed by noting the absorption of oxygen, and no attempt was made to distinguish between the first stage of the reaction (formation of perbenzoic acid) and the final conversion into benzoic acid. The specimen under examination was placed in a vessel connected to a differential manometer, the other arm of which was attached to a vessel of the same size. By reading the difference in height between the two columns of liquid, volume errors due to small variations of temperature were eliminated. In the earlier experiments (Series I—IV) mercury was used as manometric liquid, but in the remainder greater delicacy was obtained by the use of water, and the benzaldehyde was throughout assumed to be moist. [It has already been shown by Brunner (*loc. cit.*) that small variations in moisture content have little effect on velocity of oxidation.]

*Series I.*—The velocity of oxidation of pure benzaldehyde in plain glass vessels was compared with that in vessels to which had been added solid glass rods whose total geometrical surface was approximately equal to that of the portion of the containing vessel in contact with the liquid. The results were not very consistent. Sometimes the vessel with added surface showed a slightly higher velocity than the other, sometimes slightly lower. In no case was the speed of reaction increased by more than 15%.

*Series II.*—Experiments were carried out with the same amount of pure benzaldehyde in flasks and tubes of different shapes but approximately the same volume. The rate of absorption over a period of 2 hours was roughly proportional to the area of the liquid-gas interface. For example, when this interface was increased in

the ratio 7.8, the velocity increased in the ratio 7.2, and with an area ratio of 3.2 the velocity ratio was 2.6.

*Series III.*—In all vessels the benzaldehyde is drawn up on the glass wall by capillary action to some little height above the liquid surface, and it seemed possible that reaction might be very intense in these places where liquid-gas and liquid-solid interfaces are close together. Experiments were performed in which were introduced glass rods of such a length as to project slightly above the surface of the liquid and thus increase the area of this liquid film. The velocity of reaction was found to be diminished rather than accelerated.

*Series IV.*—When benzaldehyde is shaken in air, the velocity of oxidation is greater than when the liquid stands quietly. It has already been pointed out that shaking increases the diffusion of oxygen to the solid surfaces. It is also true, however, that it increases diffusion into the homogeneous phase, and again, that it increases greatly the area of the liquid-gas interface, which cannot be neglected as a possible site of reaction.

Brunner's experiments, already quoted, employed a relatively enormous increase of surface (pumice). It was desirable to try a surface comparable with that of the original flask. For obvious reasons, it is impossible to agitate violently a glass flask containing a number of loose solid glass rods. An extra surface was therefore added by fixing a spiral of solid glass of known surface area into the stopper of the flask. The flask employed had a capacity of 155 c.c., and a surface area of 130 sq. cm. to the highest point to which the benzaldehyde splashed during shaking at 160 revolutions per min. The solid coil had a surface area, exposed to the shaken benzaldehyde, of 31 sq. cm., or 24% of the area of the original surface. The volume of the coil was 6 c.c., and this was taken into account in calculating the absorption of oxygen.

The experiments A were performed in sunlight at 5°, and B in the dark at 12.4°. The solid coil was omitted in A1 and B1, and included in A2 and B2;  $t$  is the time interval from the start (in minutes) and  $R$  the average rate of absorption of oxygen (c.mm./min.).

$t$ .	$R$ .		$t$ .	$R$ .	
	A1.	A2.		B1.	B2.

25—27	300	290			
28—30	270	210			
0—30	422	383	0—70	140	135

In experiments A the oxygen consumption declined by 9.2% when extra surface was included, and in B by 3.6%, whereas an increase of about 24% was to be anticipated if the reaction took place solely on the solid surface. Two other pairs of experiments were performed in the dark, at temperatures of 10.5° and 11.0°, and in each case a diminution of speed of about 4% on inclusion of the extra surface was noted.

*Series V.*—In these experiments cylindrical glass bottles of about 330 c.c. capacity and 5.2 cm. diameter were used. In bottle B the circular bottom was almost flat, in A it was slightly convex; otherwise the bottles were similar. A differential water manometer, with a bottle of the same size containing only air saturated with water vapour, was used in each case. In those experiments where it was used, the light was supplied by a single electric bulb. For A, the distance of the bottle from the light was 88 cm., and for B, 44 cm. In all cases there was an initial rapid absorption which declined rapidly to an almost constant rate. The initial absorption was difficult to measure accurately and the irregularities are probably largely due to experimental error. The average rate of absorption over the period 14—104 minutes was taken as the significant rate for each experiment.

Three types of experiment were made with each bottle. In the first, 12 c.c. of benzaldehyde were employed, in the second 12 c.c. of benzaldehyde and eight glass rods (of total surface approximately equivalent to the submerged surface of the containing bottle), and in the third 5 c.c. of benzaldehyde. The temperature of experiment throughout was 15.3°. In most experiments the first reading of the manometer was taken  $\frac{1}{2}$  minute after the benzaldehyde began to be run into the bottle.

A repetition of the above experiments, and experiments under

the same three sets of conditions with B in the dark, and with A in the dark and the light, followed a similar course, and the following summary gives only the steady rates (values of  $R$  for 14—104 mins.).

		Values of $R$ under conditions		
		(1).	(2).	(3).
Bottle B.	Light .....	117.2, 106.7	98.2, 96.8	76.5, 84.3
"	Dark .....	48.0	41.6	48.3
Bottle A.	Light .....	62.7	67.4	55.7
"	Dark .....	40.1	45.7	47.8

These results show that the effect of doubling the solid-liquid interface is small. In A, it results in a slight increase in velocity, and in B in a reduction (a result confirmed in Series IX). The experiments of Reiff and Brunner make it probable that some portion, at least, of the reaction takes place on the solid surface. We may have here the net result of two opposite effects, an acceleration due to an increase in solid surface, and a diminution in velocity explainable in some other way. The fact that, in all experiments performed in the light, the velocity with a shallow layer of benzaldehyde is markedly less than with a deep layer suggests that the diminution in velocity is due to earlier interruption of the reaction chain postulated by Christiansen and Bäckström.

The fact that 5 c.c. of benzaldehyde absorb oxygen more slowly than 12 c.c. in a similar vessel can hardly be due to the greater proportional accumulation of benzoic acid, as the percentage of this acid formed in these experiments is always low and quite insufficient to explain the results. The latter appear to contradict Reiff's experiments in which 2 c.c. of benzaldehyde over 5 c.c. of sand absorbed oxygen twice as quickly as 5 c.c. of benzaldehyde over 5 c.c. of sand. The difference is probably due to the fact that the particular sand used had a much more active, as well as more extensive, surface than the glass vessel, and the acceleration here outweighed the diminution in velocity due to earlier interruption of the reaction chain. On this theory, the fact that addition of extra surface to A results in a small increase in velocity, in contrast to the result in B, may be due to the different distribution of liquid and solid resulting from the slight convexity of the bottom of A. The relative importance of the two opposite effects may, therefore, be different in the two bottles.

*Series VI.*—These experiments were performed with three tubes of 34 c.c. capacity and 1.4 cm. diameter, prepared from uniform soft-glass tubing. One tube (T) was left in its original condition. Another (N) was narrowed slightly, and in the third (W) a small bulb was blown, in positions such that 6 c.c. of benzaldehyde filled the

tube to the centre of the narrowing or the bulb respectively. Allowance being made for the liquid creeping on the glass to the extent of 0.3 cm., the total liquid surfaces in T, N, and W, respectively, were 3.1, 2.5, and 5.9 sq. cm., or in the ratio 1.0 : 0.81 : 1.90. (If the creep surface is neglected the ratio is 1.0 : 0.69 : 2.20.) We have, therefore, three similar vessels, containing the same amounts of air (28 c.c.) and benzaldehyde (6 c.c.), and with almost identical solid surfaces (submerged area = 22 sq. cm.), but differing in the area of the liquid-gas interface.

Experiments with the light at 44 cm., at 15.3°, showed that the relative steady velocities in T, N, and W for the period 14–104 minutes were 1.0, 0.84, and 2.03, or roughly in the ratio of the areas of the liquid-gas interface.

*Series VII.*—It was thought desirable to repeat Reiff's experiments in which contact of benzaldehyde with the glass surface was prevented by coating the glass with paraffin wax. Experiments were made simultaneously with two similar bottles, one of plain glass, the other lined with paraffin wax. After the subsidence of the short initial period of rapid oxidation (14 mins.), the velocity of reaction in the glass vessel remained almost constant for over an hour. The velocity in the wax-lined vessel, which, at the end of the 14 minutes, was little less than that in the glass vessel, fell off continuously.

An examination of Reiff's curves showed that this happened in his experiment also, although to a less extent. As melted paraffin wax and benzaldehyde are freely miscible, it seemed likely that benzaldehyde would dissolve some solid paraffin wax. It was found that benzaldehyde which had been left over-night under nitrogen in contact with paraffin wax at 15° did not oxidise appreciably for at least an hour when placed in contact with air. Paraffin wax is therefore dissolved, and is a remarkably good inhibitor. The wax used melted at 71° and may have dissolved in benzaldehyde more rapidly than that employed by Reiff.

These experiments make it clear that paraffin wax is not a suitable substance for covering the glass walls of the vessel. The possibility was next considered of floating the benzaldehyde on the surface of an inorganic liquid of higher density. Contact with the solid surface would thus be greatly reduced, and the surface of a liquid can hardly present "active points" for heterogeneous catalysis, such as are believed to be present in a solid catalytic surface. Water is not sufficiently dense, and it was found that benzaldehyde which had been left in contact with a concentrated solution of sodium chloride oxidised much less rapidly than normally, having suffered partial inhibition; a concentrated solution of calcium chloride,

however, proved satisfactory, for benzaldehyde which had been thoroughly shaken with it still oxidised almost as rapidly as before.

A glass-stoppered vessel was filled completely with equal volumes of benzaldehyde and calcium chloride solution and shaken vigorously for  $\frac{1}{2}$  hour. Three cylindrical glass bottles of 290 c.c. capacity and 5.8 cm. diameter were connected to the same water manometer. One was used as a control; into the second (A) were put 10 c.c. of the calcium chloride solution, and 10 c.c. of benzaldehyde previously shaken with calcium chloride were carefully floated on top of it; and into the third (B) were put 10 c.c. of the shaken benzaldehyde, in direct contact with the glass.

Allowing for the rise of liquid on the walls due to surface tension, the ratio of glass surface in contact with benzaldehyde in A and B was 1.0 : 3.4. The following results were obtained.

A {t .....	1-1	1-3	3-5	5-7	7-10	10-15	15-25	25-48	48-61	5-61
{R .....	120	135	141	141	126	132	126	123	117	123
B {t .....	2-4	4-5	5-7	7-9	9-12	12-17	17-27	27-50	50-63	5-63
{R .....	84	75	120	120	120	120	126	134	135	132

The velocity of oxidation in A was about 7% less than in B, instead of 70% less, as would be expected if the reaction were entirely initiated at the glass surfaces. It is noteworthy that these experiments are the only ones performed by the author in which the initial rapid absorption, subsiding after the first few minutes, was absent. The explanation of this phenomenon is still far from clear.

Experiments similar to those of Reiff with sand (already quoted) were also performed, but the geometrical surface area of the silver sand used was evaluated. 1,000 Grains of sand weighed 0.0081 g. The density was 2.6, from which it was calculated (on the assumption that the grains were spherical) that 275 grains have a surface area of 1 sq. cm.

The bottles used for the experiment were similar to those employed in Series V, and the area of glass covered by 10 c.c. of benzaldehyde was about 35 sq. cm. The weight of sand having approximately the same surface area is only 0.08 g. The following results (mean of several experiments) were obtained at 12.7°.

	R (14-74 minutes).
10 c.c. Benzaldehyde .....	50
(a) 10 c.c. Benzaldehyde + 0.08 g. sand .....	46.5
(b) 5 c.c. Benzaldehyde + 10 g. sand .....	33
(c) 11 c.c. Benzaldehyde + 10 g. sand .....	54

These results are quite unlike those of Reiff, but resemble closely those of Series V, in that addition of a sand surface comparable in area with that of the original glass (a) has little effect, while reduction

in the depth of liquid (*b*) diminishes the oxidation. When the original depth of liquid is restored (*c*) (1 c.c. of benzaldehyde extra being allowed for soakage between the grains of sand), the velocity is restored to a value only a little faster than the original. The difference between these results and Reiff's is probably due to the fact that his sand had a surface of much greater specific activity than the silver sand used in these experiments.

*Series VIII.*—The following experiments on benzaldehyde which contained sulphur as an inhibitor were made with the light at 44 cm., and with tubes T and W (see Series VI). The temperature was 15.3°. Since in many of the experiments, the reaction velocity did not become constant as quickly as in the experiments with large bottles (Series V), the mean velocity for the period 34—104 minutes was considered the significant velocity. The following is a summary of the results :

Sulphur, parts per 10 <sup>6</sup> .	<i>R</i> (34—104).		Ratio, W/T.	of original. ~		Diminution % for each part of sulphur per 10 <sup>6</sup> .	
	T.	W.		T.	W.	T.	W.
Nil	1.866	3.475	1.86	100	100		
3.3	1.582	2.927	1.85	84.8	84.2	4.61	4.79
10	0.612	1.028	1.68	32.8	29.6	7.76	8.15
20	0.555	0.920	1.66	29.8	26.5	0.30	0.31
100	0.280	0.434	1.55	15.0	12.5	0.19	0.18
1000	0.124	0.124	1.00	6.6	3.6	0.009	0.010

From these results the following facts emerge.

(1) The ratio of velocities in W and T remains fairly constant as long as the amount of inhibitor present is small.

(2) The effect of each part of sulphur per million appears to be less for the first 3.3 parts than for the next 6.7 parts. That this phenomenon is due to adsorption of sulphur on the solid surface is shown by Series IX. Proportionately more of the first sulphur added is removed from solution, for the solid surface probably becomes rapidly saturated with sulphur. This result is the opposite of what would be expected if the reaction were wholly initiated on the solid surface.

(3) The addition of sulphur causes a very rapid diminution in reaction velocity until the velocity has been reduced to about 30% of the original. After that, further addition of sulphur has a much smaller effect. This suggests that about 70% of the reaction takes place in ways readily affected by inhibitors, and about 30% (in vessels of the shape employed) in ways not readily affected.

*Series IX.*—A few experiments were made with tubes W and T, to which had been added glass rods of 10 sq. cm. surface area (about 45% of the submerged surface of the tube) and volume 1.15 c.c. Only 4.85 c.c. of benzaldehyde were used, so that the liquid level

stood at the same points as before. The other conditions were as in Series VIII.

Sulphur, parts per 10 <sup>6</sup> .	<i>R</i> (34—104).		Velocity as % of original.		Diminution % for each part of sulphur per 10 <sup>6</sup> .	
	T.	W.	T.	W.	T.	W.
Nil	1.704	3.135	100	100		
10	1.184	2.246	69.5	71.6	3.05	2.84
20	0.523	0.868	30.7	27.7	3.88	4.39

These results confirm the fact already noted, that the addition of extra glass surface to benzaldehyde containing no inhibitor is accompanied by a reduction rather than an acceleration in velocity. The further reduction due to the addition of 10 parts of sulphur per million parts is only about 30% instead of 70%, as in the case of benzaldehyde containing no extra glass surface, but 20 parts of sulphur cause a total reduction of about 71%, as against 72% in Series VIII. There is here more solid surface for adsorption of inhibitor, and therefore, with small amounts of inhibitor added, the amount of inhibitor actually available is much less than one would expect.

#### *Discussion.*

It is clear from Series II, VI, and VIII that the velocity of oxidation in unshaken vessels is approximately proportional to the area of the liquid-gas interface. This fact could be reconciled with any of the three following theories: (1) that the reaction is initiated at this interface, (2) that we are measuring a diffusion rate, the reaction taking place in the homogeneous phase, (3) that we are measuring a diffusion rate, the reaction taking place at the solid-liquid interface.

Let us first consider theory (3). It is shown in Series I, III, and IX, that addition of extra glass surface is accompanied by no increase in velocity. This can be reconciled with theory (3) only if we assume that the surface of the containing vessel is so catalytically "active" that it is already more than sufficient for all the oxygen that reaches it, and that the addition of extra surface merely means the substitution of new "active points" for some of the original.

The results of Series IV show that we must further assume an ability to cope with the much greater quantity of oxygen which would diffuse to the solid surface when the vessel is shaken at 160 revolutions per minute.

The writer has also performed experiments which show that the velocity of oxidation increases with rate of shaking (and therefore rate of diffusion of oxygen) up to the maximum velocity employed (160 r.p.m.).

The experiment performed in Series VII, with benzaldehyde

floated on calcium chloride solution, seems to prove definitely that the reaction is not, in the main, a solid surface phenomenon, for the glass-benzaldehyde interface in the vessel A is only to be found round the edges of the vessel, and is not likely to be reached at all by most of the molecules of oxygen which diffuse into the benzaldehyde near the centre of the liquid surface.

The experiments with sand in Series VII showed that the substitution for glass of an enormously greater surface of silver sand increases very little the velocity of reaction, and these experiments, as well as those in Series V, indicate that when the solid surface is brought nearer to the oxygen by diminishing the depth of liquid, the result (in experiments in the light) is a diminution of speed rather than an increase.

The sand experiments suggest that the results obtained by Reiff are exceptional and must be due to the fact that the sand used by him acted as a decided positive catalyst. This theory, however, conflicts with the idea that we are measuring a diffusion rate to the glass surface where reaction takes place practically instantaneously, for, if this be the case, the substitution of a more active solid surface can make no appreciable change in velocity.

The results quoted in Series VIII, and discussed in (2) under that series, also militate against a solid-surface theory.

The experiments described in this paper afford no means of discriminating with certainty between a homogeneous reaction in which a minute proportion of inhibitor acts by interrupting a chain which would otherwise be much longer, and a reaction initiated at the liquid surface and checked by an inhibitor adsorbed at this surface in high concentration. There are several points, however, which incline the author towards the view that the latter type of reaction is the more important.

The experiments of Series VIII show that the velocity of oxidation is reduced by 70% by the addition of 10 parts of sulphur per million parts, while the addition of further sulphur has a very much smaller effect on the velocity. If these results are plotted, a curve is obtained very similar to that obtained for the effect of pyridine on the esterification of ethyl alcohol and acetic acid (J., 1928, 1204). In the latter case, the portion of the reaction which is readily affected by small amounts of inhibitor was shown to be a surface reaction, while the portion not readily affected is probably a homogeneous reaction. It is at least possible that the similarity of curve is due to a similarity of cause.

In the second place, the idea that the reaction is largely initiated in the surface layer seems reasonable of itself. The concentration of oxygen in the surface layer is clearly higher than in the body of the

liquid, unless we assume that no reaction takes place until the solid surface is reached, an assumption which the author has given reasons for rejecting.

The higher concentration of oxygen in the surface layer should mean more reaction in that layer, but the percentage of inhibition will not be greater there than elsewhere unless there is a preferential concentration of inhibitor at the liquid-gas interface. This hypothesis is so far untested in this case, but experiments on the problem are projected. The possibility that they may yield positive results is increased by the results of experiments by McBain and Davies (*J. Amer. Chem. Soc.*, 1927, **49**, 2230) and Laing, McBain, and Harrison (*Colloid Symposium Monograph*, 1928, **6**, 63), who have shown that, in the case of aqueous solutions of such diverse substances as *p*-toluidine, camphor, amyl alcohol, and sodium oleate, the surface concentration of the solute is high even in dilute solutions, and that, when the bulk concentration reaches 1–5 g. per litre, a surface layer more than one molecule thick is composed almost entirely of solute molecules.

A theory that the reaction is initiated to a considerable extent at the liquid surface does not necessarily conflict with the belief that the reaction is a chain reaction. It merely modifies it by suggesting that the reaction chain usually begins at the liquid surface, where it is more readily interrupted by an inhibitor concentrated there than when it begins in the homogeneous phase where the concentration of inhibitor is lower. The reduction in velocity when the depth of liquid is reduced (Series V and VII) may be due to earlier interruption of the reaction chain by collision with the solid surface. The diminution of reaction in Series III has probably a similar explanation.

The writer desires to record his indebtedness to the trustees of the J. M. Purser Fund (Trinity College, Dublin) for a grant for the purchase of pure benzaldehyde.

TRINITY COLLEGE, DUBLIN.

[Received, June 25th, 1929.]

## XX.—The Conversion of N-Chloroacetanilide into *p*-Chloroacetanilide by Hydrogen and Chlorine Ions.

By JOSEPH WATKIN BELTON.

THE theory that the velocity of a chemical reaction in a homogeneous liquid system is determined by the activities of the chemical species concerned has met with some measure of success in certain cases, such as the inversion of sucrose (Jones and Lewis,

J., 1920, 117, 1120; Moran and Lewis, J., 1922, 121, 1613; Scatchard, *J. Amer. Chem. Soc.*, 1923, 45, 1580) and the catalytic decomposition of hydrogen peroxide by bromine-bromide solutions (Livingston and Bray, *ibid.*, p. 2048; Livingston, *ibid.*, 1926, 48, 53). On the other hand, the velocities of some reactions appear to be adequately expressed in terms of the concentrations of the reactants. The velocity of hydrolysis of ethyl acetate catalysed by hydrochloric acid, considered by Harned and Pfanstiel (*ibid.*, 1922, 44, 2194) to be determined by an activity relationship, has recently been found by Dawson and Lowson (J., 1928, 2146) to be proportional to the concentration of the acid over a range 0.0002—0.2*M*, through which the activity coefficient of the hydrogen ion falls by 14%. The velocity of the mutarotation of glucose in water is proportional to the concentration of glucose up to 0.6*M*, and the deviations up to five times this concentration are not great (Hudson and Dale, *J. Amer. Chem. Soc.*, 1917, 39, 320). According to the theory of reaction velocity in solutions developed by Brönsted (*Z. physikal. Chem.*, 1922, 102, 169; 1925, 115, 337), the above conflicting views are special cases of a more general velocity equation which involves the activity coefficients of the reactants and of an intermediate complex. A well-known example of a reaction in which the rate is proportional to the activities of the reactants is the conversion of *N*- into *p*-chloroacetanilide, which occurs in the presence of hydrogen and chlorine ions. It is shown below, however, that the activity theory of reaction rate is of only limited application in this case, and that it breaks down completely when the concentrations of hydrogen and chlorine ions are not equal.

This reaction, which apparently follows a unimolecular course, takes place in two stages (Orton and Jones, *Brit. Ass. Rep.*, 1910, 85):

and only in the presence of both hydrogen and chlorine ions, either ion alone being ineffective. The first stage, being slow compared with the second, determines the velocity of the change. The specific velocity was found by Harned and Seltz (*J. Amer. Chem. Soc.*, 1922, 44, 1476) to be proportional to the product of the activities of the hydrogen and the chlorine ions; at constant temperature their results were satisfactorily represented by the relation

$$K = k_1/a_{\text{H}^+}\cdot a_{\text{Cl}^-} \quad \dots \quad (1)$$

where  $k_1$  is the experimentally determined unimolecular velocity

coefficient,  $a_H$  and  $a_{Cl}$  are the activities of the respective ions, and  $K$  is a constant varying only with temperature. This expression was modified by Soper and Pryde (J., 1927, 2761), who found that better agreement was obtained when the theoretically justified equation

$$K = k_1/a_H \cdot a_{Cl} \cdot f_{NCl} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

was employed,  $f_{NCl}$  being the activity coefficient of the *N*-chloroacetanilide. If the velocity of the change is proportional to the activities of the reacting substances, then we may write

$$v = Ka_H \cdot a_{Cl} \cdot a_{NCl} = Ka_H \cdot a_{Cl} \cdot C_{NCl} f_{NCl}$$

The measured velocity coefficient is given by  $k_1 = v/C_{NCl}$ , and consequently  $K = k_1/a_H \cdot a_{Cl} \cdot f_{NCl}$ . Thus, on this basis the equation employed by Soper and Pryde, rather than that of Harned and Seltz, should be applicable.

In both these investigations the reaction was carried out in the presence of pure hydrochloric acid, in which case the hydrogen- and the chlorine-ion concentrations are necessarily equal. It would appear possible by varying independently the concentration of the two ions, by the addition of acids or of chlorides, to test the applicability of the above equation over a wider range. Measurements of the effect of neutral salts have been made by Rivett (*Z. physikal. Chem.*, 1913, 82, 201; 85, 113), but the concentration terms in which they are expressed render them unsuited for the test of an activity theory of reaction rate. The reaction has therefore been investigated in the presence of mixtures of hydrochloric acid with sodium chloride and with perchloric acid over a wide concentration range.

#### EXPERIMENTAL.

To a solution of *N*-chloroacetanilide, together with the required amount of sodium chloride or perchloric acid, was added the appropriate quantity of pure hydrochloric acid of known strength, both solutions having been first kept for some time at the temperature of reaction—in all cases  $25^\circ (\pm 0.02^\circ)$ . The reaction was then followed iodometrically: at definite times samples were removed and treated with potassium iodide solution and the liberated iodine was titrated with *N*/130-thiosulphate.

A complication is introduced by the *N*-chlorination of the anilides formed (Soper, *J. Physical Chem.*, 1927, 31, 1193), such products reacting with potassium iodide with liberation of iodine. This takes place only to a small extent, and its obviation by the presence of a chlorine acceptor is difficult in salt solutions of high concentration, in which salting-out effects are considerable. Further, in the more

dilute solutions, it was not possible to obtain reproducible results on employing *p*-cresol as such an acceptor. Hydrolysis of the *N*-chloroacetanilide also occurs to a small extent as a side reaction, the result of which is to introduce a small error in a direction opposite to that caused by *N*-chlorination. No attempt has been made here to apply a correction for either of these effects, which tend to annul each other, for it may be shown that the maximum error introduced thereby is of the order of 3%, which is only little greater than the possible experimental error and is too small to invalidate the general conclusions reached.

The velocity coefficients were calculated from the unimolecular equation  $k_1 = 1/t \cdot \log T_1/T_2$ , where  $T_1$  and  $T_2$  are two successive titres and  $t$  is the time interval between them. For each reaction

FIG. 1.

a good constant was obtained. In order to avoid errors due to lack of homogeneity and to increase in temperature on mixing, some time was allowed to elapse between the addition of hydrochloric acid and the initial titration. The specific rate of reaction of *N*-chloroacetanilide and pure hydrochloric acid at 25° was found to be in agreement with the results of Harned and Seltz (*loc. cit.*), whose values have been used in plotting  $K_1$  against  $C_H \cdot C_{Cl}$  for pure hydrochloric acid in Figs 1. and 2.

*Rate of Reaction in Hydrochloric Acid-Sodium Chloride Mixtures.*—The rate of reaction was measured in mixtures in which the concentration of hydrochloric acid was kept approximately constant whilst that of sodium chloride was progressively increased. Table I gives the values of the unimolecular velocity coefficient ( $k_1$ ) in mixtures in which the concentration of hydrochloric acid ( $C_{HCl}$ ) varied only between 0.050 and 0.053*M*, while that of sodium chloride ( $C_{NaCl}$ ) varied from 0.1 to 4.2*M*. Concentrations through-

out are expressed in terms of mols. of solute per 1000 g. of water. The product of the ionic concentrations of hydrogen and chlorine ions ( $C_H \cdot C_{Cl}$ ) is also given, these being calculated on the basis of complete electrolytic dissociation.

\* Cols. 7, 8, and 9 give the values of  $k_1/C_H \cdot C_{Cl}$ ,  $k_1/C_H \cdot C_{Cl} f_{HCl}^2$ , and  $k_1/C_H \cdot C_{Cl} f_{HCl}^2 f_{NCl}$ , respectively.

In Fig. 1 these values are compared with those obtaining in pure hydrochloric acid solutions. It will be observed that for the latter the velocity coefficient varies linearly with the product  $C_H \cdot C_{Cl}$  over the concentration range employed, while in the presence of increasing sodium chloride concentration, the corresponding curve first lies below and then, at higher concentrations, above that for the pure acid. A similar behaviour is shown in the case of reactions carried out with a higher concentration of hydrochloric acid, again with progressive addition of sodium chloride. The values of the unimolecular velocity coefficients obtained in these reactions are given in Table II, and the relation between them and the product of the concentrations of the hydrogen and chlorine ions is shown in Fig. 2. The curve obtained is similar in general form to that found for mixtures of 0.05*M*-hydrochloric acid with sodium chloride.

In order to test the applicability of equation (2), *i.e.*, of the simple activity theory of reaction rate, a knowledge is required of the activities of hydrochloric acid and of the activity coefficient of *N*-chloroacetanilide in the systems investigated. The mean activity

coefficients of hydrochloric acid in sodium chloride solutions are given with sufficient accuracy by an equation proposed on empirical grounds by Harned and Brumbaugh (*J. Amer. Chem. Soc.*, 1922, 44, 2729), viz.,

$$\log f_{\text{HCl}} = \alpha c - \beta \mu \alpha' + \alpha''(\mu - c),$$

in which  $\alpha$ ,  $\alpha'$ ,  $\alpha''$ , and  $\beta$  are constants,  $c$  is the molar concentration of hydrochloric acid, and  $\mu$  the ionic strength of the solution. The

FIG. 2.

values of  $f_{\text{HCl}}$  calculated from this expression are given in col. 5 of Table I. The activity of the hydrochloric acid is given by

$$a_{\text{HCl}} = a_{\text{H}} \cdot a_{\text{Cl}} = f_{\text{HCl}}^2 C_{\pm}^2 = f_{\text{HCl}}^2 C_{\text{H}} \cdot C_{\text{Cl}}$$

where  $C_{\pm}$  is the mean molality of the ions.

The activity coefficients of the chloroamide were determined by solubility measurements in sodium chloride solutions of concentrations between 0.1 and 4*M*. The *N*-chloroacetanilide was shaken in a thermostat for some time with a sodium chloride solution of known strength, and a sample rapidly withdrawn through a plug of cotton-wool, by means of a pump. The sample was weighed, and the amount of *N*-chloroacetanilide present estimated iodometric-

ally. From these data its solubility in mols. per 1000 g. of water is calculable. It may be assumed that the presence of 0.05*M*-hydrochloric acid would have but little effect on the solubility in comparison with the concentrations of sodium chloride employed. The activity coefficient of the chloroamide in solution is given by  $m_0/m_s$ , where  $m_0$  is the solubility in pure water, and  $m_s$  that in the salt solution. The activity coefficients found in this way are given in col. 6 of Table I. Incidentally, it may be mentioned that the function,  $\log f_{\text{NCl}}$ , varied linearly with the ionic strength of the solution up to a value  $\mu = 4.3$ .

The numerical values of the expression  $k_1/C_H \cdot C_{\text{Cl}} f_{\text{HCl}}^2$ , given in col. 8 of Table I, are seen to fall throughout with increasing sodium chloride concentration, the value in 4.3*M*-sodium chloride solution being only one-third of that in 0.1*M*-solution. For comparison, the values of  $k_1/C_H \cdot C_{\text{Cl}}$  are given in col. 7. Over the same concentration range, the activity coefficient of the *N*-chloroacetanilide increases from 1.04 to 4.91, and consequently the values of the expression  $k_1/a_H \cdot a_{\text{Cl}} f_{\text{NCl}}$  (col. 9) fall still more rapidly than those of (1). If the velocity of reaction were proportional to the activities of the reacting substances, this expression should be constant at constant temperature; hence the simple activity theory does not apply when sodium chloride is present. A similar divergence is found in the case of more concentrated hydrochloric acid solutions. The values of  $k_1/C_H \cdot C_{\text{Cl}} f_{\text{HCl}}^2$  fall rapidly, and although no numerical data are available, on account of the difficulties involved in the determination of solubilities in hydrochloric acid-sodium chloride mixtures, the activity coefficients of the chloroamide in such solutions would doubtless increase and produce a still greater decrease in the value of expression (2) than in that of (1).

On the basis of Brönsted's theory of the velocity of chemical reactions in solutions, the formation of a critical complex between hydrogen ions, chlorine ions, and chloroamide might be assumed. This would give for the velocity of reaction

$$v = KC_H \cdot C_{\text{Cl}} C_{\text{NCl}} f_H \cdot f_{\text{Cl}} f_{\text{NCl}} / f_{\text{NCl, HCl}} \quad \dots \quad (3)$$

where  $f_{\text{NCl, HCl}}$  is the activity coefficient of the critical complex. If it be assumed that this magnitude varies with the ionic strength of the solution in the same way as does  $f_{\text{NCl}}$ , this expression becomes

$$v = KC_H \cdot C_{\text{Cl}} C_{\text{NCl}} f_H \cdot f_{\text{Cl}} = K a_H \cdot a_{\text{Cl}} C_{\text{NCl}}$$

according to which expression (1) should be constant, but this has been found not to be the case. The numerical values of the terms in equation (3) are known, with the exception of the activity coefficient of the complex. The value of  $f_{\text{NCl, HCl}}/K$  is thus calculable, and is found to increase 16-fold over the concentration range

of Table I. Up to a concentration of 1*M*-sodium chloride, however, this increase is 70%, which might be regarded as a possible (although abnormal) increase for the activity coefficient, but it is found that its logarithm does not bear a linear relation to the ionic strength of the solution, as was found to be the case for *N*-chloroacetanilide itself. A further possibility is the formation of a singly charged complex between the chloroamide and either hydrogen or chlorine ions. This leads to an expression for the velocity  $v = KC_H \cdot C_{\text{NCl}} f_{\text{H}^+} f_{\text{NCl}} / f_{\text{NCl} \cdot \text{H}^+}$ , but this does not lead to a constant value of *K* if similar variation of the activity coefficients of the positively charged ions is assumed. A similar result is obtained if Cl' is substituted for H' in the above equation. It therefore appears to be impossible to formulate an expression, based on the formation of a critical complex by the reactants, which shall agree with the experimental results.

A comparison of the curves obtained with mixtures of hydrochloric acid and sodium chloride, and those of hydrochloric acid alone or with perchloric acid (described below) indicates that the sodium ion exerts some effect on the rate of reaction. In this connexion it is of interest to consider the effect of neutral salts not containing chlorine ions on the velocity coefficient. It was found that with 0.05*M*-hydrochloric acid, the addition of 4*M*-sodium nitrate produced no sensible increase in the value of  $k_1$ , but that with 0.48*M*-acid and 4*M*-nitrate ( $C_H \cdot C_{\text{Cl}'} = 0.23$ ) a slight increase in rate resulted. The latter point is plotted in Fig. 1. This behaviour might be expected if the reaction were of Brönsted's Type 0, in which little salt action is found. The action of sodium chloride is to produce first a slight negative, and then a positive salt effect, and in one case of the reaction types described by Brönsted (*loc. cit.*), the kinetic activity factor (*F*) possesses a value first less and then greater than unity (Type 1.1). This, however, involves the formation of a doubly charged complex, but it would appear difficult to formulate a mechanism of the reaction on this basis.

*The Rate of Reaction in Hydrochloric-Perchloric Acid Mixtures.*—In the experiments described above, the concentration of the chlorine ion was varied over a wide range in comparison with that of the hydrogen ion. By the addition of perchloric acid, which may be regarded as completely dissociated in solution, the concentration of the hydrogen ion may be made much greater than that of the chlorine ion. The experimental procedure was identical with that for sodium chloride solutions. In each case a good unimolecular velocity coefficient was obtained and these are given in Table III together with the corresponding concentration data.

TABLE III.

$C_{HCl}$	$C_{HClO_4}$	$C_H \cdot C_{Cl}$	$k_1 \cdot 10^4$	$C_{HCl}$	$C_{HClO_4}$	$C_H \cdot C_{Cl}$	$k_1 \cdot 10^4$

0.404	0.0187	0.171	69.5				

The relation between the specific velocity of reaction and the product of the ionic concentrations is given in Fig. 2. It shows that within the range investigated (up to  $C_H \cdot C_{Cl} = 0.65$ ), the unimolecular velocity coefficient varies linearly with the product of the molal concentrations of the hydrogen and chlorine ions. The velocity would then be represented by  $v = KC_H \cdot C_{Cl} \cdot C_{NCl}$ . There appears, then, to be no need to introduce the activity theory of reaction rate in this case, the velocity of reaction being proportional to the concentrations of the reacting substances. This result would be in agreement with Brönsted's theory of reaction velocity only if the kinetic activity factor ( $F$ ) showed no variation over the concentration range considered, but it is probable that the activity coefficient,  $f_0$ , of an uncharged molecule would decrease by about 12% in an acid solution of  $\mu = 1.5$ .

### Summary.

The rate of conversion of *N*- into *p*-chloroacetanilide in the presence of (1) hydrochloric acid-sodium chloride and (2) hydrochloric acid-perchloric acid mixtures has been measured over a wide concentration range.

In series (1) the specific rate bears no relation to the activities of the reactants, showing that the activity theory of reaction rate is only of very limited applicability to this reaction. Reaction mechanisms involving the formation of a charged complex, according to the views of Brönsted, also gave no agreement with the experimental data. In mixtures of series (2) the specific rate is proportional to the molal concentrations of hydrogen and of chlorine ions.

In conclusion, the author wishes to express his thanks to Professor H. M. Dawson for the facilities that made the work possible, and for his interest in it during its course.

# XXI.--The Unsaturation and Tautomeric Mobility of Heterocyclic Compounds. Part I. Benzthiazole and Dihydrobenzthiazole Derivatives.

By ROBERT FERGUS HUNTER.

THE objects of this series of investigations are: to study the chemistry of the azole bromides, to compare the mobility of symmetrical and unsymmetrical semicyclic triad systems, and to correlate the additive properties of such heterocyclic derivatives with their behaviour as tautomeric substances.

Benzthiazole was chosen as the starting point of the investigation. According to the conditions of bromination it gave rise either to a well-defined *dibromide* or to an unstable *tetrabromide*, to which the formulæ (I) and (II) respectively are assigned on the following grounds.

(i) The colour, thermal dissociation, and the ease with which the compounds regenerate the original base on treatment with sulphurous acid, hydriodic acid, ammonia, and similar reagents show that they are additive compounds. (ii) The inability of thiophen to give rise to anything in the nature of an additive complex with bromine under the mildest conditions, the existence of pyridine tetrabromide (Trowbridge, *J. Amer. Chem. Soc.*, 1897, **19**, 558), and the preparation of quinoline tetrabromide (Grimaux, *Bull. Soc. chim.*, 1882, **38**, 124) in a condition of reasonable purity (p. 132) indicate that the nuclear nitrogen atom is the seat of unsaturation in the thiazole ring.

Regarding the electronic formulation of such compounds, it is suggested, since the fifth nitrogen valency is always an electrovalency, that the labile bromine atoms in the dibromide (I) are held by the nuclear nitrogen atom by means of semipolar single bonds, after the manner in which the labile chlorine atoms in phosphorus pentachloride are supposed to be held by the phosphorus atom (Prideaux, *Chem. and Ind.*, 1923, **42**, 672; Ingold and Ingold, *J.*, 1926, 1315; Sugden, *J.*, 1927, 1176). On such a basis, the elimination of  $\text{Br}_2$  in preference to  $\text{Br}^-$  ion from the higher compounds and the facility with which many of the compounds, such as 1-amino-benzthiazole dibromide, pass into the hydrobromides of the corresponding 5-bromo-substituted bases (reversion to ammonium-ion structure) are readily accounted for. The inhibitory effect of the nitro-group on the formation of such compounds (Hunter, *J.*, 1926, 538) also becomes explicable, since the positive end of the semi-

polar double bond,  $\bar{O}=\ddot{N}\cdot\overset{+}{C}$ , would tend to attract electrons from all parts of the molecule.

The formation of a tetrabromide (II) by a repetition of the process of singlet sharing is not difficult to visualise, but there is, however, the possibility that the second pair of labile electrons of the nuclear sulphur atom which are not required for the formation of the sextuple group (III) (Armit and Robinson, J., 1925, **127**, 1605; Goss and Ingold, J., 1928, 1268) might become sufficiently activated, under certain conditions, to give rise to a tetrabromide of the type (IV). On the other hand, the inability of stable tetrabromides, such as 1-phenylbenzthiazole tetrabromide, to yield sulphoxides of the type (V) is strong evidence in favour of the formula (II).

The bromides of benzthiazole present a direct anomaly to all the other compounds of the series in their conversion into a *tetrabromobenzthiazole* under the influence of hydroxylic solvents.

The lack of reactivity of the halogen atoms in this tetrabromocompound in contrast to the behaviour of 1-chlorobenzthiazole towards hydroxylic and reducing agents (Hofmann, *Ber.*, 1879, **12**, 1126; 1880, **13**, 11) appears sufficient evidence for assigning the formula (VI) to the compound. The formation of a similar compound by quinoline (Claus and Istel, *Ber.*, 1882, **15**, 820) emphasises the close relationship existing between benzthiazole and quinoline derivatives.

The tautomeric mobility and the behaviour towards bromine of benzthiazole derivatives containing the triad systems  $[H]N\cdot C:N \rightleftharpoons N:C[N]H$ ,  $[H]N\cdot C:O \rightleftharpoons N:C[O]H$ , and  $[H]N\cdot C:S \rightleftharpoons N:C[S]H$  were next studied.

*1-Aminobenzthiazole*.—The mobility of the symmetrical triad system in 1-aminobenzthiazole has already been established by evidence of the symmetry and substitution type (Hunter, J., 1926, 1385; Hunter and Styles, J., 1928, 3019).

On treatment with a molecular equivalent of bromine at a low temperature, 1-aminobenzthiazole yielded a labile *dibromide* (VII), which, on exposure to air, or when the temperature of the solution

was allowed to rise, was quantitatively converted into the *hydrobromide* of 5-bromo-1-aminobenzthiazole (VIII).

The facility with which the transformation takes place suggests that the mechanism may involve a para-bridged form of 1-aminobenzthiazole, analogous to the formula which Shearer (*Proc. Physical Soc.*, 1923, **35**, ii, 81) has suggested for naphthalene on the basis of X-ray analysis (compare Hunter, J., 1926, 1390; Ingold, J., 1923, **123**, 2081).

In the presence of excess of bromine, 1-aminobenzthiazole gave rise to an unstable *tetrabromide*, which resembled the dibromide in the ease with which it was converted into 5-bromo-1-aminobenzthiazole hydrobromide.

In the course of these experiments, the bromination of phenylthiocarbamide in chloroform was reinvestigated. The "dibromide of 1-aminobenzthiazole" obtained in this reaction (Hunter, J., 1926, 1389) and described by Huguershoff (*Ber.*, 1901, **34**, 3130) as a bromocarbaminophenylbromoaminodisulphide is actually a *hydrodibromide* of 1-aminobenzthiazole, which can readily be obtained from solutions of the hydrobromide of the amino-base and bromine in inert solvents.

The constitution of this hydrodibromide is a question of considerable importance. In the first place, it is desired to emphasise that the substance is a definite compound and that it is not a eutectic mixture of the hydrobromide of 1-aminobenzthiazole and a hypothetical hydrotribromide. It crystallises from solutions of different concentrations of the components (above a certain minimum concentration of bromine) in inert solvents, and all attempts to prepare the hypothetical hydrotribromide by employing a considerable excess of bromine have failed. Moreover, the remarkable stability of the substance (p. 134) does not appear to be capable of interpretation on the basis of the "physical mixture" type of explanation. It is therefore suggested that the compound may have a structure of the type  $(\text{Base}, \text{H})^+\text{Br}_2^-$ , containing the hitherto unknown  $\text{Br}_2^-$  ion, and involving the operation of a lone singlet linkage.\*

\* Similar corrections must be applied to all the even-numbered bromides obtained from arylthiocarbamides described in earlier papers (Hunter, J., 1925, **127**, 2023, 2270; 1926, 1385, 1401, 2951; Hunter and Soyka, *ibid.*, p. 2958; Dyson, Hunter, and Soyka, *ibid.*, p. 2964; Dyson, Hunter, and

*Mobility and Bromination of 1-Hydroxybenzthiazole.*—The mobility of 1-hydroxybenzthiazole was investigated in a manner similar to that of 1-aminobenzthiazole (*loc. cit.*). 1-Hydroxybenzthiazole (XI), prepared by hydrolysis of 1-chlorobenzthiazole (Hofmann, *Ber.*, 1879, 12, 1126) (IX), was shown to be identical with the ketodihydrobenzthiazole (XII) obtained by treating *o*-aminophenylmercaptan with carbonyl chloride. The low-melting ketodihydrobenzthiazole described by Claasz (*Ber.*, 1912, 45, 1029; compare also Mills and Whitworth, *J.*, 1927, 2752) was shown to be impure 1-hydroxybenzthiazole.

On methylation with methyl sulphate in the presence of potassium hydroxide, however, 1-hydroxybenzthiazole yielded exclusively 1-keto-2-methyl-1 : 2-dihydrobenzthiazole (Besthorn, *Ber.*, 1910, 43, 1523), no trace of the isomeric *O*-methyl derivative being isolable.

On bromination in chloroform at a low temperature, 1-hydroxybenzthiazole yielded a highly unstable bromo-addition compound which immediately lost hydrogen bromide with the production of 5-bromo-1-hydroxybenzthiazole (XVI), whose constitution was established by its synthesis from *p*-bromophenylthiourethane (XIII) by

Morris, *J.*, 1927, 1186; Hunter and Styles, *ibid.*, p. 1209; *J.*, 1928, 3019; Hunter and Pride, *J.*, 1929, 943). These compounds are all *hydroperbromides* and are quite distinct from the *true* bromides obtained from the bases themselves, from which they frequently differ in composition only by a hydrogen atom which cannot be detected by analysis. The formula (I) assigned to Huguershoff's 1-anilinobenzthiazole tetrabromide (*Ber.*, 1903, 36, 3121) and to similar compounds (Hunter, *J.*, 1925, 127, 2024) is incorrect. The supposed bimeric tribromides (II) (*loc. cit.*) are hydrotribromides of the type (Base, H)  $\overset{+}{Br_3} \overset{-}{Br_3}$ .

Similar remarks apply to the supposed hexabromides (*J.*, 1925, 127, 2024, 2270, etc.).

The increase of stability in a homologous series of 1-alkylaminobenzthiazole bromides (*J.*, 1926, 2951) can no longer be regarded as due to an enhancement of tautomeric equilibrium in favour of the alkylamino-phase with increase in the atomic volume of the alkyl group.

way of 5-bromo-1-ethoxybenzthiazole (XIV), and also by its formation in the hydrolysis of 1-chloro-5-bromobenzthiazole (XV).

*Mobility and Bromination of 1-Thiolbenzthiazole.*—1-Thio-1:2-dihydrobenzthiazole (XVIII) obtained from thiocarbonyl chloride and *o*-aminophenylmercaptan proved to be identical with 1-thiolbenzthiazole (XVII), prepared from carbon disulphide and *o*-aminophenylmercaptan, whose identity with the mercaptan obtained from 1-chlorobenzthiazole and potassium hydrosulphide was established by Hofmann in 1887 (*Ber.*, 20, 1788) (XVII and XVIII are XI and XII respectively with S in place of O).

Methylation of 1-thiolbenzthiazole, however, yielded the *S*-methyl derivative (XIX), unaccompanied by the isomeric thiomethyldihydrobenzthiazole (XX).

Bromination of 1-thiolbenzthiazole gave rise to a tetrabromo-addition compound, which yielded solely benzthiazolyl 1:1-disulphide on reduction with sulphurous acid.

*Bromination of 1-Phenylbenzthiazole, -selenazole, and -oxazole.*

The bromination of 1-phenylbenzthiazole and of its selenium analogue gave rise to closely similar tetrabromides\* (compare Fromm and Martin, *Annalen*, 1913, 401, 178).

On the other hand, 1-phenylbenzoxazole yielded an unstable hexabromide, which rapidly lost bromine, giving a stable hydrotribromide of 5(?) -bromo-1-phenylbenzoxazole.

*1:2-Dihydrobenzthiazole Derivatives.*—Reduction of the double

\* Some years ago, 1-phenylbenzthiazole tetrabromide was accidentally isolated in two forms, m. p. 126° and 153° respectively (*J.*, 1926, 538). We have been unable to repeat this observation, using pure phenylbenzthiazole, only one tetrabromide (m. p. 134—136°) being isolated. Since benzthiazole prepared by Mohlau's method (*Ber.*, 1888, 21, 59) and not specially purified (p. 131) yields a bromo-addition compound quite distinct from the dibromide and the tetrabromide obtained from the pure base, the original observation was probably due to the presence of an impurity introduced in the thionation process which was used in preparing the original specimen of phenylbenzthiazole from benzylideneaniline.

bond (1 : 2) of benzthiazole would be expected to lead to a decrease in the aromatic characteristics of the heterocyclic nucleus, and the bromination of certain 2-alkyl-1 : 2-dihydrobenzthiazoles was therefore undertaken.

The 1-imino-2-alkyl-1 : 2-dihydrobenzthiazoles (XXI) passed directly into the *hydrotribromides* of the corresponding 5-bromo-derivatives on bromination under the usual conditions. On the other hand, the 1-keto-2-alkyl-1 : 2-dihydrobenzthiazoles (XXII) yielded unstable *tetrabromides*, which were rapidly converted into the corresponding 5-bromo-1-keto-derivatives by loss of bromine and hydrogen bromide.

The order of stability of the bromo-addition compounds is therefore the reverse of that observed in the case of the mobile 1-amino- and 1-hydroxy-benzthiazoles.

1-Thio-2-methyl-1 : 2-dihydrobenzthiazole (XX) yielded a *tetra-bromide*, which regenerated the original thioketone on reduction, and could not be converted into a bromo-substitution derivative.

Regarding the Hugershoff reaction, *as*-phenylmethylthiocarbamide gave rise to an unstable *hydropentabromide* of 1-imino-2-methyl-1 : 2-dihydrobenzthiazole, which lost bromine on exposure to air, giving a *hydrodibromide*. The ethyl homologue, however, yielded a stable *hydrotribromide*, which is of interest on account of its behaviour on nitration.

Under conditions of mononitration, the hydrotribromide yielded, approximately in the proportion of 2 : 5, 5-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole (XXIII) and a bromonitro-derivative, which was also obtained from the mononitration of 5-bromo-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole and its *hydrotribromide* and is presumably 5-bromo-3-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole (XXIV).

Nitration of the *hydrobromide* of 1-imino-2-ethyl-1 : 2-dihydrobenzthiazole under similar conditions also gave rise to the same products in the approximate proportion of 2 : 1 in favour of the 5-nitro-1-imino-derivative.

The first action of nitric acid (*d* 1.5) is evidently one of decomposition, possibly with the production of nitrosyl bromide, which may act as a brominating agent on the portion of the base initially escaping nitration.

Mononitration of 1-imino-2-ethyl-1:2-dihydrobenzthiazole and its *acetyl* derivative lead to exclusive nitration in the 5-position of the benzthiazole system, and 1-keto-2-ethyl-1:2-dihydrobenzthiazole behaves similarly.

The 5-bromo and 5-nitro-derivatives described in this paper were oriented by means of the following scheme [the constitution of 5-bromo-1-aminobenzthiazole (XXV) follows from its synthesis from *p*-bromophenylthiocarbamide (Hunter, J., 1926, 1397)].

## EXPERIMENTAL.

### *Benzthiazole Derivatives.*

Benzthiazole was prepared by the thionation of dimethylaniline (Mohlau, *Ber.*, 1888, **21**, 59), purified by means of the crystalline nitrate (Mills, J., 1922, **424**, 460), and redistilled over copper turnings. The pure base was a colourless, highly refractive oil, indistinguishable from quinoline in odour, b. p. 227—228°/765 mm.,  $d_{20}^{25}$  1.244. Specimens (b. p. 226—228°) of the base which had not been redistilled over copper, when kept for some months, darkened and acquired the unpleasant odour of the crude thionation product. Such specimens behaved abnormally on bromination (p. 132).

*Benzthiazole Dibromide.*—(i) A solution of the pure base (1.1 c.c.) in chloroform (12 c.c.) was treated at 0—3° with bromine (0.7 c.c. in 2 c.c. of chloroform). After a short time, the *dibromide* crystallised in glistening yellow needles, which were collected on porous earthenware and dried in a vacuum; m. p. 88—90° (decomp.) [Found: N, 4.9; Br (total), 54.5; Br (labile), iodometrically in chloroform containing a few drops of purified acetic acid, 54.4; S, 10.9.  $\text{C}_7\text{H}_5\text{NBr}_2\text{S}$  requires N, 4.7; Br (total and labile), 54.3; S, 10.8%].

(ii) The compound was prepared in a similar manner from benzthiazole (1.2 g.), glacial acetic acid (7 c.c.), and a solution of bromine

(0.7 c.c.) in acetic acid (1 c.c.); m. p. 87—88° (decomp.) [Found: Br (total), 54.1; Br (labile), 54.0%].

The yellow crystals of the dibromide were stable in a vacuum, but rapidly reddened at the edges in moist air. The compound was quantitatively reduced by sulphurous acid, giving a colourless solution from which the original base was recovered by basification and extraction with ether; a similar decomposition, accompanied by evolution of nitrogen, took place when the dibromide was treated with aqueous ammonia (*d* 0.880). It was also decomposed by sulphuric acid at a low temperature (0—3°; 20 c.c. of 99% acid per g. of dibromide) with evolution of hydrogen bromide and regeneration of benzthiazole. *Thermal decomposition.* The dibromide was heated from 60° to 140°/18 mm. in the course of 10 minutes: fusion commenced at 100—105° and was complete at 115°. Reduction of the product by sulphurous acid yielded benzthiazole unaccompanied by the tetrabromo-substitution derivative.

*Benzthiazole Tetrabromide.*—Experiment (i) was repeated, 1.8 c.c. of bromine being used. A *tetrabromide* separated in small scarlet crystals, which were dried on porous earthenware in a vacuum for 5—10 minutes and then analysed; m. p. 67—68° (Found: Br, 70.0.  $C_7H_5NBr_4S$  requires Br, 70.3%). This compound decomposed appreciably on being exposed to the atmosphere for a few minutes; in its reactions, it behaved similarly to the dibromide.\*

When an experiment similar to (i) was performed with benzthiazole which had not been purified by redistillation over copper and had been kept for some months (2 g. of base, 24 c.c. of chloroform, and 1.3 c.c. of bromine), orange crystals of a *bromo-addition* compound separated, which had m. p. 100—103° (decomp.) after drying in a vacuum [Found: Br (total), 63.2; Br (labile), 63.0.  $(C_7H_5NBr_3S)_2$  requires Br, 64.0%]. The substance dissolved in sulphurous acid, yielding a colourless solution from which, on basification and extraction with ether, benzthiazole was obtained; this was identified by its properties and by the analysis of its chloroplatinite (Found: Pt, 28.5. Calc.: Pt, 29.1%).

*3:4:5:6-Tetrabromobenzthiazole.*—When solutions of any of the preceding bromo-addition compounds in 70% alcohol were boiled for a short time and allowed to cool, the *tetrabromobenzthiazole* crystallised in glistening hair-like needles, m. p. 122° (Found: Br, 70.9; S, 6.9.  $C_7HNBr_4S$  requires Br, 70.9; S, 7.1%). This com-

\* Quinoline tetrabromide (Grimaux, *loc. cit.*) was best prepared by treating a solution of quinoline (1 c.c.) in chloroform (12 c.c.) at 25—30° with bromine (2 c.c. in 3 c.c. of chloroform) and shaking the mixture: the temperature rose some 10° and the tetrabromide crystallised in glistening red plates, m. p. 95—97° [Found: Br (total), 70.4; Br (labile), 69.2. Calc.: Br, 71.3%].

pound was recovered unchanged after being heated under reflux in alcoholic solution containing about 10% of hydrochloric acid for 40 hours; and also after being heated (0.5 g.) with tin (1 g.) and concentrated hydrochloric acid (20 c.c.) for  $\frac{1}{2}$  hour. An attempt to reduce it (0.5 g.) in absolute alcohol (20 c.c.) with sodium (0.4 g.) also proved unsuccessful. The tetrabromobenzthiazole has no basic properties in the ordinary sense; although it dissolves in 98–99% sulphuric acid, it is reprecipitated by dilution with water. All attempts to prepare a bromo-addition compound of the tetrabromobenzthiazole proved unsuccessful.

*1-Aminobenzthiazole Dibromide*.—When a solution of 1.5 g. of 1-aminobenzthiazole in 50 c.c. of chloroform at 0° was gradually treated with a solution of bromine (0.7 c.c.) in the same solvent (3 c.c.), a yellow precipitate was produced which redissolved, giving a clear solution; the *dibromide* then separated in small, soft, orange-pink crystals, which were rapidly dried in a vacuum. This compound became pale yellow at 160–170° and had m. p. 265° (decomp.) (Found: Br, 51.8.  $C_7H_6N_2Br_2S$  requires Br, 51.5%).

A solution of the compound in purified acetic acid liberated iodine from potassium iodide, but the iodometric titre was always low (ca. 30%) on account of partial isomerisation into the hydrobromide of 5-bromo-1-aminobenzthiazole.

The dibromide was converted into 5-bromo-1-aminobenzthiazole hydrobromide by exposure to air; the change, which was accompanied by loss of colour, was appreciable in  $\frac{1}{4}$  hour and complete in less than 20 hours. The product was identified by its m. p. (265°), by the m. p. of the base liberated by alkali (210°), and by the m. p. of the acetyl derivative of the latter (222°). The dibromide was also isomerised by cold acetic anhydride.

*1-Aminobenzthiazole tetrabromide*, obtained by employing an excess of bromine, formed small, soft, dark reddish-brown plates, m. p. 266° (decomp.; sintering with loss of bromine at 170°) (Found: Br, 67.6.  $C_7H_6N_2Br_4S$  requires Br, 68.1%).

*1-Aminobenzthiazole Hydrodibromide (Hugershoff's Dibromide)*.—(i) A suspension of 1.5 g. of finely ground phenylthiocarbamide in 15 c.c. of chloroform was rapidly treated with bromine (1.4 c.c. in 1.4 c.c. of chloroform), and the mixture heated under reflux for 2–3 minutes. The *hydrodibromide* separated from the hot solution in glistening, orange-coloured, rhombic crystals, which were crushed on porous earthenware and dried in a vacuum; m. p. 127–128° (decomp. with efferv. at 131°) [Found: Br (total), 51.4; Br (labile), 24.9; S, 10.3.  $C_7H_6N_2S \cdot HBr(Br)$  requires Br (total), 51.5; Br (labile), 25.6; S, 10.3%].

(ii) Bromine (1.6 c.c.) was added to a boiling solution of 1-amino-

benzthiazole (1 g.) in glacial acetic acid (24 c.c.) containing 4 g. of hydrogen bromide. The hydrodibromide crystallised in large orange-red prisms, m. p. 128—130° after drying in a vacuum [Found: Br (total), 51.2; Br (labile), 24.6; S, 10.6%]. A mixture of the two specimens melted at 128—130°.

This compound remained unchanged in a vacuum, or over potassium hydroxide in a desiccator. On prolonged exposure to the atmosphere (8—9 months), it lost bromine, yielding 1-aminobenzthiazole hydrobromide, m. p. 231—232°.

When the compound (3 g.) was heated with acetic anhydride (7 c.c.), the solution developed a pink colour and a white precipitate (2.2 g.) separated, containing impure 5-bromo-1-acetamidobenzthiazole (0.25 g.), which was identified by mixed m. p. and by hydrolysis to 5-bromo-1-aminobenzthiazole by 60% sulphuric acid, and 1-aminobenzthiazole hydrobromide (1.8 g.).

*Thermal decomposition.* A flask containing the hydrodibromide (1.7 g.) was exhausted to 11 mm., placed in an oil-bath at 125°, and heated to 210° in the course of  $\frac{1}{4}$  hour; decomposition was then complete. The greyish-white granular residue (1.25 g.) consisted of 1-aminobenzthiazole hydrobromide, m. p. 228°. *Dissociation experiments.* (i) Three experiments were made with specimens of the hydrodibromide of different surface areas: the specimens were heated at 90—100°/10 mm. for 10 minutes, and the residues analysed for labile bromine. The results [Found: Br (labile), 20.8, 19.6, 19.9%] indicate that this factor has only a slight effect on the dissociation. (ii) Two similar experiments were performed at 97—98°/12 mm. for 2 minutes [Found: Br (labile), 24.1, 23.8%]. The degree of dissociation in these circumstances is about 5%.

*1-Anilino benzthiazole Tetrabromide.*—Hugershoff's tetrabromide (Ber., 1903, 36, 3121) crystallised in red needles, m. p. 127° (decomp.) (previously given, J., 1925, 127, 2025, as 117°) [Found: Br (total), 58.8; Br (labile), 40.1. Calc. for  $C_{13}H_{10}N_2S_2HBr(Br_3)$ : Br (total), 58.6; Br (labile), 43.9%]. The *hydrotribromide* had m. p. 130° (decomp.) (previously given as 125°) [Found: Br (total), 51.5; Br (labile), 32.5. Calc. for  $C_{13}H_{10}N_2S_2HBr(Br_2)$ : Br (total), 51.7; Br (labile), 34.4%]. The *hydrotetrabromide* was also prepared from a solution of the anilino-base (0.5 g.) and hydrogen bromide (0.5 g.) in glacial acetic acid (5.5 c.c.) and bromine (0.5 c.c.), and identified by m. p., mixed m. p., and analysis [Found: Br (total), 58.4; Br (labile), 39.8%].

*1-p-Toluidino-5-methylbenzthiazole hydrotetrabromide*, prepared from *s-di-p-tolylthiocarbamide* (J., 1925, 127, 2027), formed red needles, m. p. 130—132° (decomp.) (previously given as 145°) [Found:

Br (total), 55.2; Br (labile), 36.6. Calc. for  $C_{15}H_{14}N_2S, HBr(Br_3)$ : Br (total), 55.6; Br (labile), 41.7%. Its composition was not appreciably affected by keeping over potassium hydroxide in a desiccator for 2 days [Found: Br (labile), 36.4%]. It was also prepared from the toluidinobenzthiazole and hydrogen bromide in acetic acid and excess of bromine, and identified by m. p., mixed m. p., and analysis [Found: Br (labile), 36.4%]. The *hydrotribromide* had m. p. 145–147° (previously given as 148°) [Found: Br (total), 48.8; Br (labile), 31.5. Calc. for  $C_{15}H_{14}N_2S, HBr(Br_2)$ : Br (total), 48.5; Br (labile), 32.3%]. 3:2'-Dibromo-1-anilino-5:4'-dimethylbenzthiazole, prepared by heating a mixture of *s*-di-*o*-bromo-*p*-tolylthiocarbamide (0.5 g.), chloroform (6 c.c.), and bromine (0.6 c.c.) under reflux for 15 minutes and reducing the product with sulphurous acid, separated from alcohol in small prisms, m. p. 159–160°, which did not depress the m. p. of a specimen of the dibromotoluidinobenzthiazole described in 1925 (J., 127, 2027).

5:4'-Dibromo-1-anilino-3:2'-dimethylbenzthiazole.—(i) The dibromo-base obtained from the hydrohexabromide of 1-*o*-toluidino-3-methylbenzthiazole (J., 1925, 127, 2026) separated from alcohol-ethyl acetate in small needles, m. p. 210–211° (Found: Br, 38.6. Calc.: Br, 38.9%).

(ii) The *bromo*-addition compound obtained by heating a mixture of *s*-di-*p*-bromo-*o*-tolylthiocarbamide (1 g.), chloroform (17 c.c.), and bromine (1.3 c.c.) under reflux for 15 minutes formed dark crimson crystals, which became colourless at 180–190° and charred at 270° (Found: Br, 60.0.  $C_{15}H_{12}N_2Br_2S, HBr(Br_2)$  requires Br, 61.3%). 5:4'-Dibromo-1-anilino-3:2'-dimethylbenzthiazole obtained by reduction of this bromo-addition compound proved identical with that described under (i).

*The Mobility of 1-Hydroxybenzthiazole. Synthesis from 1-Chlorobenzthiazole and from o-Aminophenylmercaptan and Carbonyl Chloride.*

—(i) 1-Hydroxybenzthiazole was prepared by heating an alcoholic solution of 1-chlorobenzthiazole containing hydrochloric acid for 25 hours; on recrystallisation from alcohol, it formed glistening prisms, m. p. 138°.

(ii) *Claasz's experiment.* 25 G. of a 12% solution of carbonyl chloride in toluene were added to an ethereal solution of *o*-aminophenylmercaptan (2.5 g. in 40 c.c.) and the mixed liquids were decanted from the precipitate of *o*-aminophenylmercaptan hydrochloride and evaporated on a steam-bath. Extraction of the resulting oil with alkali, acidification of the extract, extraction with chloroform, and recrystallisation of the product from methyl alcohol yielded 1-hydroxybenzthiazole, which melted at 128–130° and at 134° when mixed with a genuine specimen prepared by Hofmann's

method. The identity was confirmed by conversion of the product into 5-bromo-1-hydroxybenzthiazole, identical with that prepared by other methods.

(iii) A solution of *o*-aminophenylmercaptan (1.2 c.c.) in chloroform (10 c.c.) was treated with carbonyl chloride from a cylinder for  $\frac{1}{2}$  hour, the mixture evaporated on a steam-bath, and the product extracted with ether. After removal of the ether, the crystalline residue separated from methyl alcohol in prisms (0.9 g.), m. p.  $135^{\circ}$ , and  $135\text{--}136^{\circ}$  when mixed with the specimen prepared under (i).

*Methylation of 1-Hydroxybenzthiazole and the Isolation of 1-Keto-2-methyl-1:2-dihydrobenzthiazole.*—1-Hydroxybenzthiazole was recovered unchanged after it had been heated with methyl sulphate (1.5 c.c. for 1 g.) at  $100^{\circ}$  for  $\frac{1}{2}$  hour, the solution diluted with water (8 c.c.), and the heating continued for another hour.

4 C.c. of methyl sulphate were added to a mixture of 0.5 g. of 1-hydroxybenzthiazole and 1 c.c. of chloroform in 10 c.c. of 25% potassium hydroxide solution and the whole was shaken and kept for an hour. Extraction with chloroform and slow removal of the solvent yielded a gum which set to a crystalline mass of 1-keto-2-methyl-1:2-dihydrobenzthiazole, m. p.  $74^{\circ}$ , and  $76^{\circ}$  when mixed with an authentic specimen prepared from the 1-nitrosoimino-derivative (Besthorn, *Ber.*, 1910, 43, 1523). The identity was further established by conversion of the product into 5-bromo-1-keto-2-methyl-1:2-dihydrobenzthiazole, which melted at  $126\text{--}127^{\circ}$  alone and when mixed with the specimen described on p. 140.

*Bromination of 1-Hydroxybenzthiazole and the Synthesis of 5-Bromo-1-hydroxybenzthiazole from 1-Chloro-5-bromobenzthiazole and from p-Bromophenylthiourethane by Way of 5-Bromo-1-ethoxybenzthiazole.*—(i) When a solution of 0.5 g. of 1-hydroxybenzthiazole in chloroform (6 c.c.) was treated with 0.5 c.c. of bromine at  $0\text{--}3^{\circ}$ , hydrogen bromide was evolved; the solution was concentrated under reduced pressure at laboratory temperature, and 5-bromo-1-hydroxybenzthiazole obtained. On recrystallisation from methyl alcohol, this formed needles, m. p.  $225\text{--}226^{\circ}$  (Found: Br, 35.1.  $\text{C}_7\text{H}_4\text{ONBrS}$  requires Br, 34.8%). It dissolved in alkalis and was reprecipitated by mineral acids. It was recovered unchanged after being heated with methyl iodide (more than 3 equivs.) at  $100^{\circ}$  for 25 hours.

(ii) 0.5 G. of 1-chloro-5-bromobenzthiazole (b. p.  $158\text{--}159^{\circ}/18$  mm.; Dyson, Hunter, and Soyka, *J.*, 1929, 461) was heated with alcohol, containing hydrochloric acid, for 40–45 hours. The resulting solution was made alkaline, filtered, and acidified with 20% acetic acid. The precipitate of 5-bromo-1-hydroxybenzthiazole was recrystallised from alcohol and identified by m. p. and mixed m. p. determination with the specimen prepared in (i).

(iii) *p*-Bromophenylthiourethane, prepared in 80–90% yield by heating a solution of *p*-bromophenylthiocarbimide (15 g.) in absolute alcohol (100 c.c.) under reflux for 30 hours, separated from methyl alcohol in prisms, m. p. 106–107° (Found: S, 12.5.  $C_9H_{10}ONBrS$  requires S, 12.3%).

5-Bromo-1-ethoxybenzthiazole. 10 G. of *p*-bromophenylthiourethane, previously ground with a little alcohol, were dissolved in 75 c.c. of 30% aqueous sodium hydroxide; the solution was diluted to 200 c.c. with water and added in 20 c.c. portions at 5-minute intervals to a well-stirred solution of potassium ferricyanide (60 g.) in water (300 c.c.) which was maintained at 80–90°. Extraction with ether yielded a brown oil, which was distilled in steam; the bromoethoxybenzthiazole obtained (yield, 35%) separated from 90% methyl alcohol in pale yellow plates, m. p. 75–76° (Found: Br, 31.4.  $C_9H_8ONBrS$  requires Br, 31.0%). *Hydrolysis*. A solution of the bromoethoxythiazole in 40% hydrobromic acid was heated under reflux for 20 minutes and cooled; crystals then separated. The mixture was diluted with water and extracted with chloroform and the chloroform was removed on a steam-bath; the 5-bromo-1-hydroxybenzthiazole obtained crystallised from methyl alcohol in needles, m. p. 222–223°, 223° when mixed with the specimen prepared in (i).

*The Mobility of 1-Thiolbenzthiazole. Synthesis by Hofmann's Method and from o-Aminophenylmercaptan and Thiocarbonyl Chloride*.—(i) 1-Thiolbenzthiazole was prepared by heating a solution of *o*-aminophenylmercaptan (3 g.) in alcohol (10 c.c.) and carbon disulphide (15 c.c.) under reflux for 8 hours. After two recrystallisations from methyl alcohol (animal charcoal), it formed colourless needles, m. p. 179° (Hofmann, *Ber.*, 1887, 20, 1879; Jacobson and Frankenbacher, *Ber.*, 1891, 24, 1403, recorded m. p. 174°).

(ii) Thiocarbonyl chloride (1 c.c.) in chloroform (2 c.c.) was gradually added to *o*-aminophenylmercaptan (2 c.c.) in chloroform (10 c.c.) at 5°, the mixture being shaken after each addition. A vigorous reaction took place with the separation of yellow crystals; the chloroform and the excess of thiocarbonyl chloride were removed on a steam-bath, the product was extracted with ether (8 extractions), and the united extracts were filtered from the hydrochloride of *o*-aminophenylmercaptan. On removal of the ether and subsequent recrystallisation from methyl alcohol, 1-thiolbenzthiazole (0.7 g.) was obtained in pale yellow needles, m. p. 176–177°, and 177–179° when mixed with the specimen prepared by Hofmann's method.

*Methylation*. A mixture of 1-thiolbenzthiazole (1 g.), methyl sulphate (3 c.c.), and methyl alcohol (3 c.c.) was heated under reflux

for an hour. The solution was cooled, the excess of methyl sulphate decomposed with aqueous ammonia ( $d$  0.880), and the mixture extracted while still warm with chloroform. A clear gum was obtained which on crystallisation from methyl alcohol yielded 0.9—1 g. of 1-methylthiolbenzthiazole in colourless prisms, *m. p.* 47—49°.

*Bromination of 1-Thiolbenzthiazole.*—A solution of the thiol (1 g.) in chloroform (50 c.c.) was treated with bromine (1.5 c.c. in an equal volume of the same solvent) at 10°; the *tetrabromide* formed orange plates, *m. p.* 147° (decomp. with efferv. after previous shrinking) (Found: Br, 65.6.  $C_7H_5NBr_4S_2$  requires Br, 65.7%). On reduction with sulphurous acid, the tetrabromide yielded benzthiazolyl 1 : 1-disulphide, which crystallised from acetic acid in silvery plates, *m. p.* 180°, and 180—181° when mixed with a genuine specimen. (A mixture of this product with 1-thiolbenzthiazole melted at about 140°.)

*1-Phenylbenzthiazole Tetrabromide.*—1 G. of the base, purified by distillation under reduced pressure, was brominated as previously described (Hunter, J., 1926, 539); the *tetrabromide* crystallised in orange-red plates, *m. p.* 134—136° [Found: Br (total), 60.0; Br (labile), 45.3. Calc. for  $C_{13}H_9NBr_4S$ : Br, 60.25%]. Further crops of crystals, *m. p.* 130—132°, of the same tetrabromide were obtained from the mother-liquor by concentration under reduced pressure at laboratory temperature [Found: Br (labile), 45.0%].

*Action of mercuric oxide.* (i) When a mixture of precipitated mercuric oxide (1 g.) and the tetrabromide (0.6 g.) in chloroform (50 c.c.) was shaken, the colour was discharged. Evaporation of the filtered solution on a steam-bath yielded 1-phenylbenzthiazole unaccompanied by any trace of the 5-bromo-derivative (Bogert and Abrahamson, *J. Amer. Chem. Soc.*, 1922, 44, 826).

(ii) A similar result was obtained with "dry" materials, excepting that the discharge of colour was somewhat retarded.

By treating a solution of 1-phenylbenzthiazole (1 g.) in chloroform (11 c.c.) with bromine (1.4 c.c.) at 0°, a red oil was obtained which sometimes crystallised in red needles; the *hexabromide* was unstable, *m. p.* 156° (decomp. with efferv. after sintering with loss of bromine over a range of about 40°) (Found: Br, 67.2.  $C_{13}H_9NBr_6S$  requires Br, 69.5%).

#### *Benzoxazole and Benzselenazole Derivatives.*

*Bromination of 1-Phenylbenzoxazole.*—A solution of the phenylbenzoxazole (Ladenburg, *Ber.*, 1876, 9, 1524) (0.5 g.) in chloroform (4 c.c.) was treated with bromine (0.9 c.c. in 1 c.c. of chloroform) at 0°. After an hour, the *hexabromo*-addition compound separated in small, soft, red crystals, *m. p.* 153—155° after rapid drying on

porous earthenware in a vacuum [Found: Br (total), 73.8; Br (labile), 54.9.  $C_{13}H_9ONBr_6$  requires Br, 71.1%]. This substance lost bromine when kept over potassium hydroxide in a vacuum for 2 hours, giving a stable, yellow, microcrystalline *hydrotribromide* of 5(?)-bromo-1-phenylbenzoxazole, m. p. 154—155° (with previous shrinking) [Found: Br (total), 61.8; Br (labile), 31.5.  $C_{13}H_8ONBr, HBr(Br_2)$  requires Br (total), 62.1; Br (labile), 31.1%]. A specimen of this compound prepared from the bromo-substituted benzoxazole, hydrogen bromide, and bromine in acetic acid had a higher m. p. (164—166° after previous shrinking) [Found: Br (labile), 31.3%], but lacked the stability in moist air of the specimen obtained from the hexabromide.

5(?) - *Bromo-1-phenylbenzoxazole*, obtained by reduction of the hydrotribromide with sulphurous acid, or by dissolution of the hexabromide in alcohol, crystallised from methyl alcohol in small needles, m. p. 106—107° (Found: Br, 28.3.  $C_{13}H_8ONBr$  requires Br, 29.1%).

1-*Phenylbenzselenazole tetrabromide*, obtained from the selenazole, chloroform, and excess of bromine at 0°, and also at 18°, crystallised in orange-red needles, m. p. 148° [Found: Br (total), 55.1; Br (labile), 41.0.  $C_{13}H_9NBr_4Se$  requires Br, 55.4%]. It regenerated the original phenylselenazole on treatment with sulphurous acid, but all attempts to prepare a 5-bromo-substitution derivative led only to brown gummy products, which could not be crystallised.

### 1 : 2-Dihydrobenzthiazole Derivatives.

1-*Imino-2-methyl-1 : 2-dihydrobenzthiazole Hydropentabromide*.—A solution of *as*-phenylmethylthiocarbamide (1 g.) in chloroform (10 c.c.) was treated with bromine (2 c.c. in 3 c.c. of the same solvent) and heated under reflux for a few minutes. The *hydropentabromide* crystallised in red plates (or needles), m. p. 121—122° (decomp. with efferv.), which were rapidly dried in a vacuum and immediately analysed [Found: N, 5.25; Br (total), 71.0; Br (labile), 57.0; S, 5.7.  $C_8H_8N_2S, HBr(Br_4)$  requires N, 4.95; Br (total), 70.8; Br (labile), 56.7; S, 5.6%]. On exposure to air for some weeks, it lost bromine, giving a stable, yellow, insoluble *hydrodibromide*, m. p. 194—196° (decomp.; sintering at 190°) [Found: Br, 49.3.  $C_8H_8N_2S, HBr(Br)$  requires Br, 49.4%]. Both compounds yielded 1-imino-2-methyl-1 : 2-dihydrobenzthiazole, m. p. 123°, on reduction with sulphurous acid, but failed to undergo nuclear substitution when heated with alcohol, giving the *hydrobromide* of 1-imino-2-methyl-1 : 2-dihydrobenzthiazole (prepared also from the base and hydrogen bromide) in small needles, m. p. 275° (decomp.) (Found: Br, 32.5.  $C_8H_8N_2S, HBr$  requires Br, 32.8%). The hydropenta-

bromide was also prepared by treating a solution of the hydrobromide in glacial acetic acid with excess of bromine.

*1-Acetimido-2-methyl-1:2-dihydrobenzthiazole*, prepared by acetylation of the imino-base with acetic anhydride, crystallised from alcohol in needles, m. p. 141—142° (Found: S, 15.8.  $C_{10}H_{10}ON_2S$  requires S, 15.5%).

*Bromination of 1-Imino-2-methyl-1:2-dihydrobenzthiazole*.—The *hydrotribromide* of 5-bromo-1-imino-2-methyl-1:2-dihydrobenzthiazole, obtained by treatment of the imino-base (0.5 g.) in chloroform (15 c.c.) with bromine (1 c.c. in 2 c.c. of the same solvent) at 0°, formed orange-yellow crystals which lost bromine at 100—110° and were unmelted at 280° [Found: N, 5.8; Br (total), 66.2; Br (labile), in acetic acid, 33.4; S, 6.6.  $C_8H_7N_2BrS \cdot HBr(Br_2)$  requires N, 5.8; Br (total), 66.1; Br (labile), 33.0; S, 6.6%]. The *hydrobromide* of 5-bromo-1-imino-2-methyl-1:2-dihydrobenzthiazole, obtained by boiling a solution of the hydrotribromide in alcohol, formed small needles, which were unmelted at 290° [Found: Br, 49.3.  $C_8H_7N_2BrS \cdot HBr$  requires Br, 49.3%]. The *5-bromo-base* crystallised with difficulty from methyl alcohol in needles, m. p. 110° (Found: N, 11.8; Br, 32.9; S, 13.4.  $C_8H_7N_2BrS$  requires N, 11.5; Br, 32.7; S, 13.2%). The *acetyl* derivative, prepared by means of acetic anhydride, crystallised from much ethyl acetate in feathery needles, m. p. 219—220° (Found: N, 9.8; Br, 28.2.  $C_{10}H_9ON_2BrS$  requires N, 9.8; Br, 28.05%).

*Bromination of 1-Keto-2-methyl-1:2-dihydrobenzthiazole and the Synthesis of 5-Bromo-1-keto-2-methyl-1:2-dihydrobenzthiazole from 5-Bromo-1-imino-2-methyl-1:2-dihydrobenzthiazole by Way of 5-Bromo-1-nitrosoimino-2-methyl-1:2-dihydrobenzthiazole*.—When a solution of 1-keto-2-methyl-1:2-dihydrobenzthiazole (0.4 g.) in chloroform (4 c.c.) was treated with bromine (0.5 c.c. in 1 c.c. of chloroform) at 0°, traces of hydrogen bromide were evolved and a dark purple-brown *tetrabromide* separated, which was rapidly dried in a vacuum and immediately analysed (Found: Br, 67.8.  $C_8H_7ONBr_4S$  requires Br, 65.9%). It softened at 100° and melted to a clear red liquid at 120°; in a vacuum, it lost bromine, yielding red crystals, m. p. 101—103°, of a substance having the composition of a *dibromide* (Found: Br, 48.6.  $C_8H_7ONBr_2S$  requires Br, 49.2%). *5-Bromo-1-keto-2-methyl-1:2-dihydrobenzthiazole* crystallised in feathery tufts of silky needles, m. p. 126—127° (Found: N, 5.9; Br, 32.5; S, 13.2.  $C_8H_6ONBrS$  requires N, 5.7; Br, 32.6; S, 13.1%).

*5-Bromo-1-nitrosoimino-2-methyl-1:2-dihydrobenzthiazole*.—A solution of 5-bromo-1-imino-2-methyl-1:2-dihydrobenzthiazole (2 g.) in glacial acetic acid (16 c.c.) was kept at 15° during the addition

of a solution of sodium nitrite (1 g.) in water (5 c.c.), the mixture being well shaken; the *nitroso*-derivative soon separated in orange crystals (2.1 g.), which exploded at  $161^{\circ}$  (Found: N, 15.5.  $C_8H_6ON_3BrS$  requires N, 15.4%).

A solution of the nitroso-compound (1 g.) in xylene (6 c.c.), when heated, turned yellow and nitrogen was evolved; the solution was concentrated to about 2 c.c., diluted with methyl alcohol, boiled with animal charcoal, filtered, and concentrated; 5-bromo-1-keto-2-methyl-1:2-dihydrobenzthiazole (0.8 g.) was obtained in slender needles, m. p.  $126-127^{\circ}$ , alone and when mixed with the specimen already described.

1-Thiol-2-methyl-1:2-dihydrobenzthiazole tetrabromide, prepared from the thiol derivative and bromine in chloroform, formed small orange crystals, m. p.  $124-126^{\circ}$  (decomp.; reddening at  $115-120^{\circ}$ ) (Found: Br, 63.7; S, 12.6.  $C_8H_7NBr_4S_2$  requires Br, 63.9; S, 12.8%). When heated with absolute alcohol, it rapidly regenerated the original thiol derivative.

The bromination of 1-nitrosoimino-2-methyl-1:2-dihydrobenzthiazole yielded a brown tetrabromide, m. p.  $280^{\circ}$  (decomp.) (Found: Br, 61.9.  $C_8H_7ON_3Br_4S$  requires Br, 62.4%).

1-Imino-2-ethyl-1:2-dihydrobenzthiazole is conveniently prepared in quantity by the following method, which is generally applicable to iminoalkyldihydrobenzthiazoles and alkylaminobenzthiazoles. A solution of *as*-phenylethylthiocarbamide (50 g.) in chloroform (250 c.c.) was treated with bromine (30 c.c. in 50 c.c. of the same solvent) with cooling. After being heated under reflux for 10 minutes, the mixture was treated with excess of sulphurous acid and basified, and the product obtained by removal of the chloroform was recrystallised from alcohol, the iminoethyldihydro-derivative forming large crystals, m. p.  $84-85^{\circ}$ . Yield, 49 g. (98%).

1-Imino-2-ethyl-1:2-dihydrobenzthiazole hydrotribromide, prepared from 1.5 g. of the ethylthiocarbamide in chloroform (12 c.c.) and bromine (2 c.c.), crystallised from the hot solution in orange-red plates, m. p.  $160-161^{\circ}$  (decomp.) [Found: N, 6.9; Br (total), 57.5; Br (labile), 38.5.  $C_9H_{10}N_2S_3HBr(Br_2)$  requires N, 6.7; Br (total), 57.3; Br (labile), 38.2%]. It was also prepared from the imino-base (0.5 g.) and hydrogen bromide (1 g.) in glacial acetic acid (9 c.c.) and bromine (1 c.c.). The alleged tetrabromide previously described (J., 1926, 1394) was a "wet" specimen of the hydrotribromide. An alcoholic solution of this compound, on being concentrated, yielded the *hydrobromide* of 1-imino-2-ethyl-1:2-dihydrobenzthiazole (which was also prepared from the base and hydrobromic acid) in plates, m. p.  $247-248^{\circ}$  (decomp.) (Found:

Br, 30.5.  $C_9H_{10}N_2S.HBr$  requires Br, 30.9%). 1-Acetimido-2-ethyl-1:2-dihydrobenzthiazole formed prisms, m. p. 127—128° (Found: N, 13.0; S, 14.6.  $C_{11}H_{12}ON_2S$  requires N, 12.7; S, 14.55%).

*Bromination of 1-Imino-2-ethyl-1:2-dihydrobenzthiazole and the Ethylation of 5-Bromo-1-aminobenzthiazole.*—(i) The hydrotribromide of 5-bromo-1-imino-2-ethyl-1:2-dihydrobenzthiazole, obtained by bromination of the imino-base, crystallised in orange needles, m. p. 182—184° (decomp.) [Found: Br (total), 64.2; Br (labile), iodometrically in acetic acid, 32.6.  $C_9H_9N_2BrS.HBr(Br_2)$  requires Br (total), 64.2; Br (labile), 32.1%]. It was also prepared from the 5-bromo-base, hydrogen bromide, and bromine in acetic acid. Attempts to isolate an intermediate bromo-addition compound of the iminoethyl base by using dried materials were unsuccessful. The hydrotribromide was completely dissociated into the hydrobromide and bromine on being heated from 150° to 220°/16 mm. in the course of  $\frac{1}{2}$  hour. 5-Bromo-1-imino-2-ethyl-1:2-dihydrobenzthiazole formed a tenacious gum, which crystallised with difficulty from 80% methyl alcohol in small needles, m. p. 68—70° (Found: Br, 30.7.  $C_9H_9N_2BrS$  requires Br, 31.1%). The acetyl derivative formed silvery needles, m. p. 187° (Found: Br, 26.7; S, 10.7.  $C_{11}H_{11}ON_2BrS$  requires Br, 26.7; S, 10.7%). The hydrobromide crystallised from alcohol, containing a small quantity of hydrogen bromide, in small needles, m. p. 270—272° (Found: Br, 47.0.  $C_9H_9N_2BrS.HBr$  requires Br, 47.3%).

(ii) A mixture of 5-bromo-1-aminobenzthiazole (0.5 g.) and ethyl iodide (1.5 c.c.) was heated at 100° for 18 hours, and the product basified and extracted with chloroform. After removal of the chloroform a gum remained which could not be crystallised. On acetylation, 5-bromo-1-acetimido-2-ethyl-1:2-dihydrobenzthiazole was obtained unaccompanied by other products; it was identified by m. p. and mixed m. p. determination. No trace of the isomeric 5-bromo-1-ethylaminobenzthiazole, m. p. 158° (previously misrecorded by Hunter and Soyka, J., 1926, 2962, as 256°), could be detected.

*Nitration of 1-Imino-2-ethyl-1:2-dihydrobenzthiazole and the Orientation of 5-Nitro-1-imino-2-ethyl-1:2-dihydrobenzthiazole.*—(i) 10 G. of the imino-base were added to 50 c.c. of nitric acid ( $d$  1.5) at 8° in the course of 40 minutes, the temperature not being allowed to rise above 10°. The solution was poured into 400 c.c. of water, the precipitated nitrate [small orange-pink crystals, m. p. 210—212° (decomp.), from alcohol] decomposed with 25% aqueous sodium hydroxide, and the nitro-base recrystallised from alcohol (yield, 9 g.). A further quantity (0.5—1 g.) was obtained by

basifying the filtrate from the nitrate and extracting it with chloroform. 5-Nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole forms small orange-yellow needles, m. p. 139—140° (Found : N, 19.3; S, 14.4.  $C_9H_9O_2N_3S$  requires N, 18.9; S, 14.4%). The acetyl derivative crystallised from much ethyl acetate in soft, pale yellow needles, m. p. 242—243° (Found : N, 16.2; S, 12.2.  $C_{11}H_{11}O_3N_3S$  requires N, 16.0; S, 12.1%).

(ii) *Methylation of 5-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole.* 6 C.c. of methyl sulphate were added to a suspension of 5 g. of the 5-nitro-1-imino-base in water (100 c.c.) and the mixture was boiled for 40 minutes and then basified with warm 20% sodium hydroxide solution. On recrystallisation from alcohol and thereafter from methyl alcohol, 1 g. of 5-nitro-1-methylimino-2-ethyl-1 : 2-dihydrobenzthiazole was obtained (m. p. 140°, depressed to 115—118° by admixture with 5-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole), which yielded the pure compound (see below) on further recrystallisation.

(iii) *Methylation of 1-imino-2-ethyl-1 : 2-dihydrobenzthiazole and nitration of 1-methylimino-2-ethyl-1 : 2-dihydrobenzthiazole.* A mixture of 20 g. of 1-imino-2-ethyl-1 : 2-dihydrobenzthiazole, 100 c.c. of water, and 22 c.c. of methyl sulphate was boiled under reflux for 1½ hours. The product was made strongly alkaline with potassium hydroxide, boiled, and extracted with chloroform, and the chloroform removed through a fractionating column. The residual 1-methylimino-2-ethyl-1 : 2-dihydrobenzthiazole, a viscous oil which could not be crystallised, was added drop by drop with continuous shaking to 100 c.c. of nitric acid ( $d$  1.5) at  $-2^\circ$  in the course of an hour, the temperature not being allowed to rise above  $7^\circ$ . The nitration mixture was poured into water (1000 c.c.) and basified; the nitro-base (23—24 g.), recrystallised from alcohol-ethyl acetate and thereafter from methyl alcohol (animal charcoal), formed yellow plates (10 g.), m. p. 154° (Found : N, 18.0; S, 13.6.  $C_{10}H_{11}O_2N_3S$  requires N, 17.7; S, 13.5%).

(iv) *5-Amino-1-methylimino-2-ethyl-1 : 2-dihydrobenzthiazole.* The 5-nitro-compound (7 g.) was heated with tin (14 g.) and concentrated hydrochloric acid (100 c.c.) on a steam-bath for 20 minutes, and the mixture was diluted with 150 c.c. of water, filtered, and made strongly alkaline with 30% potassium hydroxide solution. The 5-amino-base, which was isolated by extraction with chloroform, crystallised from methyl alcohol in small plates (3.5—4 g.), m. p. 124—125° (Found : S, 15.2.  $C_9H_{11}N_3S$  requires S, 15.5%). It dissolved in concentrated hydrochloric acid, giving a pink solution which became pale yellow and finally colourless on dilution with water; on diazotisation, it yielded a diazonium chloride which

coupled with alkaline  $\beta$ -naphthol, giving a red azo-dye. The amino-base slowly darkened and after some weeks the m. p. was  $115^{\circ}$ .

(v) *5-Bromo-1-methylimino-2-ethyl-1:2-dihydrobenzthiazole*. (A) A diazotised solution of the 5-amino-base (2.4 g.) in 20% hydrochloric acid (9 c.c.) was added to a cuprous bromide solution (prepared from 4.5 g. of copper sulphate crystals) at  $0^{\circ}$ . The mixture was heated on a steam-bath for  $\frac{1}{4}$  hour and basified; the black oil obtained, isolated by means of chloroform, yielded yellowish needles of *5-bromo-1-methylimino-2-ethyl-1:2-dihydrobenzthiazole*, m. p.  $89^{\circ}$ , on crystallisation from methyl alcohol (animal charcoal) (Found: Br, 29.05.  $C_{10}H_{11}N_2BrS$  requires Br, 29.1%). Yield, 60–70%. (B) A cleaner product was obtained by Gattermann's method. 0.8 G. of the amino-base was dissolved in 6 c.c. of hydrobromic acid ( $d$  1.45) and water (3 c.c.) and diazotised; finely divided copper (prepared from 0.6 g. of zinc dust and 1.8 g. of copper sulphate crystals) having been added, the mixture was heated on a steam-bath for 10 minutes, diluted with 20 c.c. of water, basified, and extracted with chloroform. The 5-bromo-base obtained on recrystallisation from methyl alcohol was identical with that prepared in (A) and (C). (C) A mixture of 5-bromo-1-imino-2-ethyl-1:2-dihydrobenzthiazole (1 g.), water (10 c.c.), and methyl sulphate (1.5 c.c.) was heated under reflux for  $\frac{1}{2}$  hour, boiled with excess of 30% alkali solution, and extracted with chloroform. The oil obtained from the extract was dissolved in absolute methyl alcohol; when the solution was concentrated under reduced pressure at laboratory temperature, the methyl derivative sometimes crystallised in colourless needles which alone and when mixed with the specimens synthesised from 5-amino-1-methylimino-2-ethyl-1:2-dihydrobenzthiazole, melted at  $88$ – $89^{\circ}$  (Found: Br, 29.1%).

*Dinitration of 1-Imino-2-ethyl-1:2-dihydrobenzthiazole*.—(i) The iminoethyl base (2 g.) was gradually added to 20 c.c. of nitric acid ( $d$  1.5), the temperature rising to  $55^{\circ}$ . The mixture was poured into 100 c.c. of water; the precipitated nitrate, decomposed with 20% potassium hydroxide solution, gave *dinitroiminoethyl-dihydrobenzthiazole*, which crystallised from methyl alcohol-ethyl acetate in golden plates, m. p.  $242$ – $244^{\circ}$  (Found: N, 21.2.  $C_9H_8O_4N_4S$  requires N, 20.9%). The alkaline liquid on acidification yielded a substance which separated from methyl alcohol-ethyl acetate in yellow-brown needles, m. p.  $200^{\circ}$ .

(ii) *5-Nitro-1-imino-2-ethyl-1:2-dihydrobenzthiazole* (0.5 g.) was gradually added to 10 c.c. of nitric acid ( $d$  1.5), the solution was warmed, diluted with water, and basified, and the dinitro-compound was recrystallised; it formed golden plates, m. p.  $242$ – $244^{\circ}$ , identical with the specimen already described.

1-Nitrosoimino-2-ethyl-1 : 2-dihydrobenzthiazole, prepared from 5 g. of iminoethyldihydrobenzthiazole in glacial acetic acid (35 c.c.) and sodium nitrite (2.6 g.) in water (13 c.c.), separated from alcohol in orange-red plates (4–4.5 g.), which exploded at 153° (Found : N, by slow combustion with twice the usual amount of fine CuO, 20.5; S, 15.2.  $C_9H_9ON_3S$  requires N, 20.3; S, 15.5%).

1-Keto-2-ethyl-1 : 2-dihydrobenzthiazole.—The nitrosoiminoethyldihydrobenzthiazole (3 g.) in xylene (20 c.c.) was heated until nitrogen was no longer evolved and the xylene was removed. The oily residue was distilled in steam, and the distillate extracted with chloroform; the ketoethyldihydrobenzthiazole was a colourless refractive oil (1.3 g.) which could not be crystallised (Found : S, 17.2.  $C_9H_9ONS$  requires S, 17.8%).

The tetrabromide, obtained as in the case of the methyl derivative, formed unstable purple-brown crystals, m. p. 80–82° (turning yellow at 60–70°) (Found : Br, 64.2.  $C_9H_9ONBr_4S$  requires Br, 64.1%). 5-Bromo-1-keto-2-ethyl-1 : 2-dihydrobenzthiazole crystallised from absolute methyl alcohol in needles, m. p. 96–97° (Found : N, 5.6; Br, 30.8; S, 12.8.  $C_9H_8ONBrS$  requires N, 5.4; Br, 31.0; S, 12.4%).

*Synthesis of 5-Bromo-1-keto-2-ethyl-1 : 2-dihydrobenzthiazole from 5-Bromo-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole by Way of 5-Bromo-1-nitrosoimino-2-ethyl-1 : 2-dihydrobenzthiazole.*—5-Bromo-1-nitrosoimino-2-ethyl-1 : 2-dihydrobenzthiazole crystallised in salmon-pink plates, which exploded at 157–158° on being fairly rapidly heated (Found : Br, 27.4; S, 11.4.  $C_9H_8ON_3BrS$  requires Br, 27.6; S, 11.2%). The residue obtained by evaporation of a solution of the nitroso-derivative (4 g.) in xylene (25 c.c.), on recrystallisation from alcohol (animal charcoal), yielded 2.8 g. of 5-bromo-1-keto-2-ethyl-1 : 2-dihydrobenzthiazole, identical with that obtained above from the tetrabromide.

5-Nitro-1-keto-2-ethyl-1 : 2-dihydrobenzthiazole.—(i) 5-Nitro-1-nitrosoimino-2-ethyl-1 : 2-dihydrobenzthiazole, prepared from 5-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole, formed soft salmon-pink crystals, which exploded at 154° (Found : S, 12.5.  $C_9H_8O_3N_4S$  requires S, 12.7%). 5-Nitro-1-keto-2-ethyl-1 : 2-dihydrobenzthiazole, obtained by heating the nitrosoimino-compound (1 g.) in xylene (5 c.c.), separated from hot benzene in tufts of yellow needles, m. p. 198° (Found : S, 14.4.  $C_9H_8O_3N_2S$  requires S, 14.3%).

(ii) The 5-nitro-1-keto-derivative was also obtained in 80–90% yield by adding the 1-keto-2-ethyldihydro-derivative to nitric acid (*d* 1.5) (10 vols.) at 0–5°.

1-Thiol-2-ethyl-1 : 2-dihydrobenzthiazole.—A finely powdered, intimate mixture of 1-nitrosoimino-2-ethyl-1 : 2-dihydrobenzthiazole

(3 g.) and phosphorus pentasulphide (Kahlbaum) (3 g.) was heated in an oil-bath at  $120^{\circ}$ , a violent reaction taking place. The product was twice extracted with 50 c.c. of boiling benzene; the united extracts were boiled with copper turnings and filtered. The gum obtained by removal of the benzene crystallised from methyl alcohol in yellow plates, m. p.  $75^{\circ}$  (Found: S, 32.9.  $C_9H_9NS_2$  requires S, 32.8%).

*Nitration of 1-Imino-2-ethyl-1:2-dihydrobenzthiazole Hydrotribromide.*—The hydrotribromide (7 g.) was added to 60 c.c. of nitric acid ( $d$  1.5) at  $3-6^{\circ}$  in the course of 20 minutes; the solution was decanted from the liquid bromine which separated and poured into 250 c.c. of water. The filtrate from the precipitated nitrate, on basification, extraction with chloroform, and recrystallisation of the product from methyl alcohol, yielded 0.8 g. of 5-nitro-1-imino-2-ethyl-1:2-dihydrobenzthiazole. The precipitated nitrate, on decomposition with 20% alkali solution, yielded 2 g. of 5-bromo-3-nitro-1-imino-2-ethyl-1:2-dihydrobenzthiazole, which was identified by its m. p. and mixed m. p. and by the m. p. and mixed m. p. of its acetyl derivative.

*Decomposition of 1-Imino-2-ethyl-1:2-dihydrobenzthiazole Hydrotribromide by Sulphuric Acid.*—3 G. of the hydrotribromide were gradually added to 25 c.c. of 99% sulphuric acid at  $0-2^{\circ}$ ; hydrogen bromide was evolved and liquid bromine separated. The solution was poured on ice (200 g.), the mixture basified and extracted with chloroform, and the gum obtained by removal of the chloroform was acetylated with acetic anhydride (7 c.c.) and alcohol (15 c.c.). Fractional crystallisation of the product yielded 0.5 g. of 1-acetimido-2-ethyl-1:2-dihydrobenzthiazole and 0.7 g. of 5-bromo-1-acetimido-2-ethyl-1:2-dihydrobenzthiazole, which were identified by m. p. and mixed m. p. determinations.

*Nitration of 1-Imino-2-ethyl-1:2-dihydrobenzthiazole Hydrobromide.*—4 G. of the hydrobromide were gradually added to 50 c.c. of nitric acid ( $d$  1.5) at  $3-7^{\circ}$ , and the solution poured into 200 c.c. of water. The mixture was cooled to  $20^{\circ}$ , and the precipitated nitrate collected; the filtrate, on basification and extraction with chloroform, yielded 2.2 g. of 5-nitro-1-imino-2-ethyl-1:2-dihydrobenzthiazole. On decomposition with 20% alkali solution, the nitrate yielded 1.3 g. of 5-bromo-3-nitro-1-imino-2-ethyl-1:2-dihydrobenzthiazole, which was identified as in the previous case.

*Nitration of 1-Acetimido-2-ethyl-1:2-dihydrobenzthiazole.*—4 G. of the acetyl derivative were gradually added to 40 c.c. of nitric acid ( $d$  1.5) at  $0-2^{\circ}$ ; the temperature was allowed to rise to  $15^{\circ}$ , the mixture poured into 250 c.c. of water, and the precipitated nitro-derivative collected and extracted with 35 c.c. of boiling alcohol.

The residue (2.1 g.) had m. p. 240—242° (241—242° when mixed with 5-nitro-1-acetimido-2-ethyl-1 : 2-dihydrobenzthiazole); the alcoholic extract on evaporation yielded a small quantity of what appeared to be impure nitrate of 5-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole. Basification of the original acid filtrate yielded a further 1.9—2 g. of the 5-nitro-1-acetyl derivative.

*Nitration of 5-Bromo-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole.*—This was carried out at 0—5° in the usual way. 5-Bromo-3-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole formed orange needles, m. p. 168—169° (Found: N, 14.0; Br, 26.3; S, 10.4.  $C_9H_8O_2N_3BrS$  requires N, 13.9; Br, 26.4; S, 10.6%). The acetyl derivative crystallised from alcohol-ethyl acetate in pale yellow needles, m. p. 252—253° (Found: Br, 23.1.  $C_{11}H_{10}O_3N_3BrS$  requires Br, 23.2%). The nitrate separated from alcohol in yellow needles, m. p. 230° (decomp.).

Nitration of 5-bromo-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole hydrotribromide yielded solely 5-bromo-3-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole.

*Nitration of 1-Imino-2-ethyl-1 : 2-dihydrobenzthiazole in Sulphuric Acid Solution.*—The nitration of 5 g. of the base in 20 c.c. of 99% sulphuric acid at 70° with a mixture of nitric acid (*d* 1.4) (4 c.c.) and sulphuric acid (5 c.c.) gave 3.7 g. of impure 5-nitro-1-imino-2-ethyl-1 : 2-dihydrobenzthiazole, accompanied by a small quantity of the dinitro-derivative.

The author wishes to express his gratitude to Professor J. F. Thorpe, F.R.S., for his kind interest in these experiments, to the Trustees of the Ramsay Memorial Fellowship Trust for the award of a Fellowship which enabled this work to be completed, and to the Trustees of the Dixon Fund of the University of London and to the Chemical Society for grants which have defrayed the cost of the materials.

## XXII.—*Nitration of 2'- and 4'-Nitro-1-phenyl-piperidines.*

By RAYMOND JAMES WOOD LE FÈVRE.

ORDINARY nitric acid (*d* 1.4) nitrates 4'-nitro-1-phenylpiperidine quantitatively in the 2'-position, but dissolves the 2'-nitro-isomeride unchanged. By the most extreme conditions of nitration under which the latter remains unaffected the former is destroyed.

Similar but less pronounced differences have been observed in the nitrations of 1 : 4-*di*(2'- and 4'-nitrophenyl)piperazines.

No such disparity is recorded in the literature concerning the conditions requisite for the production, by nitration of the corresponding mononitro-compounds with nitric acid of density not less than 1.42, of 2 : 4-dinitrodimethyl- or 2 : 4-dinitrodiethyl-aniline. An observation by Pinnow (*Ber.*, 1899, **32**, 1667), that dimethylaniline gave 95% of its weight of 2 : 4-dinitrodimethylaniline and 50% of its weight of 2-nitrodimethylaniline when treated with dilute sulphuric and nitric acids (see also Schuster and Pinnow, *Ber.*, 1896, **29**, 1053), would seem to indicate, however, that, of the initially formed *o*- and *p*-mononitro-compounds, only the latter underwent further nitration. Even were this so, the deductions from the present work would be unaffected, since the weakest nitrating acid used in the experiments on the nitrophenyl-piperidines was ordinary nitric acid (*d* 1.42). For comparison, it is now shown that the interaction of this reagent with 2-nitrodimethylaniline at room temperature leads to high yields of 2 : 4 : 6-trinitrophenylmethylnitroamine, and the observation of Weber (*Ber.*, 1877, **10**, 763), that by nitration of dimethylaniline with a solution of nitric acid in glacial acetic acid complete 2 : 4-dinitration is readily effected, has been verified experimentally.

Moreover, with regard to Pinnow's results, from general principles it would be expected that progressive dilution of the attacking reagent would render any slight difference in reactivity of two positions in a substituted benzene nucleus increasingly obvious, and the experiments of Clemo and Smith (*J.*, 1928, 2414) have shown that dilution of the nitrating acids with *water* is, in the case of certain dimethylanilines, a change of experimental conditions likely to lead to fundamentally different results.

The tendency of 2'- and 4'-nitro-1-phenylpiperidines to undergo salt formation is apparently strong; combination of either with mineral acid was violent (much more so than the analogous reactions with the nitrodimethylanilines) and each gave a stable *perchlorate*, *ferrichloride*, and *mercurichloride*.

An explanation of the present observations must therefore be sought in the relatively (to dialkyl) rigid structure of the piperidine ring, which, in the case, for example, of the *o*-nitro-compound, would more effectively (a) *spread* the area of direct influence of the

two positive charges  $\left[ \text{CH}_2 \begin{array}{c} \text{CH}_2 \cdot \text{CH}_2 \\ \text{CH}_2 \cdot \text{CH}_2 \end{array} \text{N}^+ \begin{array}{c} \text{R} \\ \text{NO}_2 \end{array} \right] \text{X} \text{ (I)}$  by its

spatial interactions with the bulky *o*-nitro-group and (b) prevent the nearer approach of the negative anion  $\bar{\text{X}}$  and consequent reduction

of the strong inductive and direct effects set up by the positive poles indicated in (I) (compare Pollard and Robinson, J., 1927, 2770).

#### EXPERIMENTAL.

*Action of Nitric Acid on 2'-Nitro-1-phenylpyperidine.*—(a) When the nitro-compound (2 g.) was added cautiously and in portions to 10 c.c. of fuming nitric acid at the ordinary temperature, it dissolved with a hissing noise (addition of too large a portion caused inflammation). After 5 minutes, dilution with water and basification with ammonia gave nearly 2 g. of a bright red solid, m. p. 76—77° (alone, or mixed with authentic 2'-nitro-1-phenylpyperidine). (b) The nitro-compound (2 g.), after being dissolved in 10 c.c. of sulphuric acid, treated with 10 c.c. of fuming nitric acid, and heated on the water-bath for 15 minutes, was largely recovered unchanged; considerable decomposition, however, occurred.

*Action of Nitric Acid on 4'-Nitro-1-phenylpyperidine.*—The nitro-compound gave an uncrystallisable red oil under conditions (a) and was destroyed under conditions (b). When a solution of the nitro-compound (2 g.) in ordinary nitric acid (*d* 1.4) at 0° was left for 1 minute, then diluted with water and made alkaline, an almost quantitative yield of 2':4'-dinitro-1-phenylpyperidine, m. p. 92°, was obtained.

*Preparation of 1:4-Di(2'- and 4'-nitrophenyl)piperazines.*—Equal weights of the appropriate chloronitrobenzene and piperazine hydrate were gently boiled together for 15 minutes. The product was extracted repeatedly with boiling alcohol, and the residue crystallised. 1:4-Di(2'-nitrophenyl)piperazine separated in orange plates, m. p. 193—194°, from much glacial acetic acid (Found: N, 17.2.  $C_{16}H_{16}O_4N_4$  requires N, 17.1%), and the corresponding 4'-nitro-compound as a microcrystalline red powder, m. p. 263—264°, from phenol-nitrobenzene although the crude substance was yellow (Found: N, 17.2%).

*Nitration of 1:4-Di(2'- and 4'-nitrophenyl)piperazines.*—1 G. of each compound was dissolved in separate equal large volumes of hot acetic acid and 5 c.c. of nitric acid (*d* 1.5) were added. The production of 1:4-di(2':4':6'-trinitrophenyl)piperazine (Le Fèvre and Turner, J., 1927, 113) from the former compound was complete after the mixture had been kept at the ordinary temperature for 12 hours; in the case of the 4'-nitro-compound, 10 minutes were sufficient.

*Action of Nitric Acid on 2-Nitrodimethylaniline.*—This substance was prepared in good yield by 8 hours' boiling of a mixture of *o*-chloronitrobenzene (15 g.), 30% dimethylamine solution (35 g.), and sufficient alcohol to produce a homogeneous solution. The

product, after dilution with water, was extracted with benzene, and the extract washed with water and finally with dilute sulphuric acid. The acid solution was basified and again shaken with benzene. 2-Nitrodimethylaniline distilled at 145—155°/ca. 30 mm. as a clear red oil.

By addition of 1 g. to 15 c.c. of nitric acid ( $d$  1.42) at the ordinary temperature, followed after 15 minutes' solution by precipitation by dilution with water, a cream-coloured crystalline product was obtained, brief treatment of which with hot aqueous-alcoholic ammonia gave picramide, m. p. 188—189° (alone or mixed with an authentic specimen). Crystallisation of the nitration products from alcohol afforded cream plates, m. p. 131° (alone or mixed with authentic 2 : 4 : 6-trinitrophenylmethylnitroamine). Since 2 : 4-dinitrodimethylaniline is undoubtedly a precursor of "tetryl" in its direct formation from dimethylaniline, it is obvious that the 4-mononitration of 2-nitrodimethylaniline is a readily effected process and that 2-nitrodimethylaniline differs markedly from 2'-nitro-1-phenylpyperidine in this respect.

*Dinitration of Dimethylaniline.*—Dimethylaniline (12 g.; 1 mol.), dissolved in glacial acetic acid (80 g.), was slowly treated at 0—5° with fuming nitric acid (15 g.; 2 mols.) diluted with an equal volume of acetic acid. The resulting mixture was left until its temperature had risen to 15°; it was then diluted with much water. The yellow crystalline precipitate obtained, after drying, had m. p. ca. 75° (after two crystallisations from carbon disulphide the m. p. was 78.5—79.5°) and its weight (19 g.) corresponded to a 90% yield of 2 : 4-dinitrodimethylaniline.

*Complex Salts from 2'- and 4'-Nitro-1-phenylpyperidines.*—The two nitro-compounds dissolved readily in concentrated hydrochloric acid. To the solutions, slightly diluted with water, concentrated ferric chloride solution was added slowly. After filtration and crystallisation from acetic acid, 2'-nitro-1-phenylpyperidinium ferrichloride, dark yellow needles, m. p. 147—148° (Found: N, 7.0.  $C_{11}H_{15}O_2N_2Cl_4Fe$  requires N, 6.9%), and 4'-nitro-1-phenylpyperidinium ferrichloride, straw-yellow needles, m. p. 130—135°, were obtained. No ferrichloride formation could be observed with 2' : 4'-dinitro-1-phenylpyperidine.

Addition of aqueous mercuric chloride to the above hydrochloric acid solutions gave the corresponding mercurichlorides, which formed cream-coloured plates, m. p. 170—175°, and bright yellow plates, m. p. 70—80°, respectively.

Addition of aqueous perchloric acid to mineral acid solutions of 2'-nitro-1-phenylpyperidine precipitated a white microcrystalline perchlorate which, after crystallisation from glacial acetic acid, had

m. p. 240—243° (decomp.) (Found : N, 9.3.  $C_{11}H_{15}O_6N_2Cl$  requires N, 9.15%). The corresponding 4'-nitro-1-phenylpiperidinium perchlorate was apparently soluble in water, since a hydrochloric acid solution of 4'-nitro-1-phenylpiperidine could, after addition of aqueous perchloric acid, be diluted with a large excess of water without any precipitation occurring.

### XXIII.—*Sugar Carbonates. Part IV. The Dicarbonates of Glucose, Fructose, Mannose, Galactose, and Arabinose.*

By WALTER NORMAN HAWORTH and CHARLES RAYMOND PORTER.

A SERIES of new crystalline derivatives of sugars has been prepared

containing two carbonate residues of the type  $\begin{array}{c} \text{CH}-\text{O} \\ | \quad \diagup \\ \text{CH}-\text{O} \end{array} \text{CO}.$

Hitherto the attempts to prepare these substances have led either to the introduction of only one such residue or to the formation of sugar carbonates containing also carbonic ester groups. The present results have been obtained by the condensation of various sugars with carbonyl chloride in pyridine solution. Accompanying the crystalline dicarbonate there is usually an amorphous by-product of higher molecular weight which appears to be a polysaccharide derivative. The latter reaction has not been studied in detail.

The dicarbonates of the sugars are well-defined and easily characterised products which resemble closely the diacetone derivatives of the sugars. For instance, they are hydrolysed by dilute acids to the parent sugars; this change, however, does not proceed nearly so readily as with the sugar-acetones. On the other hand, the sugar carbonates are instantly attacked by alkali even in the cold. It is these properties that suggested the utilisation of the dicarbonates in synthetic operations such as those recently described (J., 1929, 2796).

The specific rotations of the dicarbonates derived from glucose, fructose, and mannose are analogous to those of the corresponding diacetone derivatives, but arabinose dicarbonate,  $[\alpha]_{5780} + 61.3^\circ$ , and galactose dicarbonate,  $[\alpha]_{5780} - 86.5^\circ$ , have higher rotations than arabinose-diacetone and galactose-diacetone,  $[\alpha]_{5780} \pm 1^\circ$  and  $-56^\circ$  respectively (in aqueous acetone). These variations appear to be due to differences of conformation rather than of structure.

The constitutional formulæ suggested are indicated below and

are based on the similarity in properties to the diacetones, the constitutional formulæ of which have been elucidated.

Evidence of the constitution here assigned to mannose dicarbonate is furnished by the fact that this substance gives rise to a crystalline anilide and a crystalline methylmannoside dicarbonate which does not reduce Fehling's solution. This interesting mannoside will form the subject of a further communication.

The behaviour of the glucose dicarbonate, including its relationship to glucose-acetone carbonate (*loc. cit.*), provides support for the constitution which is here assigned.

#### EXPERIMENTAL.

*Glucose Dicarbonate.*—In the first attempts to condense carbonyl chloride with glucose the sugar was dissolved in pyridine, cooled in ice, and vigorously stirred while a 20% solution of carbonyl chloride in toluene was added drop by drop. The addition caused the precipitation of a yellow crystalline solid (possibly the addition compound of carbonyl chloride and pyridine), and the removal of the reagent in this form was probably the reason for the minute amount of sugar carbonate formed in this way.

In subsequent experiments gaseous carbonyl chloride, obtained from a cylinder of the compressed gas, was passed into the solution of the sugar in pyridine. At the end of the reaction the mixture was treated with ice, to decompose the carbonyl chloride-pyridine complex, and the liquid was filtered. When the reaction was arrested after about an hour, an almost clear solution was obtained, but if the reagents had been in contact for several hours, or if a very rapid current of carbonyl chloride had been passed, or the temperature allowed to rise, a considerable amount of an insoluble

amorphous condensation product (A) was formed, which was removed by filtration.

The aqueous filtrate contained pyridine, pyridine hydrochloride, glucose dicarbonate, and glucose. The pyridine and its hydrochloride were removed together by adding an excess of barium carbonate and evaporating the solution to a small bulk at 30—35° under reduced pressure. The glucose dicarbonate was sparingly soluble in water and was extracted with ethyl acetate in a mechanical extractor. Another and somewhat more rapid method of separating the sugar carbonate from the original mixture consisted in treatment of the latter with excess of barium carbonate and repeated extraction with ethyl acetate: the whole of the pyridine was thus removed, and with it the sugar carbonate, which was much more soluble in pyridine than in ethyl acetate. The latter solvent was eliminated by distillation at 40—50° under diminished pressure. The residual pyridine solution was evaporated at the ordinary temperature in a vacuum desiccator containing sulphuric acid. The residue was a viscid liquid or glassy solid, which became crystalline on trituration with alcohol. In this method, some unchanged glucose as well as the glucose carbonate was extracted by the pyridine.

In a typical preparation, carbonyl chloride was passed for 1 hour, from a delivery tube with a bell-shaped orifice in order to prevent stoppages, into an ice-cooled, vigorously stirred solution of 18 g. of glucose in about 50 c.c. of pyridine. The product was treated with ice-water, filtered, and extracted with ethyl acetate. During the extraction, sufficient barium carbonate was added to neutralise the hydrochloric acid liberated by the removal of pyridine from the solution of its hydrochloride. Evaporation of the solvents from this extract left a viscid mass which deposited crystals on treatment with alcohol. Further crops of crystals were deposited on concentration of the alcoholic solution, and finally a viscid residue remained which yielded no further crystalline material (yield, 1 g.).

An attempt was also made to prepare a glucose carbonate by passing carbonyl chloride into a thoroughly stirred, concentrated aqueous solution of glucose cooled in ice and salt. The hydrochloric acid and excess of carbonyl chloride were then removed by the addition of silver carbonate, and the solution was evaporated at a low temperature. The product crystallised and appeared to be mainly unchanged glucose; a very small amount of glucose carbonate was, however, detected.

The amorphous product A (see above) was insoluble in the usual organic solvents except pyridine, but was soluble in a mixture of acetone and water. It gave a precipitate of barium carbonate when warmed with barium hydroxide solution, and reduced Feh-

ling's solution. On treatment with dilute alkali it dissolved, a polysaccharide being probably formed.

*Glucose dicarbonate* is sparingly soluble in most solvents, the decreasing order of solubility being pyridine, acetone (about 1.5% in cold), ethyl acetate, alcohol (about 0.4% when boiling), water, and chloroform. It crystallises well from alcohol, being about four times as soluble in the hot as in the cold, yielding needles or lustrous flakes, m. p.  $224^{\circ}$  (efferv.; sintering at  $200^{\circ}$ ).

Glucose dicarbonate is hydrolysed rapidly by dilute alkalis, but is not readily decomposed by dilute acids in the cold. When it is warmed with aqueous barium hydroxide solution, a precipitate of barium carbonate is formed. The alkali present in Fehling's solution is sufficient to effect hydrolysis, followed by reduction. The dicarbonate has  $[\alpha]_D - 29^{\circ}$  ( $c = 1.0$  in acetone containing 25% of water). No change in this value was observed, even after the addition of a drop of aqueous hydrochloric acid (Found: C, 41.5; H, 3.6;  $\text{CO}_2$ , 37.5;  $M$ , ebullioscopic in acetone, 239.  $\text{C}_8\text{H}_8\text{O}_8$  requires C, 41.4; H, 3.5;  $\text{CO}_2$ , 37.9%;  $M$ , 232).

*Galactose Dicarbonate*.—This compound was prepared in the same manner as glucose dicarbonate. Several variations of the method of extraction were tried, but the process ultimately adopted for the glucose analogue was found to be the most effective.

In general, *galactose dicarbonate* is similar in its properties to glucose dicarbonate. It is, however, somewhat more soluble in water, from which it crystallises well in long needles, m. p.  $212^{\circ}$  (efferv.; slight sintering at  $190^{\circ}$ );  $[\alpha]_{D}^{21.3} - 86.5^{\circ}$  in acetone containing 25% of water ( $c = 0.6$ ). The addition of a trace of hydrochloric acid did not alter the rotation in 22 hours (Found: C, 41.7; H, 3.7.  $\text{C}_8\text{H}_8\text{O}_8$  requires C, 41.4; H, 3.5%).

*Mannose Dicarbonate*.—This preparation proceeded rather more readily than in the previous examples, and the product was more easily extracted.

In a typical preparation, 6 g. of mannose were dissolved in 20 c.c. of pyridine, the solution was cooled in an ice-bath and vigorously stirred, and a fairly rapid current of carbonyl chloride was passed for about  $\frac{3}{4}$  hour. Ice-water was then added, and 1.5 g. of an amorphous carbonate, probably a polysaccharide carbonate, were collected. The filtrate was treated with an excess of barium carbonate and evaporated to small bulk under diminished pressure at  $30-35^{\circ}$ . After removal of the pyridine by this process, the solution was filtered and extracted with ethyl acetate in the mechanical extractor. Yield, 0.5 g.

*Mannose dicarbonate* crystallised well from water in lustrous flakes or needles, m. p.  $122-123^{\circ}$  (efferv.; slight sintering at  $118^{\circ}$ ).

It gave a precipitate with barium hydroxide solution, and reduced Fehling's solution suddenly, on heating (Found: C, 41.4; H, 3.6;  $\text{CO}_2$ , 36.7.  $\text{C}_8\text{H}_8\text{O}_8$  requires C, 41.4; H, 3.5;  $\text{CO}_2$ , 37.9%).  $[\alpha]_{5780}^{25} + 26^\circ$ ;  $[\alpha]_{5461}^{21} + 28.5^\circ$  in dry acetone ( $c = 1.0$ ). The substance showed no appreciable mutarotation in this solvent even after the addition of a trace of hydrochloric acid.

The *anilide* of mannose dicarbonate was prepared by heating mannose dicarbonate and aniline (2 mols.) in alcoholic solution for 2 hours. The solution was then allowed to evaporate at the ordinary temperature. The residue, after being triturated with several solvents, crystallised from ethyl acetate, containing dry ether, in hard white prisms, m. p.  $174\text{--}175^\circ$ . The substance was sparingly soluble in alcohol or ethyl acetate and slowly became discoloured on exposure to the air.  $[\alpha]_{5780}^{30} - 70^\circ$  (after 5 minutes);  $-32^\circ$  (after 18 hours) in ethyl alcohol ( $c = 0.2$ );  $[\alpha]_D^{18} - 83^\circ$  in methyl alcohol ( $c = 0.1$ ) (Found: C, 54.85; H, 4.5; N, 4.65.  $\text{C}_{14}\text{H}_{13}\text{O}_7\text{N}$  requires C, 54.7; H, 4.25; N, 4.55%).

*Fructose Dicarbonate*.—Fructose (10 g.) was dissolved in 25 c.c. of pyridine and cooled in ice and vigorously stirred. A fairly rapid current of carbonyl chloride was admitted during  $\frac{3}{4}$  hour; ice-water was then added, and an amorphous fructose carbonate derivative removed by filtration. After addition of excess of barium carbonate, the filtrate was extracted with ethyl acetate, first by hand and then mechanically. The ethyl acetate was distilled at  $40\text{--}50^\circ$  under slightly reduced pressure and the pyridine was evaporated from the residue at the ordinary temperature in a vacuum desiccator containing sulphuric acid. When only a trace of pyridine remained, a little water was added, which caused the fructose dicarbonate to become crystalline (yield, 1 g.).

The aqueous solution remaining after the extraction with ethyl acetate was evaporated to dryness at  $30\text{--}35^\circ$ , and the finely powdered residue extracted repeatedly with boiling acetone in the hope of isolating an isomeric fructose dicarbonate. Only a small amount of a syrupy product was extracted and this yielded a further amount of the same fructose dicarbonate.

*Fructose dicarbonate* has solubilities intermediate between those of the corresponding derivatives of glucose and mannose, being quite easily soluble in acetone and alcohol. It crystallised well from water, separating in hard prisms if not quite pure, but when pure it was obtained in clusters of needles. It contained  $\frac{1}{2}$  mol. of water of crystallisation, which was not removed in a vacuum over sulphuric acid at the ordinary temperature, but was eliminated in a vacuum at  $90^\circ$ . M. p.  $173\text{--}174^\circ$ ; effervescence occurred at this temperature after a few seconds. The rotation was similar to that

of the  $\alpha$ -form of fructose diacetone, and mutarotation was not observed on the addition of a trace of hydrochloric acid.  $[\alpha]_{5780}^{16^\circ} - 143^\circ$  and  $[\alpha]_{5461}^{16^\circ} - 159^\circ$  (in 50% aqueous acetone,  $c = 1.14$ ) (Found: C, 40.1; H, 3.95;  $\text{CO}_2$ , 36.4;  $\text{H}_2\text{O}$ , 3.4.  $\text{C}_8\text{H}_8\text{O}_8 \cdot \frac{1}{2}\text{H}_2\text{O}$  requires C, 39.9; H, 3.75;  $\text{CO}_2$ , 36.5;  $\text{H}_2\text{O}$ , 3.7%).

The amorphous substance which was collected after the addition of ice-water to the pyridine solution in the above reaction appeared to be insoluble in most liquids except pyridine, but was soluble in acetone containing a little water. The acetone was allowed to evaporate from such a solution and the precipitated solid was removed. The aqueous filtrate left only a small amount of glassy residue on evaporation. The precipitated solid was washed with water and was then almost completely soluble in dry acetone. It was extracted with this solvent, and the solution allowed to evaporate; the vitreous residue became opaque on trituration with water. It reduced Fehling's solution, and gave a precipitate when warmed with barium hydroxide solution. The product decomposed without melting between  $150^\circ$  and  $180^\circ$ .  $[\alpha]_{5780}^{15^\circ} - 58^\circ$  ( $c = 1.29$  in acetone) (Found:  $\text{CO}_2$ , 37.7%;  $M$ , ebullioscopic in acetone, 780, 765). This molecular weight is intermediate between those required by three (660) and four (874) fructose dicarbonate residues joined by loss of water. The carbonate values required by these substances are 40.0 and 40.3% respectively.

A further attempt was made to separate the obviously complex mixture by fractional precipitation from acetone solution by the addition of ether. By this process four fractions were collected, the rotations of which did not vary greatly [(1)  $[\alpha]_{5780} - 64^\circ$ ; (2)  $[\alpha]_{5780} - 58.5^\circ$ ; (3)  $[\alpha]_{5780} - 63^\circ$ ; (4)  $[\alpha]_{5780} - 65^\circ$ ], and, although the solubilities of the fractions differed considerably, pure substances were not obtained. The examination of this mixture is therefore held over until larger quantities are available.

*Arabinose Dicarbonate.*—The reaction of arabinose with carbonyl chloride in pyridine did not proceed so quickly as was the case with the other sugars. The gas was passed for 2 hours into a cooled and vigorously stirred solution of 10 g. of arabinose in 30 c.c. of pyridine. The product was an extremely thick paste, and stirring was impracticable. Ice-water was added, and the clear solution extracted with ethyl acetate, barium carbonate being added to keep the solution neutral. After removal of the solvent from the extracts as in previous cases, a viscid syrup remained which deposited crystals on treatment with water. The filtrate from this solid deposited more crystalline material after being kept for some weeks (yield, 2 g.).

*Arabinose dicarbonate* is slightly soluble in chloroform, but rather more soluble in ethyl acetate, alcohol, water, and acetone. It

crystallises well from water (solubility in hot water, 1 part in 140 parts). It separated in short hard prisms when not quite pure, and in longer crystals when pure. M. p. 200—202° (efferv.). It gave a precipitate with barium hydroxide and reduced Fehling's solution.

When heated to 160° in a vacuum, this dicarbonate very slowly sublimes, and at a slightly higher temperature, *e.g.*, 180—190°, can be economically purified by this procedure. This behaviour is in marked contrast to that of the dicarbonates of the hexoses, which appeared to possess a negligible vapour pressure and decomposed on prolonged heating.

Arabinose dicarbonate did not exhibit mutarotation in aqueous acetone, even after the addition of a trace of hydrochloric acid.  $[\alpha]_{D}^{25} + 61.3^{\circ}$ ;  $[\alpha]_{D}^{25} + 66.0^{\circ}$  (in acetone containing 33% of water,  $c = 1.3$ ) (Found: C, 41.7; H, 3.1; CO<sub>2</sub>, 41.6. C<sub>7</sub>H<sub>8</sub>O<sub>7</sub> requires C, 41.6; H, 3.0; CO<sub>2</sub>, 43.5%).

The authors are grateful to the Government Grant Committee of the Royal Society for a contribution towards the cost of materials.

## XXIV.—*The Action of Bromine upon the p-Tolylhydrazones of Benzaldehyde and of the Nitrobenzaldehydes.*

By FREDERICK DANIEL CHATTAWAY and ARTHUR B. ADAMSON.

BROMINE reacts very readily with the *p*-tolylhydrazones of benzaldehyde and of the nitrobenzaldehydes.

When 2 mols. of bromine are allowed to act upon 1 mol. of any one of the hydrazones, one atom of bromine enters the *p*-tolyl nucleus in an *o*-position with respect to the nitrogen atom and a second the  $\omega$ -position.

The action of 1 mol. of bromine upon 1 mol. of hydrazone yields a mixture of the  $\omega\omega$ -dibromo-derivative and unchanged hydrazone.

The  $\omega\omega$ -dibromo-hydrazones are also obtained by the action of 1 mol. of bromine upon the hydrazones of 3-bromo-*p*-tolylhydrazine.

When a large excess of bromine is used, a third atom of bromine can be introduced into the remaining *o*-position in the *p*-tolyl nucleus. A larger excess of halogen is required to effect complete tribromination of benzaldehyde- and *p*-nitrobenzaldehyde-*p*-tolylhydrazones than of *m*-nitrobenzaldehyde-*p*-tolylhydrazone.

Compounds containing more than three atoms of bromine in the

molecule cannot be obtained by the direct bromination of these hydrazones.

The course of the reactions may be represented thus :

In these  $\omega$ -bromo-hydrazones the  $\omega$ -bromine atom is very reactive. When heated with sodium acetate and acetic acid, they are converted into the corresponding  $\beta$ -acetyl-hydrazides of benzoic or nitrobenzoic acid :

These hydrazides may be hydrolysed with aqueous-alcoholic hydrochloric acid, a substituted *p*-tolylhydrazine and an acid corresponding to the aldehyde forming the original hydrazone being produced. When only one *o*-bromine atom is present in the *p*-tolyl nucleus, the  $\beta$ -acetyl group of the hydrazide is removed by hydrolysis

but when both *o*-positions are occupied by bromine atoms, this acetyl group is protected and an  $\alpha$ -acetylated dibromo-*p*-tolylhydrazine is obtained :

The  $\omega$ -bromo-hydrazones are converted into the corresponding hydrazidines by the action of concentrated aqueous ammonia :

These are highly-coloured weak bases and form colourless crystalline hydrochlorides which are rather unstable and sparingly soluble in alcohol or dilute hydrochloric acid.

*o*-Nitrobenzaldehyde-*p*-tolylhydrazone does not behave in quite the same way as its isomerides, this hydrazone being rather less stable. When 2 mols. of bromine are used, an  $\omega$ -bromo-compound is obtained in the normal manner. A larger proportion of bromine has no further action at the ordinary temperature, but when the temper-

ature is allowed to rise, the hydrazone breaks down and the bright orange *perbromide* of 3 : 5-dibromo-*p*-toluidine is formed :

Although not produced by the direct bromination of *o*-nitrobenzaldehyde-*p*-tolylhydrazone,  $\omega$ -bromo-*o*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone is readily obtained by brominating *o*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone, the  $\omega$ -position being easily substituted.

The  $\omega$ -bromo-compounds derived from *o*-nitrobenzaldehyde-*p*-tolylhydrazone have different properties from those derived from other *p*-tolylhydrazones and readily lose hydrogen bromide, forming the violently explosive ketoendoaryliminodihydrobenzisodiazole oxides (I) (the so-called isodiazomethane derivatives) (J., 1925, 127, 2407).

This loss takes place even on cautious recrystallisation from alcohol. When boiled for several hours with alcohol, the explosive compounds lose one atom of oxygen and form ketoendoaryliminodihydrobenzisodiazole derivatives (II) (J., 1927, 323).

If bromination is carried out in the presence of sodium acetate, the formation of the  $\omega$ -bromo-compound and the elimination of hydrogen bromide from this take place successively and the explosive compound is obtained as the product of the one operation (J., 1925, 127, 2408).

When *o*-nitrobenzaldehyde-*p*-tolylhydrazone is brominated in the presence of sodium acetate, no substitution occurs in the *p*-tolyl nucleus at the ordinary temperature, even when excess of bromine is used, and consequently the explosive compound formed under these conditions contains no halogen.

#### EXPERIMENTAL.

$\omega$ -Bromo-*m*-nitrobenzaldehyde-3-bromo-*p*-tolylhydrazone.—To a suspension of 5 g. (1 mol.) of *m*-nitrobenzaldehyde-*p*-tolylhydrazone in 70 c.c. of acetic acid was slowly added a solution of 2.1 c.c. (2 mols.)

of bromine in 10 c.c. of acetic acid. The hydrazone dissolved, forming an orange solution from which  $\omega$ -bromo-*m*-nitrobenzaldehyde-3-bromo-*p*-tolylhydrazone separated as a bright yellow solid. After being washed with water, this crystallised from acetic acid, in which it was moderately easily soluble, in long, slender, bright yellow prisms, m. p.  $145.5^\circ$  (Found: Br, 39.1.  $C_{14}H_{11}O_2N_3Br_2$  requires Br, 38.7%).

$\omega$ -Bromo-*m*-nitrobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone.—A solution of 3.1 c.c. (3 mols.) of bromine in 10 c.c. of acetic acid was added to a suspension of 5 g. (1 mol.) of *m*-nitrobenzaldehyde-*p*-tolylhydrazone in 100 c.c. of the same solvent. The dibromo-compound separated as a bright yellow solid, which became paler as it was converted into the tribromo-compound. The mixture was heated on a water-bath to complete the reaction and cooled, and the solid collected.  $\omega$ -Bromo-*m*-nitrobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone crystallises from acetic acid, in which it is moderately easily soluble, in pale yellow prisms, m. p.  $154.5^\circ$  (Found: Br, 48.8.  $C_{14}H_{10}O_2N_3Br_3$  requires Br, 48.8%).

The same compound was easily prepared by the action of 1 mol. of bromine upon *m*-nitrobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone.

$\omega$ -Bromo-*p*-nitrobenzaldehyde-3-bromo-*p*-tolylhydrazone.—This was obtained in a similar manner by the action of 2.1 c.c. (2 mols.) of bromine upon 5 g. (1 mol.) of *p*-nitrobenzaldehyde-*p*-tolylhydrazone suspended in 100 c.c. of acetic acid. It crystallised from acetic acid, in which it was moderately easily soluble, as a felted mass of bright orange needles, m. p.  $176^\circ$  (Found: Br, 39.1.  $C_{14}H_{11}O_2N_3Br_2$  requires Br, 38.7%).

$\omega$ -Bromo-*p*-nitrobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone.—When 3 mols. of bromine were used to 1 mol. of *p*-nitrobenzaldehyde-*p*-tolylhydrazone, the product was almost exclusively  $\omega$ -bromo-*p*-nitrobenzaldehyde-3-bromo-*p*-tolylhydrazone. Not until 8 mols. of bromine were used was there any appreciable formation of the tribromo-compound and to ensure complete tribromination it was found advisable to use a still larger excess of bromine.

5 G. of *p*-nitrobenzaldehyde-*p*-tolylhydrazone (1 mol.) were suspended in 100 c.c. of acetic acid, and 10 c.c. (excess) of bromine added with vigorous shaking. The mixture was heated on a water-bath for 30 minutes to complete the reaction.  $\omega$ -Bromo-*p*-nitrobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone, which separated as an orange solid, crystallised from acetic acid, in which it was easily soluble, in long orange-yellow prisms, m. p.  $161^\circ$  (Found: Br, 48.7.  $C_{14}H_{10}O_2N_3Br_3$  requires Br, 48.8%).

$\omega$ -Bromobenzaldehyde-3-bromo-*p*-tolylhydrazone.—This was obtained

by the action of 2.5 c.c. (2 mols.) of bromine upon 5 g. (1 mol.) of benzaldehyde-*p*-tolylhydrazone suspended in 25 c.c. of acetic acid. It crystallised from hot alcohol, in which it was easily soluble, in long colourless needles, m. p. 74° (Found: Br, 43.8.  $C_{14}H_{12}N_2Br_2$  requires Br, 43.5%).

*ω*-Bromobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone.—This could be prepared from benzaldehyde-*p*-tolylhydrazone only by the use of a large excess of bromine. 10 C.c. of bromine were added to 5 g. of the hydrazone in 25 c.c. of acetic acid. The product crystallised from hot acetic acid, in which it was easily soluble, in long colourless needles, m. p. 106° (Found: Br, 53.8.  $C_{14}H_{11}N_2Br_3$  requires Br, 53.7%).

*m*-Nitrobenz-β-acetyl-3-bromo-*p*-tolylhydrazide,

was obtained as a white viscid solid which could not be made to crystallise. Its constitution was shown by hydrolysis with alcohol and hydrochloric acid; it then yielded acetic acid, *m*-nitrobenzoic acid, and 3-bromo-*p*-tolylhydrazine.

*m*-Nitrobenz-β-acetyl-3:5-dibromo-*p*-tolylhydrazide crystallised from alcohol in fine colourless prisms, m. p. 170° (Found: Br, 33.8.  $C_{16}H_{13}O_4N_3Br_2$  requires Br, 33.9%). On hydrolysis it yielded *m*-nitrobenzoic acid and α-acetyl-3:5-dibromo-*p*-tolylhydrazine. The latter was identified by conversion into its *m*-nitrobenzaldehydehydrazone, which crystallised from acetic acid in colourless shining plates, m. p. 218°, and was identical with the compound prepared by the action of acetic anhydride upon *m*-nitrobenzaldehyde-3:5-dibromo-*p*-tolylhydrazone.

*p*-Nitrobenz-β-acetyl-3-bromo-*p*-tolylhydrazide crystallised from alcohol in colourless prisms, m. p. 173° (Found: Br, 20.6.  $C_{16}H_{14}O_4N_3Br$  requires Br, 20.4%). On hydrolysis it yielded acetic acid, *p*-nitrobenzoic acid, and 3-bromo-*p*-tolylhydrazine.

*p*-Nitrobenz-β-acetyl-3:5-dibromo-*p*-tolylhydrazide crystallised from alcohol in colourless prisms, m. p. 183° (Found: Br, 33.7.  $C_{16}H_{13}O_4N_3Br_2$  requires Br, 33.9%). On hydrolysis it yielded *p*-nitrobenzoic acid and α-acetyl-3:5-dibromo-*p*-tolylhydrazine.

*Benz*-β-acetyl-3:5-dibromo-*p*-tolylhydrazide crystallised from alcohol in colourless prisms, m. p. 190° (Found: Br, 37.4.  $C_{16}H_{14}O_2N_2Br_2$  requires Br, 37.5%). On hydrolysis it yielded benzoic acid and α-acetyl-3:5-dibromo-*p*-tolylhydrazine.

The following hydrazidines were prepared by the action of 5 c.c. of concentrated aqueous ammonia upon a suspension of 5 g. of the *ω*-bromo-compounds in 50 c.c. of alcohol.

3-Bromo-*p*-tolyl-*m*-nitrobenzenylhydrazidine,

crystallises from alcohol in red prisms, m. p.  $136^{\circ}$  (Found: Br, 22.8.  $C_{14}H_{13}O_2N_4Br$  requires Br, 22.9%). It forms a hydrochloride which crystallises from alcohol and hydrochloric acid in colourless plates, m. p.  $230^{\circ}$  (decomp.).

3 : 5-Dibromo-*p*-tolyl-*m*-nitrobenzenylhydrazidine crystallises from alcohol in yellow prisms, m. p.  $151^{\circ}$  (Found: Br, 37.6.  $C_{14}H_{12}O_2N_4Br_2$  requires Br, 37.4%), 3-bromo-*p*-tolyl-*p*-nitrobenzenylhydrazidine in deep purple prisms, m. p.  $155^{\circ}$  (Found: Br, 22.8.  $C_{14}H_{13}O_2N_4Br$  requires Br, 22.9%), and 3 : 5-dibromo-*p*-tolyl-*p*-nitrobenzenylhydrazidine in orange-yellow rhombic plates, m. p.  $145^{\circ}$  (Found: Br, 37.2.  $C_{14}H_{12}O_2N_4Br_2$  requires Br, 37.4%).

*The Bromination of o-Nitrobenzaldehyde-p-tolylhydrazone.*

$\omega$ -Bromo-*o*-nitrobenzaldehyde-3-bromo-*p*-tolylhydrazone.—2.1 C.c. of bromine (2 mols.) were added to 5 g. (1 mol.) of *o*-nitrobenzaldehyde-*p*-tolylhydrazone suspended in 50 c.c. of acetic acid. A dark brown solution was formed from which  $\omega$ -bromo-*o*-nitrobenzaldehyde-3-bromo-*p*-tolylhydrazone slowly separated in yellow crystals. Recrystallised from acetic acid, it formed yellow rhombic plates, m. p.  $105^{\circ}$  (decomp.). The recrystallisation must be rapidly effected, since the compound quickly decomposes when heated with acetic acid (Found: Br, 38.3.  $C_{14}H_{11}O_2N_3Br_2$  requires Br, 38.7%).

The compound cannot be recrystallised from alcohol, as it then loses hydrogen bromide and is converted into the highly explosive 3-keto-1 : 2-endo-3'-bromo-*p*-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole 1-oxide (I;  $R = C_6H_3MeBr$ ). This crystallises from alcohol in bright yellow, rhombic plates, explosion point  $139^{\circ}$  (Found: Br, 24.0.  $C_{14}H_{10}O_2N_3Br$  requires Br, 24.1%).

When 2 g. of the explosive compound were boiled for 2 hours under reflux with 25 c.c. of alcohol, a brown solution was obtained which, on cooling, deposited 3-keto-1 : 2-endo-3'-bromo-*p*-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole. This crystallised from alcohol in pale yellow prisms, m. p.  $166^{\circ}$  (Found: Br, 25.2.  $C_{14}H_{10}ON_3Br$  requires Br, 25.3%).

*The Action of Excess of Bromine upon o-Nitrobenzaldehyde-p-tolylhydrazone.*—5 G. of the hydrazone were suspended in 100 c.c. of acetic acid, and 10 c.c. of bromine added. A dark brown solution was formed from which, on shaking and cooling, 3 : 5-dibromo-*p*-toluidine perbromide separated. This, recrystallised from a 16% solution of bromine in acetic acid, formed bright orange prisms, m. p.  $134^{\circ}$  (decomp.) (Found: Br, 78.2.  $C_7H_8NBr_5$  requires Br, 79.0%).

This perbromide is fairly stable in the solid state and can be dried at  $100^{\circ}$  with only slight decomposition. It loses bromine and

hydrogen bromide on being washed with water or kept for several weeks over lime in a vacuum desiccator. It is easily soluble in acetic acid and when the solution is boiled, bromine is evolved; on cooling, 3 : 5-dibromo-*p*-toluidine separates in colourless needles, m. p. 73°.

The perbromide was also prepared by the action of an excess of bromine upon a solution of *p*-toluidine in acetic acid.

$\omega$ -Bromo-*o*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone was obtained by the action of 1 mol. of bromine upon *o*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone. It decomposes very readily when warmed with acetic acid, but can be recrystallised from a mixture of benzene and high-boiling petroleum, from which it separates in pale yellow prisms, m. p. 123° (decomp.) (Found: Br, 48.3.  $C_{14}H_{10}O_2N_3Br_3$  requires Br, 48.8%).

When boiled for a few minutes with alcohol, it loses hydrogen bromide and is converted into the highly explosive 3-keto-1 : 2-endo-3' : 5'-dibromo-*p*-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole 1-oxide, which crystallises from alcohol in bright yellow, rhombic plates, explosion point 167° (Found: Br, 39.1.  $C_{14}H_9O_2N_3Br_2$  requires Br, 38.9%).

The explosive compound (2 g.), when boiled with 25 c.c. of alcohol for 6 hours, gives the corresponding endoaryliminobenzisodiazole derivative, which crystallises from alcohol in yellow rhombic plates, m. p. 190° (decomp.).

*Bromination of o-Nitrobenzaldehyde-p-tolylhydrazone in the Presence of Sodium Acetate.*—5 G. of this hydrazone and 5 g. of anhydrous sodium acetate were suspended in 50 c.c. of acetic acid, and 1.1 c.c. of bromine (1 mol.) added. A dark solution was formed from which crystals of the explosive 3-keto-1 : 2-endo-*p*-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole 1-oxide slowly separated. It crystallised from alcohol in bright yellow prisms, explosion point 143°. The same compound, containing no halogen, was obtained even when 2 or 3 mols. of bromine were used at the ordinary temperature.

*Second Liversidge Lecture.*

DELIVERED BEFORE THE CHEMICAL SOCIETY ON DECEMBER 12TH,  
1929.

By HERBERT FREUNDLICH.

*Surface Forces and Chemical Equilibrium.*

I INTEND to discuss a problem of surface chemistry. It is well known that surface reactions are of the greatest importance in technical and biological processes. But these reactions are generally very complicated and it is therefore worth while to examine what we know about the simple case of a chemical equilibrium being influenced by surface forces.

J. J. Thomson ("Applications of Dynamics to Physics and Chemistry," London, 1888, p. 234) was the first to point out that a chemical equilibrium ought to be influenced by capillarity. This celebrated treatise has always appeared to me as the true successor of Gibbs's thermodynamical papers from which the chemist of to-day may still derive many suggestions. In it we find the sentence: "If the surface tension increases as a chemical action goes on, the capillarity will tend to stop the action, while, if the surface tension diminishes as an action goes on, the capillarity will tend to increase the action." Thomson attempted to prove this theoretical conclusion by experiments on the so-called "dead space." As is well known, alkali acts on chloral hydrate in aqueous solutions to yield chloroform, which separates throughout the solution as a white deposit of droplets except for a thin surface film where the solution is in contact with the air. This phenomenon was noticed first by Liebreich (*Z. physikal. Chem.*, 1890, 5, 529). Now Monkman showed that the surface tension increases while this reaction is proceeding. This might at first sight make an explanation of the "dead space" possible on the assumption that the formation of the chloroform is retarded in the surface, since surface tension increases. Yet, however satisfactory this explanation may appear, it is inadequate. The real explanation is probably much simpler. Budde (*ibid.*, 1891, 7, 586; *Wied. Ann.*, 1892, 46, 173) showed that the absence of chloroform droplets in the uppermost layer is probably merely the result of evaporation, the whole phenomenon being most sensitive to small differences in temperature. This earlier attempt to verify Thomson's theory was therefore not altogether successful.

In the 40 years which have elapsed since then, a number of investigators have taken up this question. No case has been found simple and clear enough to afford a complete test of the theory;

the facts, however, agree with it on the whole. Before entering upon these investigations in detail, permit me to discuss some generalisations which I shall use.

Increase and decrease of surface tension caused by the dissolved substances are related to a change of concentration of these substances in the surface according to Gibbs's equation. If the surface tension increases or decreases with increasing concentration, the surface contains respectively less or more of the dissolved substance

FIG. 1.

than the liquid in bulk. Let us call this change of concentration in the surface "adsorption." We then may assume that a substance is adsorbed negatively if it raises the surface tension, and is adsorbed positively if it lowers the surface tension. And Thomson's relation between capillarity and chemical equilibrium may be expressed in the following way: the displacement of chemical equilibrium in a surface takes place in a direction favouring those substances which lower the surface tension and are therefore adsorbed positively. Such substances are said to exert "capillary action," an expression which is perhaps not defined quite sharply.

It may be rather bold not to confine these speculations to liquid-gas or liquid-liquid surfaces, where we are really able to measure surface tension, but to extend them to surfaces of solid substances. Here we are not able to measure surface tension, at least not with any degree of precision, but we can easily enough find phenomena which may be considered as phenomena of adsorption. There is a great similarity in the behaviour of these different boundaries. Let me remind you of two facts. First, the so-called rule of Traube

FIG. 2.

holds good in aqueous solutions even if the second phase is a gas, a liquid such as mercury, or a solid such as charcoal. According to this rule, capillary activity increases strongly and regularly as we ascend any homologous series of organic substances. This becomes clear, for instance, in the decrease of surface tension in solutions of fatty acids as shown in Fig. 1, and in accordance with Gibbs's rule the adsorption increases as we rise in such a series. Figs. 2 and 3 show adsorption isotherms of fatty acids on charcoal and on siloxen ( $\text{Si}_6\text{O}_3\text{H}_6$ ), an enormously porous and strongly adsorbing substance prepared from

calcium silicide ( $\text{CaSi}_2$ ). The second fact is that organic (and many inorganic) acids and bases exhibit much greater capillary activity than their salts: they lower the surface tension more strongly and are accordingly adsorbed in a higher degree by most adsorbents. This may be explained by assuming that the ions are less active in this respect than the undissociated molecules.

I am sure that surface chemistry will suffer many changes in the near future. But even if the ground on which we tread is not very firm, nevertheless I believe that we may generalise Thomson's relation and say that, on any surface, substances which are adsorbed

strongly are formed in large amount and the chemical equilibrium is therefore shifted in this direction.

Let me now return to the subject of my lecture. I shall commence by discussing a phenomenon which is rather complicated but has been known for a long time. If charcoal is shaken with salt solutions, especially those of salts with organic ions like dyes or alkaloids, the two ions are not always adsorbed in equivalent amounts; a dye kation, for instance, may be adsorbed more strongly than an inorganic anion, hydrogen ions replacing the lacking kations in the solution. This kind of exchange adsorption was perhaps considered to be of no great interest; it was assumed simply that some foreign substance (e.g., ash) in the charcoal exchanged some of its ions for ions from the solution. This explanation had to be given up, however, when Bartell and Miller (*J. Amer. Chem. Soc.*, 1922, 44, 1866; 1923, 45, 1106; Miller, *ibid.*, 1924, 46, 1150; 1925, 47, 1270) showed that a very pure charcoal made from sugar and containing less than 0.01% of ash behaved in a similar way: it adsorbed acids from salt solutions, the solution being alkaline after adsorption had taken place. The amount of acid calculated from the alkalinity of the solution agreed excellently with the amount found directly by washing the sugar charcoal with an organic solvent and titrating the acid. There was also a very distinct parallelism between the amount of acid adsorbed from the salt solution and the adsorbability of these acids in pure solution, for instance, for a benzoate, an oxalate, and a chloride. Here we really seem to have a hydrolysis of the salt caused by adsorption, a shifting of an equilibrium in such a direction that the production of the more strongly adsorbed substances—the acids—is favoured.

Recent investigations by Frumkin (Frumkin and Donde, *Ber.*, 1927, 60, 1816; Bruns and Frumkin, *Z. physikal. Chem.*, 1929, A, 141, 141; Burstein and Frumkin, *ibid.*, pp. 158, 219) have shown, however, that the conditions are more complicated and that the

FIG. 3.

electrical influence of the ions cannot be neglected. He activated an ash-free sugar charcoal in an electric furnace under a high vacuum up to  $1000^{\circ}$ , taking care that no air came in contact with the charcoal before it had adsorbed the dissolved substances. This charcoal did not appreciably adsorb weakly adsorbable inorganic substances such as hydrochloric acid or sodium hydroxide. If, however, the charcoal came in contact with air or oxygen it was able to adsorb acids such as hydrochloric acid but not alkalis. On the other hand, if the sugar charcoal was heated to  $1000^{\circ}$  in an atmosphere of hydrogen and carefully kept from the air, its behaviour was reversed : it adsorbed alkalis but not acids. Frumkin believes, therefore, that charcoal behaves like a gas electrode. If it contains oxygen, it gives off hydroxyl ions to the solution and takes up anions from it; the solution turns alkaline and loses an equivalent amount of anions. If the charcoal contains hydrogen, hydrogen ions are given off to the solution, kations are taken up from it, and it turns acid, losing an equivalent amount of kations. The adsorption of a weak and strongly adsorbable acid such as benzoic acid is not influenced by treating the sugar charcoal with hydrogen in the way described. In the case of the salts of weak acids, we may assume, therefore, that we really have a displacement of the equilibrium in the first sense, but especially for strong electrolytes the conditions are markedly modified by the presence of gases. In any case, we have no very well-defined case of the shifting of a chemical equilibrium by surface forces.

Experiments which leave no doubt as to the existence of such a displacement were recently made by Deutsch (*Ber.*, 1927, **60**, 1036; *Z. physikal. Chem.*, 1928, **136**, 353), in the Dahlem laboratory of the Kaiser Wilhelm Institut für physikalische Chemie. He found that indicators in solutions near their turning point changed their colour if the solution was shaken with an indifferent fluid such as benzene, toluene, etc. If, for instance, a solution of bromothymol-blue in a hydrogen-ion concentration of  $p_H$  7.4 is treated in this way, the colour changes from blue to yellow. This change of colour only takes place as long as fine drops of benzene are emulsified in the aqueous solution; it disappears as soon as the two phases have separated again. The more strongly the fluid is shaken, the more pronounced the colour becomes, because the droplets formed are finer and more numerous, their interface being accordingly larger. There can be no doubt that the colour change is caused by the emulsification, that is, by the formation of the large interface. The phenomenon is absolutely reversible, and may be repeated indefinitely. The colour changes as if the  $p_H$  had altered from 7.4 to 6.2. The shifting of the equilibrium between the different ions

and molecules characteristic for this indicator is of this order of magnitude.

This might be explained by assuming that the hydrogen-ion concentration in the surface of the droplets is different from that in the bulk of the liquid; but this does not hold, for if we take an indicator which is not an acid dye, such as malachite-green, it also changes on being shaken with an indifferent fluid. The change of the  $p_H$  which we would like to make responsible for the colour change has, however, a reversed sign in this case. With malachite-green the colour changes from yellow to green; this would correspond to a change of  $p_H$  from 0.5 to 1.5. Table I, as given by Deutsch, shows that acid and basic dyes seem to behave throughout in this way.

TABLE I.

Indicator.	Solvent.	Colour of solution.	Colour on shaking.	Change of $p_H$ corresponding to colour change.
Guinea-green	About 1.0N-HCl	Yellow	Bluish-green	From 0.0 to 0.6
Malachite-green	„ 0.4 „	Yellow	Bluish-green	„ 0.5 „ 1.5
Brilliant-green	„ 0.25 „	Yellow	Greenish-blue	„ 0.7 „ 2.0
Methyl-violet	„ 0.1 „	Green	Blue	„ 1.0 „ 2.0
Thymol-blue	„ 0.016 „	Yellow	Reddish-violet	„ 2.8 „ 1.6
Tropæolin 00	„ 0.016 „	Orange-yellow	Red	„ 2.8 „ 1.8
Bromothymol-blue	Mixture of distilled and undistilled water.	Blue	Yellow	„ 7.4 „ 6.2

The change of interfacial tension agrees with Thomson's relation, as far as it has been tested hitherto, and in so far as it was sufficiently large to be tested. With malachite-green, for instance, the interfacial tension is lowered to 22% if the concentration of hydrochloric acid is changed from 0.43 to 0.25N, and the hydrogen-ion concentration ( $p_H$ ) alters correspondingly from about 0.5 to 0.7. This change causes a colour change similar to that which happens on shaking.

Before entering into the intricate question of determining what chemical changes are taking place in the interface, and how they are to be explained, I should like to point out that this phenomenon is found, not only at the interface of two liquids, but also at the surface of fluids in contact with a gas phase. It is not quite so easy to demonstrate it there, because the foam of the liquid has to be sufficiently stable to make the colour change visible. This is the case with thymolsulphonephthalein. If we shake a solution of this indicator having a  $p_H$  of about 2.8 with air or in a vacuum, where the

gas phase contains only water vapour, the foam turns reddish-violet, whereas the bulk of the liquid remains brownish-yellow.

It is no easy question to determine what chemical reactions are occurring in the interface. The reactions of these indicators are far from simple. There are generally quite a number of ions of different valency, a series of isomeric forms, and in many cases also amphoteric ions. Deutsch believes that the case of malachite-green permits us to draw certain conclusions. Under the conditions of the experiments, we have to consider 5 kinds of molecules (Rötger, Diss., Berlin, 1924) : 3 of a carbinol structure—an undissociated form and 2 ions—and 2 of a quinonoid structure—a univalent blue

kation and a bivalent yellow kation. It seems very likely that we have to deal only with the transformation of this yellow kation into the blue one. This would account for the colour change and for the fact that the reactions proceed quickly, whereas the conversions of the carbinol into the quinonoid forms go much more slowly. We have accordingly the change of a bivalent ion into a univalent one. This means that at the interface a less dissociated substance is formed. A similar conclusion may be drawn from the acid dye bromothymol-blue: the colour change at the interface agrees with the formation of a less dissociated molecule. Deutsch ventured to generalise these experiences and assumed that in all cases the formation of undissociated or less dissociated molecules is favoured in the

interface touching the gas phase or the phase of an organic liquid. This would agree with the general conception that the undissociated molecules are more strongly adsorbed than the ions by many adsorbents. I must confess, however, that Thiel (*Z. Elektrochem.*, 1929, 35, 266), for instance, who is a very good specialist in indicators, is not convinced that these colour changes found by Deutsch are always in accordance with the production of less dissociated molecules. He believes that in quite a number of cases, for instance with tropæolin and thymol-blue, the colour change at the interfaces is caused by the formation of other ions which need not be considered as less dissociated. In the case of tropæolin it is an amphoteric ion, and in that of thymol-blue most likely the ion of a carbonium base. We do not know enough about such ions to say whether their capillary activity is especially pronounced.

Rather surprising results were found by investigating the interface from the other side, so to speak. Deutsch dissolved the colourless base of rhodamine-0 in benzene and shook this solution with water. The emulsion formed turns deep red; in this case the phenomenon depends upon the droplets of water dispersed in the benzene. The colour disappears practically when the phases are separated again, the water in bulk being only weakly coloured from the red base of the dyestuff. This phenomenon is again markedly independent of the nature of the interface. If a piece of filter paper is dipped into the colourless solution of the base in benzene it turns red; this is also the case if dry quartz powder is used instead of filter paper.

These experiments seem important in many respects. We see that a substance—in this case, the red base of the dye—may be formed at an interface, remaining very stable there, this substance being only formed in a very small amount or practically not at all when the area of the interface is too small. Further, it looks very much as if the change on the benzene side of the interface were a reversal of that on the aqueous side; that is, on the latter side, less dissociated substances seem to be favoured, these substances very often being such as would have dissolved in the organic liquid or in the gas phase (generally in the phase of the smaller dielectric constant) if such a solution were possible. On the benzene side, on the other hand, the same red substance, which is dissolved in the water, seems to be favoured. That this form is more dissociated than the colourless form in the benzene is most probable. We have to take into account the following possibilities. The colourless base is most likely a lactoid form. This is made plausible by the fact that some rhodamine dyes, which are esters, dissolve in benzene with a red or yellow colour and do not have a colourless base. Now the

constitution of these esters is such that conversion into the lactoid form is impossible. Therefore, this is most probably a colourless

Lactoid base.

*p*-Quinonoid ammonium base.

Betaine form.

Ester.

form of the base which is able to be formed by those dyes that are not esters. The red form of the base has most likely a quinonoid structure. We have two possibilities: an ammonium base of quinonoid structure, or the betaine form of the base. Some facts seem to indicate that we ought to prefer the latter. The ammonium base would need one more molecule of water than the betaine form. Now the presence of water does not seem absolutely necessary for the formation of the red base at an interface, for, if the benzene solution of the base is carefully dried with sodium, and if quartz powder, previously heated to redness and carefully protected from moisture, is added, the quartz turns red nevertheless. The change we are dealing with is therefore most likely the transition from the colourless lactoid form into the red betaine form. Now, according to the investigations of Bredig, Küster, and others, the betaine form has a great tendency to exist as an amphoteric ion. This is most likely the red substance with which we have to deal. The latter is to be considered as decidedly more dissociated, or at any rate as less saturated, than the lactoid form. The substance formed in the benzene side and soluble in water is therefore one which we may consider to be more dissociated.

Also, in the case of those rhodamine dyes like "rhodamine 6G extra" and "rhodamine 3G extra," which have the constitution of esters and dissolve in organic liquids in a coloured form, a change of colour takes place on shaking with water and on other interfaces. The bases of the two dyes mentioned are yellow in benzene solution,

and red in aqueous solution, in which they are much less soluble. When the benzene solution is shaken with water the colour turns red, and the same is the case if quartz is added to the benzene solution. The change is always in favour of the substance in the aqueous solution. This is perhaps in every case the amphoteric ion of the betaine form. In order that this substance be formed we must assume that the esters partly undergo a dissociation at the interface into the betaine form and alcohol.

I should like to mention some more experiments which show in quite different cases how different interfaces may behave similarly. Fajans (Fajans and Hassel, *Z. Elektrochem.*, 1923, **29**, 495; Fajans and Wolff, *Z. anorg. Chem.*, 1924, **137**, 221) has investigated the adsorption of dyes on silver halides. Substances like silver eosinate suffer a distinct change of colour provided that the adsorbing surface of silver halides is covered with silver ions. This is the case if it is precipitated from a solution containing a surplus of silver ions. The colour changes from a pinkish-yellow with a green fluorescence to a distinct red on the surface of the halide. Now Deutsch and Fajans showed that the same colour change takes place at other interfaces. If a solution containing 0.01% of sodium cosinate and 0.01 mol. of silver nitrate (a solution which is pinkish-yellow with a green fluorescence) is shaken with benzene or pentane, a red precipitate is formed at the interface. The same happens if it is merely shaken with air. Instead of the silver salt a copper salt may also be used.

This may be explained in the following way. We start with a dilute solution of the eosinate of the heavy metal which is strongly dissociated and therefore shows the colour of the anion of the dye. On shaking, a large interface is formed, and the equilibrium is shifted in the direction of the undissociated salt, which, being less soluble, is precipitated. On the surface of the silver halide we also have the formation of the undissociated salt. This is why the colour change is the same at all interfaces. We are not able to decide whether this change of colour is caused by a deformation of the dye molecule, as Fajans believes, or whether an isomeric molecule (in the strict sense of the word) is formed.

Here we are already dealing with cases which are not strictly reversible and therefore do not belong rigidly to the scope of this lecture. Numerous irreversible reactions at interfaces are known in which insoluble substances are formed. I need only mention the acid soap on the surface of soap solutions (Laing, *Proc. Roy. Soc.*, 1925, *A*, **109**, 28) and the denaturation which proteins undergo if we shake their solution with air or other gases (Ramsden, *Z. physikal. Chem.*, 1904, **47**, 336).

Deutsch's experiments are valuable in that they show definitely that a displacement of chemical equilibrium at interfaces really exists and may be found in quite a number of cases. In some respects they leave much to be desired. It seems hardly possible to develop them in a quantitative form, since we are unable to assign a definite area to the interface. Furthermore, the chemical changes occurring are rather complicated. I therefore should like to discuss yet another case where precisely these points seem to be much simpler. Certainly there is another gap which cannot be filled in yet.

We may consider with certain restrictions that an equilibrium constant is equal to the ratio of the velocity coefficients of the forward and the reverse reaction. If we have a displacement of equilibrium at an interface, we may expect that the velocity of the one reaction will be increased, and that of the other diminished. A case of that kind was investigated by Juliusburger and myself. In homogeneous aqueous solutions we have the following two reactions:

Bromoethylamine is unstable in alkaline solution and is transformed into the isomeric hydrobromide of dimethyleneimine, whereas in hydrobromic acid solution the hydrobromide of the latter is reconverted into bromoethylamine. [The formula of the substance formed in alkaline solution was the cause of some discussion. It was first considered to be the hydrobromide of vinylamine,  $\text{CH}_2\text{:CH}\cdot\text{NH}_2$ , but later investigations of Marckwald (Howard and Marckwald, *Ber.*, 1899, **32**, 2036; Marckwald, *Ber.*, 1900, **33**, 765; Marckwald and Frobenius, *Ber.*, 1901, **34**, 3544) showed that we have in any case to deal with an imine.] The velocity of the two reactions is easy to measure quantitatively: in the alkaline solution the amount of bromine ions increases—it is just doubled if, as is generally done, we start with the hydrobromide of bromoethylamine; and in the hydrobromic acid solution the amount of bromine ions diminishes. Now in acid solutions a secondary reaction goes on, the dimethyleneimine polymerising to a small extent; although this disturbance is not sufficiently marked to prevent us from measuring the velocity coefficients in acid solution, yet, since it is irreversible, it does not allow us to find the point of equilibrium in neutral solutions. Both reactions are well defined and are not affected by impurities. The transformation of the bromoethylamine is a reaction of the first order, and the reverse reaction is of the second

order, the velocity being proportional to the imine and bromine-ion concentrations.

Now these reaction velocities were measured in a heterogeneous system, the solutions being shaken with animal charcoal. It was necessary to know the adsorption of the following four substances: bromoethylamine, dimethyleneimine, and the hydrobromide of each. Fig. 4 shows, first, that the well-known adsorption isotherm agrees well with the measurements, for straight lines are obtained in a logarithmic plot. We see further that the bromoethylamine is adsorbed much more strongly than dimethyleneimine, and its

FIG. 4.

hydrobromide more strongly than that of dimethyleneimine. [Here we have a good example of salts being adsorbed much less than their bases.] According to the rule governing the displacement of chemical equilibrium at interfaces, we may expect that bromoethylamine, which has a stronger capillary activity, is more stable on the surface of the charcoal than in homogeneous solutions. The transformation of bromoethylamine into dimethyleneimine in alkaline solution ought therefore to be retarded, and the formation of bromoethylamine in acid solution to be accelerated. This is, indeed, the case, and in a very marked degree, as Figs. 5 and 6 show. We have first (Fig. 5) the velocity of the reaction in alkaline solution, the abscissæ indicating the time (in minutes), and the ordinates the percentage of bromoethylamine transformed; the reaction on the

FREUNDLICH:

charcoal goes distinctly more slowly than in homogeneous solutions. In acid solutions (Fig. 6) the reaction on the charcoal is strongly accelerated. This latter reaction is disturbed, but only to a very small

Fig. 5.

Fig. 6.

extent, by the adsorption of hydrobromic acid and some unknown change it undergoes at the surface of the charcoal. It is important to mention that under the conditions of these experiments the adsorption of the reacting substances was very strong, especially in the case of the alkaline solution. The amount of charcoal used was so large (several grams), and the concentration

of the reacting substances so low (generally  $N/20$  to  $N/50$ ), that the bromoethylamine was adsorbed to about 100%. We are really dealing with a reaction where the reacting substance is entirely in the adsorption layer. The conditions are therefore quite different from those prevailing in most catalytic gas reactions, in which only a small and generally unknown amount is adsorbed and reacts on the surface. In the reverse reaction the degree of adsorption is much lower; the hydrobromide of the dimethyleneimine is adsorbed at the commencement to about 15%.

It might have been objected to these experiments that we were not sure whether the reactions going on in the heterogeneous system are identical with those in the homogeneous system, but we were able to show that this is indeed the case. In alkaline solution the concentration of the bromine ion is doubled under both conditions, and in presence of charcoal the dimethyleneimine formed could be distilled off at temperatures below  $60^{\circ}$  (its boiling point is  $55^{\circ}$ ), and it formed its characteristic red crystalline salt with potassium bismuth iodide. It is not so easy to show that the reverse reaction is the same as in homogeneous solution, for we have no similar characteristic reagent for bromoethylamine. This, however, could also be shown in the following way: after the reaction had proceeded in acid solution in presence of charcoal, the solution was made alkaline, and the velocity measured with which dimethyleneimine was re-formed from the bromoethylamine originally produced in the acid solution. The reaction velocity coefficient thus measured was identical with that which had been found when bromoethylamine hydrobromide was used at the outset.

The mechanism of the two reactions in presence of charcoal is distinctly different, especially in one point, from that in homogeneous solutions. The reaction of the dimethyleneimine in acid solution is of the second order as in homogeneous solutions, the coefficient being much larger, however. On the other hand, the reaction of the bromoethylamine in alkaline solution does not follow the first order as it does in homogeneous solution. Since the reacting substance is, so to speak, totally in the adsorption layer, it is necessary to use as variable a surface concentration, *viz.*, the amount of amine divided by the amount of charcoal, and with this variable the velocity of the reaction is proportional to the  $\frac{3}{2}$  power of the surface concentration. We have not yet found an explanation for this empirical formula, but its discovery would probably provide the clue to a kinetic interpretation of this change of reaction velocity in presence of charcoal.

The behaviour in neutral solution presents some features of interest. As I said before, the equilibrium to be expected cannot be

measured exactly because of a secondary reaction which also disturbs the reaction in presence of charcoal; but it is quite clear that the formation of bromoethylamine is favoured strongly. For, starting with a neutral solution of bromoethylamine, about 90% is transformed in the course of a long time in homogeneous solution, whereas in presence of charcoal the reaction stops almost entirely when about 63% is transformed. If, on the other hand, we start with a neutral solution of the hydrobromide of dimethyleneimine, only about 10% is transformed in homogeneous solution, but more than 36% in presence of charcoal.

These experiments agree well with what we might expect from the theory: the equilibrium is displaced in the sense required by Thomson's relation, the formation of capillary active substances being favoured. The experiments show further that a substance, in this case the bromoethylamine, may be more stable at an interface than in homogeneous solution under similar conditions.

May I return once more to the question as to how far surface reactions are of biological importance? I need not emphasise the importance of microstructure and interfaces for protoplasma and life in general, since Professor Donnan did so most convincingly in his Liversidge lecture last year (J., 1929, 1387). Although life never means an equilibrium, but at most a stationary state like a flame or a water jet, a displacement of a chemical equilibrium may make itself felt in the change of reaction velocities, as in our case of the transformation of bromoethylamine into dimethyleneimine. We may therefore assume that the formation of capillary active and strongly adsorbable substances is favoured generally if the aqueous phase which certainly constitutes some part of a protoplasmic entity comes into contact with a solid or a liquid organic substance of small dielectric constant. Many substances of biological importance, indeed, exhibit capillary activity, *e.g.*, the alkaloids and fats.

The fact that at interfaces substances may be formed, and even possess considerable stability, whereas at the same concentrations without the interfaces their existence is transitory, may account for the extraordinary structure of many substances playing important biological rôles. I have always been astonished at the great difference between the organic chemistry of our laboratories and that under biological conditions. Not only is the difference in the methods used remarkable—in laboratories we use a large range of temperatures and a great variety of solvents, whereas Nature utilises a small range of temperatures and a great variety of interfaces—but the substances formed also seem to me to be very different. I doubt whether an organic chemist, knowing nothing about natural products

but, on the other hand, well trained in all methods of work and master of all our knowledge of the possibilities of chemical valency and even more, I doubt whether he could have conceived the existence of substances like most alkaloids or cholesterol, lecithin, adrenaline, thyroxine, and many others. This may be caused partly by the fact that we know a good deal of what happens in the bulk of solutions, but very little about what takes place at interfaces. And I mean not only comparatively inert interfaces, such as air or charcoal, but also those which are very reactive. We must realise that we have to deal, not only with the relatively simple displacements discussed in this lecture, but also with a great number of further reactions which may take place if the unstable substances stabilised at an interface react with other substances at the interface or with the molecules of the adsorbent itself. I should not be surprised if the great difficulty which we meet in trying to explain the nature of enzymes is partly due to similar causes. They may be very unstable and active organic substances, perhaps even organic radicals which are stabilised because they are adsorbed at a suitable interface, but they are able to react very energetically in intermediate reactions with other substances also adsorbed on these interfaces.

## NOTES.

*An Apparatus for the Determination of Solubility.* By

ALAN N. CAMPBELL.

IN some very accurate work on the physical properties of optical antipodes (*Nature*, 1929, **124**, 792), it became necessary to determine solubilities with great accuracy, and any such method as the removal of samples from a bottle in the thermostat by means of a warmed pipette was obviously out of the question. Previous work with Goldschmidt's apparatus (*Z. physikal. Chem.*, 1895, **17**, 153) had shown that, although this embodies the important principle of filtering in the thermostat, it had certain objections: (1) it is too cumbrous; (2) suction is employed, whereby, if the solid is fine or slimy, it becomes clogged in the filter-plug and the apparatus has to be cleaned out. Accordingly the apparatus shown in the diagram was designed. It possesses the advantages of compactness and simplicity, for when it is inverted in the thermostat, filtration takes place.

The bottles are of the ordinary wide-mouthed 1-oz. type, except that the mouth of the top one is ground. Glass tubes pass through the bungs as shown. The wider tube (of 3 mm. internal diameter)

is constricted at the top and packed with glass wool. The other (quill) tube is drawn out to a capillary and bent into an S. As the liquid entering this tube at the beginning is pure solvent, which would dilute the saturated solution when subsequently expelled by the air pressure from below, it is advisable to arrange that all the immersed tube is of capillary diameter. The very small amount of pure solvent then expelled (perhaps 0.1 c.c.) is negligible in comparison with the total volume, especially when it is remembered that the whole solution then passes slowly through a layer of the solid.

× One-half.

The lower bottle is charged with solid and solvent and the apparatus fixed in a vertical position on the horizontal paddle of the thermostat stirrer. When dissolution is complete, the apparatus is inverted in the thermostat, and the solution filters through the plug, air being displaced into the upper chamber through the narrow tube. The double bend at the mouth of the latter prevents the entrance of solid matter into the lower bottle. The apparatus is then removed from the thermostat and the appropriate (weighed) bottle closed with a ground-glass plate.

The apparatus works perfectly, and should be very suitable for phase-rule studies, involving the analysis of the wet solid phase. The slight increase of gas pressure in the apparatus at the temperature of the thermostat prevents the leaking in of thermostat water. At high temperatures the apparatus should be enclosed in a grip to prevent the increased pressure forcing out the bungs.—UNIVERSITY OF ABERDEEN. [*Received, December 9th, 1929.*]

*2'-Nitro-2- and -4-aminodiphenyl Sulphides and 4'-Nitro-2- and -4-aminodiphenyl Sulphides.* By HERBERT HENRY HODGSON and WOLF ROSENBERG.

THE requisite diaminodiphenyl sulphide (25 g.) was dissolved in alcohol (200 c.c.), and sodium wire (5 g.) added at a rate sufficient to maintain regular ebullition (under reflux); after boiling for one hour, the mixture was treated with *o*- or *p*-chloronitrobenzene in slight excess of the amount required for the condensation

$\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{SNa} + \text{C}_6\text{H}_4\text{Cl} \cdot \text{NO}_2 \longrightarrow \text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{S} \cdot \text{C}_6\text{H}_4 \cdot \text{NO}_2 + \text{NaCl}$ , then boiled 2 hours longer and filtered hot. Only 4'-nitro-4-amino-diphenyl sulphide crystallised from solution on cooling; in the other cases alcohol, unchanged chloronitrobenzene, and any chloroaniline formed as by-product were removed by steam distillations and the tarry residue was crystallised three times from alcohol (charcoal). Constitutions were confirmed by reduction to the known diamino-diphenyl sulphides.

*The Solubility of Sodium Thiocyanate in Alcohol.* By JAMES  
RIDDICK PARTINGTON.

IN a recent communication (Hughes and Mead, J., 1929, 2282) the authors state that, for the solubility of sodium thiocyanate in alcohol, "no data are at present available." This statement is incorrect, since Dr. F. E. King and I published a series of experiments on this subject some little time ago (*Trans. Faraday Soc.*, 1927, 23, 522). The method of preparation of the salt was the same as that described by Hughes and Mead; their value for the solubility at 25° is, however, somewhat lower than ours, which may be due to the fact that the salt used by them was somewhat purer than ours, or, equally possibly, to some other cause. It may be mentioned that several experiments on the solubilities of salts in non-aqueous solvents have been published from this laboratory, and that several more are in progress.—EAST LONDON COLLEGE, UNIVERSITY OF LONDON.  
[Received, November 29th, 1929.]

*An Improved Receiver for Vacuum Distillation.* By GEORGE  
ARMAND ROBERT KON.

THE accompanying figure illustrates a form of receiver for vacuum distillation which has been in use in these laboratories for some time. It is simpler and cheaper than the ordinary "Perkin triangle," as it has only two taps instead of three; another advantage is that when air is admitted through the tap *A* to the lower portion of the appar-

atus in order that the receiving flask may be changed, the last few drops of distillate remaining in the tube *B* are blown into the receiving vessel, thus minimising waste. The three-way tap *C* enables connexion to be made between the pump and either or both halves of the apparatus. It is, of course, possible to construct the apparatus with two rubber joints at *D* and *E* to allow receivers of different sizes to be used, but the all-glass apparatus illustrated is preferable, and as it is very compact, breakages are rare.\*—IMPERIAL COLLEGE OF

\* The apparatus described can be obtained from Messrs. Howard Rawson & Co., Pond Place, Fulham Road, London, S.W. 3.

SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON, S.W. 7. [Received, December 11th, 1929.]

*Preparation of 4- and 6-Hydroxy-3-nitrophenylarsinic Acids.*

By ISIDORE ELKANAH BALABAN.

CLAUS and STIEBEL (*Ber.*, 1887, **20**, 1379) reduced 2:4-dinitrochlorobenzene and obtained a mixture of 4- and 6-chloro-3-nitroaniline consisting almost wholly of the 6-chloro-compound: no yields are stated. These bases can be readily obtained by West's method (*J.*, 1925, **127**, 494), the yields being 23.0% and 45.0% of 4- and 6-chloro-3-nitroaniline respectively.

When the bases are submitted to the Bart-Schmidt reaction, 4-chloro-3-nitrophenylarsinic acid (yield, 32.4%) and 6-chloro-3-nitrophenylarsinic acid (yield, 32.9%) are obtained (compare Balaban, *J.*, 1928, 809); and when these acids are boiled under reflux with 25% aqueous sodium hydroxide (10 c.c. for each gram) for 3 hours, they are converted into 4-hydroxy-3-nitrophenylarsinic acid (yield, 45.6%) and 6-hydroxy-3-nitrophenylarsinic acid (yield, 73.0%).—RESEARCH LABORATORY, MESSRS. MAY & BAKER LTD., WANDSWORTH, S.W. 18. [Received, December 7th, 1929.]

*Anserine.* By FRANK LEE PYMAN.

LINNEWEH, KEIL, and HOPPE-SEYLER (*Z. physiol. Chem.*, 1929, **183**, 11) have recently shown that anserine yields on hydrolysis  $\beta$ -aminopropionic acid and an *N*-methyl derivative of *dl*-histidine. On distillation with soda-lime, anserine gave a dimethylglyoxaline which they identified with the dimethylglyoxaline obtained by Jowett (*J.*, 1903, **83**, 438) by distilling *isopilocarpine* with soda-lime, since it gave a chloraurate, m. p. 220—225°, Jowett giving m. p. 214—215°. They have overlooked the fact that the constitutions of the 1:4- and 1:5-dimethylglyoxalines have since been determined (Pyman, *J.*, 1910, **97**, 1814; 1922, **121**, 2616; Burtles, Pyman, and Roylance, *J.*, 1925, **127**, 581), and that it has been shown that the chloraurates melt at 137—138° and 218—219° respectively. Their dimethylglyoxaline is thus 1:5-dimethylglyoxaline and consequently their methylhistidine is *dl*- $\beta$ -(1-methylglyoxalanyl-5)- $\alpha$ -aminopropionic acid,

and not the 1:4-isomeride formulated in their paper. The relative positions of the side chains and the *N*-methyl groups are thus the

same in anserine and pilocarpine.—RESEARCH LABORATORIES, MESSRS. BOOTS PURE DRUG CO. LTD., NOTTINGHAM. [Received, December 18th, 1929.]

*The Mechanism of Cyanoacetamide and Cyanoacetic Ester Condensations.* By CHRISTOPHER KELK INGOLD.

BARDHAN'S account (J., 1929, 2233) of the author's views on the condensation of ethyl cyanoacetate and similar substances with keto-enolic compounds requires adjustment. The only reference given by Bardhan in this connexion is to a paper (1921) by the author in which the conclusion was drawn that, since tendency to enolisation bears a close relation to tendency to condensation, the latter reaction involves the enol. Kohler and Corson's later demonstration (1923) that, notwithstanding the experience of previous observers (Thorpe, 1905; Haworth, 1908), condensation is possible with a ketone incapable of enolisation was naturally accepted by the author as proving that his former view was inadequate as a general conception, and in 1926, with Cooper and E. H. Ingold, he again discussed the Michael and aldol reactions in terms the application of which to cases of the type considered by Bardhan is that the cyanoacetamide or ethyl cyanoacetate anion may unite with the acetylacetone analogue either at  $C_\alpha$  (electron-displacements  $\alpha$ ; aldol reaction) or at  $C_\gamma$  (displacements  $M$ ; Michael reaction),

$\text{HO}-\overset{\overset{M}{\curvearrowright}}{\underset{(\gamma)}{\text{C}}}=\overset{\overset{\alpha}{\curvearrowright}}{\underset{(\alpha)}{\text{C}}}-\text{O}$ , and that a similar statement should apply to

ketones generally, unless the second alternative disappears because the unsaturated system is insufficiently extended to admit of displacements  $M$ . It is also part of the theory that tendency to condensation (aldol reaction; or Michael reaction, if constitutionally

possible) and tendency to enolisation,  $\text{H}-\overset{\overset{\alpha}{\curvearrowright}}{\text{C}}=\overset{\overset{\beta}{\curvearrowright}}{\text{C}}-\text{O}$  (if constitutionally possible), are different manifestations of the same electron-attraction of carbonyl oxygen—which is why the two phenomena are related. The omission by Bardhan of any reference to this and subsequent cognate papers, together with his consistent use of the present tense in ascription to the author of the older views which these papers modify and supersede, are misleading features in his account.

With regard to the decision between  $C_\alpha$ - and  $C_\gamma$ -carbon-coupling (where both possibilities are open, as in enolising 1:3-dicarbonyl compounds), a method of envisaging such problems has been advanced by Burton and the author (1928), and a mass of consistent

empirical observation is available. It is therefore surprising that Bardhan, whose own observations on the reaction between cyanoacetamide and enolising 1 : 3-dicarbonyl compounds are indecisive in the absence of knowledge of the direction of enolisation, nevertheless contends that carbon coupling at  $C_\alpha$  (carbonyl carbon) is the general mode of reaction in this and allied condensations. No reference is made to the large body of significant contrary indications—even to such as directly relate to the particular reaction studied, as, for instance, the observations of Errera (1900), Simonsen (1908), and Sen-Gupta (1915) that in the condensation of cyanoacetamide with hydroxymethylene-ketones, in which the direction of enolisation is beyond doubt, and with ethoxymethylene-ketones, in which, furthermore, it is fixed, carbon coupling consistently

THE UNIVERSITY, LEEDS. [Received, November 6th, 1929.]

## XXV.—*The Influence of Hydrogen and of Water Vapour on the Ignition of Carbon Monoxide.*

By ARTHUR SMITHELLS, HENRY WHITAKER, and THEODORA HOLMES.

### *Introduction.*

THE experimental work now recorded was commenced some years ago at the University of Leeds by Mr. H. Whitaker, and the point at issue seemed to be determined satisfactorily by 1923. Subsequently, however, further verification was deemed desirable before publication. Professor H. B. Baker advised the continuation of the work and, thanks to his kindness and to the generosity of the Worshipful Company of Salters in providing assistance, the experiments were resumed after a long interval by Miss Holmes. The greater part of the designing of the apparatus and the whole of the actual execution of the work fell to Mr. Whitaker and Miss Holmes, and in the second stage we have had the great advantage of being able always to count upon Professor Baker for advice.

The experiments arose from some rather speculative deductions (which I no longer entertain) from the Lewis-Langmuir cubical atom conceptions soon after they appeared. In attempting to apply them to the standing problem of the combustion of carbon monoxide, I found they appeared to give a plausible explanation of a striking observation made shortly before by Bone and Haward

(*Proc. Roy. Soc.*, 1921, *A*, **100**, 67). In their experimental study of gaseous combustion at high pressures, they had obtained results which showed a "peculiar influence of hydrogen in accelerating the rise of pressure in the explosion of hydrogen-carbon monoxide mixtures at high pressures, an effect which can be shown to be altogether disproportionate to the volumetric amount of it present." They add: "Our experiments seem to point to hydrogen being even more potent than its equivalent of steam as a promoter of the combustion of carbonic oxide (though this is a matter needing further investigation)." It appeared desirable to try to measure the relative catalytic influence of hydrogen and water vapour on the initial ignitability of a carbon monoxide-oxygen mixture in a eudiometer at or near atmospheric pressure.

Since 1921, the relative catalytic influence of water and steam on the combustion of carbon monoxide has acquired greater interest and has been the subject of much investigation. Professor Bone and his collaborators have followed up the original experiments and made many new ones of an exact quantitative character bearing on the subject during their researches on the combustion of gases at high pressure. Bone, Newitt, and Townend (*J.*, 1923, **123**, 2008) obtained definite evidence that the substitution of hydrogen for a small part of the carbon monoxide had a specific accelerating effect on the rising pressure curve much greater than that produced by an addition of water vapour. Later, the same authors (*Proc. Roy. Soc.*, 1928, *A*, **120**, 546) and Bone, Townend, and Smith (*ibid.*, p. 563) recorded further experiments on the relative influence of hydrogen and steam on the carbon monoxide combustion. These cannot be summarised without quoting numerical values, but they confirm and amplify Bone's earlier conclusions in reference to the relative influence of hydrogen and water vapour as catalysts. An important matter in the last-named paper is the reference to "the sensitiveness as regards explosion time of theoretical carbon monoxide-air explosions to slight changes in hygroscopic conditions at high initial pressures, even though the moisture actually present in the system be less than 0.04 per cent."

Other relevant observations are those of Dixon and Walls (*J.*, 1923, **123**, 1025), who found that the carbon monoxide-oxygen mixture with 5.5% of water vapour had a maximum rate of explosion of 1738 m./sec., whereas with 5.5% of hydrogen the rate was 1782 m./sec.

Payman and Wheeler (*ibid.*, p. 1251) concluded that "whereas a trace of water vapour is more effective in enabling propagation of flame to take place in dried mixtures of carbon monoxide and air, twice as much of it is required to give to that propagation its com-

plete freedom." They found that the amounts necessary for this were 6% of water and 3% of hydrogen.

Fenning (*Phil. Trans.*, 1926, *A*, 225, 331), in a study of carbon monoxide-air explosions in a closed vessel, found that with hydrogen less time was taken to reach maximum pressure than with water vapour.\*

An excellent account of investigations relating to the combustion of carbon monoxide, beginning with Dixon's primary discovery of the influence of water, is given by Bone and Townend ("Flame and Combustion in Gases," Longmans, 1927).

(A. S.)

The present experiments aimed at a direct comparison of the efficiency of hydrogen and water vapour in facilitating the ignition of a mixture of carbon monoxide and oxygen by passing a spark through two eudiometers in series, one containing, beside the carbon monoxide and requisite oxygen, a known amount of hydrogen, and the other an equimolecular amount of water vapour.

*Preparation and Purification of Gases.*—The carbon monoxide was prepared in an apparatus similar to that used by Waran (*Phil. Mag.*, 1921, 42, 246) by adding redistilled formic acid to pure sulphuric acid. The gas was passed through (1) potassium hydroxide solution to remove any carbon dioxide, (2) sulphuric acid to catch any alkaline spray and act as a preliminary drying agent, (3) phosphoric oxide tubes for final drying, and (4) a tube cooled by liquid air.

The oxygen, prepared by heating potassium permanganate, passed through (1) a tube containing solid potassium hydroxide and glass wool, (2) phosphoric oxide tubes, and (3) a liquid-air tube.

The hydrogen was prepared by electrolysis (see Baker, J., 1902, 81, 7, 400) between platinum electrodes, of baryta, recrystallised three or four times, dissolved in conductivity water. It was passed through (1) an electrically heated tube containing copper gauze, which had previously been heated to redness first in a current of dry air and finally in a current of dry hydrogen, to remove any oxygen which might have diffused into the hydrogen during electrolysis; (2) a liquid-air tube; (3) a calcium chloride tube for preliminary drying; and (4) phosphoric oxide for final drying.

*Water Vapour.*—To obtain an admixture of water vapour in desired proportion with the combustible gases, dilute sulphuric

\* The paper just published by Garner and Roffey (J., 1929, 1123) on "The Effect of the Addition of Hydrogen and Water on the Radiation emitted from the Carbon Monoxide Flame" is of great interest in relation to our own experiments.

acid was used, 1 c.c. of the liquid being passed into the eudiometer by means of a bent pipette, and the temperature at which the tube must be kept to maintain the required vapour pressure was calculated. The vapour-pressure values used were taken from Regnault's tables; although doubt has been thrown upon his values at such high concentrations, it is believed that they are not so inaccurate as to invalidate the conclusions drawn from these

FIG. 1.

150 c.c., (B) 2 c.c., (C) 12 c.c., and a fourth tube (H) of approximately 100 c.c. capacity. The apparatus was cleaned with chromic acid mixture, washed with distilled water, steamed out for some hours, and dried by the passage of hot dry air, the apparatus itself being heated wherever possible.

After calibration of the graduated tubes, the apparatus was dried finally and filled with freshly distilled mercury. The carbon monoxide and oxygen were mixed in the required proportion in the large tube A by connecting the apparatus at X successively to the two generating apparatus. From this mixture the required

experiments. Careful tests showed no measurable evolution of gas from the contact of the diluted acid with mercury under all the conditions of the experiments.

*Phosphoric Oxide.*—The phosphoric oxide used was prepared by redistillation in a current of oxygen, and was shown to be of a high degree of purity. For some of the earlier experiments, highly purified material kindly supplied by Sir Richard Threlfall, F.R.S., was used.

*Ignition Arrangements.*—The gas mixture was subjected to a spark from the secondary of an induction coil run at a constant voltage.

*Gas Storage and Dilution Apparatus.*—The gases were collected and mixed in the proportion of 2 vols. of carbon monoxide to 1 vol. of oxygen in the apparatus shown in Fig. 1. This consisted of three graduated tubes of approximate capacities (A)

volume for an experiment was withdrawn into the graduated tube C, where it was exactly measured, before being passed through B and the delivery tube into the eudiometer.

As accurately known, very small volumes of hydrogen were required in the experiments, this gas was first mixed in measured proportion with a large volume of carbon monoxide-oxygen mixture and then added in small quantities to the main bulk of the two gases used in an experiment. This was carried out by filling the narrow-bore tube B with pure hydrogen and passing any desired volume of it into the carbon monoxide-oxygen mixture in A. After allowing time for complete admixture, the diluted hydrogen was passed into H for storage.

*Explosion Tubes.*—The experiments were carried out in glass eudiometers of approximately 1.5 cm. internal diameter with platinum wire electrodes. The gap between the electrodes was fixed and measured under a travelling microscope.

The eudiometers were cleaned as previously described, and carefully dried by the passage of purified, dry air while the ends were heated strongly.

To remove occluded gas in the electrodes, sparks were passed across them for some hours while a current of pure, dry oxygen was passed through the eudiometers. They were then filled with freshly distilled mercury, which was immediately replaced by a known volume of the gas mixture from the storage apparatus.

As the eudiometers had to be water-jacketed during an experiment, it was necessary to insulate the junctions of the electrodes with the leads. This was done in the earlier experiments by fitting vertical glass tubes with their ends bent suitably to cover the projecting loops of the electrodes, the junction being held and covered by a ring of rubber tube. These vertical tubes were filled with mercury and the leads dipped into their open ends. In the later experiments, the projecting ends of the electrodes were protected with enamel beads to which rubber tubes were attached as shown in Fig. 2. By attachment of a second limb of tubing, as a levelling tube, to the mouth of the eudiometer, and adjustment of the mercury column in it, atmospheric pressure was secured in the gas mixture. The ends of the levelling tubes were closed with rubber caps during the sparking to prevent scattering of the mercury.

*Temperature Control.*—The arrangements for temperature control are shown in Fig. 3. The eudiometers were fixed in inverted bell-jars which served as water-jackets, and water flowed into these continuously from a thermostat reservoir.

*Procedure.*—In each experiment one eudiometer, containing only carbon monoxide and oxygen in combining proportion and phos-

phoric oxide, was used as a control. Immediately upon charging the first eudiometer a second was taken, and to it was added the gas mixture containing a known small quantity of hydrogen. A small stick of compressed phosphoric oxide was passed up this tube and floated on the mercury surface. (The volume of the stick was about 1 c.c., and the entangled air not more than 0.1% of the total volume of gas in the eudiometer.) In a third eudiometer containing the carbon monoxide-oxygen mixture, 1 c.c. of suitably diluted sulphuric acid was brought on to the mercury surface by means of a bent pipette. The eudiometers so arranged were allowed to stand for at least 10 days, and if a spark then failed to fire the mixture in the control eudiometer, the experiment was

proceeded with. The water-jackets of the two other eudiometers were connected with the thermostat reservoir and kept at a temperature sufficient to give in the third eudiometer a concentration of water vapour molecularly equal to that of the hydrogen in the second eudiometer. After 3 days had been allowed for the attainment of liquid-vapour equilibrium, the electrodes of the two eudiometers were connected in series to the coil and a single spark was passed. If this failed to produce ignition in either tube, sparking was continued for some seconds.

### Results.

The results of the first two series of experiments are in Tables I and II, those in Table I, which were made at Leeds, being merely preliminary. It was, of course, sought in each experiment to have

equal volumes of the carbon monoxide-oxygen mixture for trial with equal hydrogen and water additions. The exact measurements of these volumes with hydrogen and water vapour respectively in each experiment show such a close approach to equality that, to avoid complicating the table, a mean figure is used.

8.	5.50	0.058	80.5%; 30.2	10		
9.	7.45	0.032	81.7%; 20.0	23		No ignition

Table I indicates that below approximately 0.04% of catalyst there is a difference in the effects of hydrogen and water vapour. From Table II, it is seen that with proportions of both hydrogen and water vapour throughout the range of about 0.03 to 0.06% the hydrogen alone conferred ignitability, except in Expt. 9, where there was no ignition in either tube. This value is slightly higher than that found in the preliminary experiments. The difference may well be due to the different sparking conditions, for a different sparking coil was used. Also, in the earlier experiments (Table I) the pressure was only approximately atmospheric and varied slightly in the two tubes.

*Minimum Proportions of Hydrogen and Water Vapour required to permit Spark Ignition.*—It will be seen in Expt. 9 of Table II that, when the concentration of hydrogen had been reduced to 0.032%, the mixture no longer ignited. This observation was verified, and an attempt was made to ascertain the limit more closely by beginning with a mixture containing approximately 0.02% of hydrogen and adding further small quantities of hydrogen.

Table III gives the results, from which it appears that the 0.032% of Expt. 9 was in fact about the limiting concentration.

TABLE III.

Volume, c.c.	Hydrogen, %.		Temp.	Press., mm.	Time of drying.
	No ignition.	Ignition.			
7.2	0.023	0.033	18°	760	18 days

7.3	0.018	0.032	17	760	19 „
4.63	0.018	0.038	19	768	3 months

An attempt was also made to discover the limiting concentration of water vapour that determined ignitability. This was done by a step-wise elevation of the temperature of a submerged eudiometer containing the gas mixture and diluted sulphuric acid. The results given in Table IV show that the limiting concentration is approximately 0.12% of water vapour.

TABLE IV.

Volume of gas, c.c.	Conc. of H <sub>2</sub> SO <sub>4</sub> , %.	Time, days.	Press., mm.	Temp. between which igni- tion occurred.	Equivalent percentage of water vapour.
6.3	80.5	110	765	34—39.6°	0.12—0.14
4.8	80.5	103	768	32—36	0.10—0.13
4.9	80.5	100	768	32—36	0.10—0.13
7.45	82.4	143	775	36—42	0.07—0.12

In the experiments described in the foregoing pages, the drying of the gas mixtures used was not carried to an extreme degree. It has been shown by Baker (J., 1902, 81, 7, 400) that considerably more thorough drying is necessary to prevent the combination of hydrogen and oxygen than that of carbon monoxide and oxygen. It seemed desirable, therefore, to find whether the catalysing influence of hydrogen on the combination of carbon monoxide and oxygen would be affected by a more thorough drying of the gas mixture. Experiments were accordingly carried out in the same way as those already described, but with considerably more intense and prolonged drying of the apparatus, as rapid filling as possible, and more protracted exposure of the gases to phosphoric oxide. The results are in Table V.

TABLE V.

	Volume of gas, c.c.	% Volume of hydrogen.	Time of drying.	Result of first sparking.	Sparking on addition of undried air.
1.	4.5	0.043	12 weeks	No ignition	Ignition
2.	4.2	0.040	19 „	No ignition	Ignition
3.	4.2	0.042	20 „	No ignition	Ignition

Since in all cases the admission of a small bubble of undried air to these mixtures made them ignitable by the spark, it appears from these experiments that the catalytic action of hydrogen is conditioned by the presence of a minimal quantity of water vapour.

*Variation of Electrodes.*—With a view to find whether a change in the material of the electrodes would reveal anything of interest, eudiometers were made with electrodes of copper, nickel, silver, and gold. After the usual experimental procedure, it was found in all cases that the results were the same as those obtained by the use of the eudiometers with platinum electrodes. In these experiments, the difficulty of sealing metals directly into glass was overcome by the use of seals of "red platinum" (copper deposited electrolytically on a nickel alloy).

*General Observations on the Results.*—It is, of course, to be understood that the significance of the numerical results recorded in this paper may be considerably restricted by the particular conditions of the experiments. Slight variation in procedure and especially in the conditions of spark ignition may be suspected to have far-reaching effects. Experiments now in progress have shown that the effective proportion of the catalyst gases varies considerably with the length of the spark gap and the character of the discharge. But, working within the conditions described, precautions have been taken to interchange the eudiometers used respectively for the hydrogen and the water vapour additions, and to change the material of the electrodes.

### *Summary.*

A comparison has been made of the relative influence of hydrogen and water vapour on the ignitability of a mixture of carbon monoxide and oxygen by the spark discharge. To the purified gases, mixed in combining proportions and contained in two eudiometers, hydrogen and water vapour were added in equivalent proportion, and after time had been allowed for admixture a spark was passed simultaneously in series through each mixture.

It appeared in the first instance, when the drying of the carbon monoxide-oxygen mixture had not been greatly prolonged, that hydrogen was more effective than water vapour in conferring ignitability. Through a range of concentrations varying from approximately 0.03 to 0.06%, hydrogen was effective, whilst water vapour was not. An estimation of the minimum quantities necessary gave 0.03% for hydrogen and 0.12% for water vapour. These figures are not to be taken as absolute values, for they are affected by the particular conditions of the experiments.

In later experiments with more intensive drying of the com-

bustible mixture, it was found that the activity of the hydrogen was altogether inhibited. In other words, the superior catalytic effectiveness of hydrogen just described was in its turn conditioned by the presence of a minimal quantity of water vapour. It may equally well be said, alternatively, that in the presence of hydrogen a minimal quantity of water sufficed to confer ignitability.

These results are in harmony with our earlier observations and with those of other workers.

[Received, November 27th, 1929.]

## XXVI.—*The Effect of Hydrogen-ion Concentration on the Electrode Potential of Iron.*

By A. L. MCAULAY and GEOFFREY L. WHITE.

CORROSION of iron in practical cases is almost entirely due to the electrolytic effect of currents flowing between points on its surface which are in different electrical conditions. A trace of moisture on the surface is sufficient to permit corrosion to take place in this manner. The existence of such differences in electrode potential is known to be caused to a great extent by differences in exposure to oxygen of adjoining regions in the corroding iron. It is also known that the electrode potential of iron varies greatly with other external conditions, and it is important to know what effect the variation of some of these conditions will produce. The two most powerful factors in determining the behaviour of a corroding iron surface are (i) exposure to oxygen, and (ii) the hydrogen-ion concentration of the electrolyte causing corrosion.

It was thought that an investigation of the electrical behaviour of iron surfaces under varying conditions of  $p_H$  would give information of fundamental importance, provided that the initial difficulties in the realisation of a standard reproducible state could be overcome. It was further hoped that, with rigorously simplified conditions, results of theoretical interest might be obtained which would throw light on the general mechanism of the production of electrode potentials.

A previous investigation (McAulay and Bastow, J., 1929, 85) led to the recognition of a standard condition in neutral solutions, and gave the results of varying the degree of exposure to oxygen of a surface brought to this standard state. The present paper is mainly concerned with an investigation of the effect of varying hydrogen-ion concentration on electrode potential in an air-free solution. The results differed according to the anion present, but

were completely reproducible with the two anions (chloride and phosphate) investigated. Further experiments were carried out in solutions in a normal state of aeration; here no attempt was made to obtain accurate quantitative reproducibility, but certain large-scale effects are described which were qualitatively reproducible. In particular, conditions were observed where, with an extremely small change in  $p_{\text{H}}$ , a very great change in electrode potential was brought about.

#### EXPERIMENTAL.

The apparatus and experimental technique for obtaining an iron electrode in an air-free solution and for measuring its potential were the same as in the previous paper (*loc. cit.*). *M/5*-Solutions of potassium chloride and potassium phosphate were used, and the  $p_{\text{H}}$  was lowered by adding to each its appropriate acid, or raised by adding sodium hydroxide. The  $p_{\text{H}}$  naturally altered when the unbuffered solutions in the neighbourhood of neutrality were boiled; and it also changed, when on the acid side, owing to dissolution of oxide from the electrode. The solution was tapped and the  $p_{\text{H}}$  measured when equilibrium had been reached and the electrode was at a steady potential. The  $p_{\text{H}}$  measurements were made by the use of appropriate indicators standardised by solutions of the B.D.H. Universal Buffer, which were in their turn standardised with a hydrogen electrode, as it was found that they changed considerably with time. Some difficulty was experienced in obtaining steady conditions when the electrolyte was alkaline, probably owing to a decreasing tendency for destruction of the oxide film formed on the electrode before immersion. Up to a  $p_{\text{H}}$  of about 10, this difficulty could be overcome by the passage of a quantity of electricity of the order of 100 millicoulombs to the electrode as cathode. The electrode would in these conditions polarise to a high negative potential (of the order of 1.0 volt on the saturated calomel scale) and, when this polarisation had disappeared, would be found to be in a steady reproducible condition. The inconsistency between this effect of current and that found in the case of neutral solutions described in the earlier paper is a real one, and it is intended to make this and certain other peculiarities the subject of further investigation.

At higher alkalinity than  $p_{\text{H}}$  10, it was not possible to bring iron to an electrically reproducible state. The electrode then showed all the features associated with the presence of a film of oxide, gradually drifting to an indeterminate potential of the order of  $-0.4$  on the standard calomel scale.

## Results.

(a) *In air-free solutions.* Fig. 1 shows the relation between  $p_H$  and equilibrium electrode potential of pure iron\* against the saturated calomel electrode. Fig. 1(a) represents points given by potassium chloride and Fig. 1(b) those given by potassium phosphate. The solution was  $M/5$  in anion concentration, with the exception of the most acid point on the chloride curve and of the two check points A and B in Fig. 1(a).

FIG. 1 (a).

Equilibrium potentials (saturated calomel scale) in  $N/5\text{-KCl}$  (point A, electrolyte =  $N/100\text{-Cl'}$ ; point B, electrolyte =  $4.2N\text{-Cl'}$ .)

These final equilibrium potentials required very different times for their establishment. The rise in the extreme alkaline region was very slow indeed, and the slightest trace of oxygen would prevent an equilibrium potential being reached, presumably owing to the formation of an oxide film which caused the potential to drift to a more positive value than the equilibrium potential. Difficulties of a different sort were encountered in the acid region, where the potential tended to become unsteady at a higher value than the equilibrium potential. In the neutral region with chloride solutions, difficulty was experienced in maintaining the  $p_H$  constant and in measuring its true value in the cell. Occasionally, in

\* The iron electrodes were supplied by Hilger and the following analysis given: Sn, 0.02; Pb, 0.001; As, 0.005; P, 0.010; Mn, 0.031; Mo, 0.05; Cu, 0.04; Ni, 0.007; Cr, 0.016%; Si and Sb, traces; Al, Mg, Ca, Ti, V, none; Co is not mentioned.

making check experiments, an indicator was introduced into the cell.

It will be seen that in each case the relation between  $p_H$  and equilibrium electrode potential is expressed fairly exactly by a pair of straight lines, the one of less slope in the alkaline region being the same for both anions, but that in the acid part being specific for each anion. A tentative explanation is attempted later.

FIG. 1 (b).

Equilibrium potentials (saturated calomel scale) in  $M/5$ -phosphate solutions.  
[The broken lines are reproduced from Fig. 1 (a).]

In order to test whether the concentration of the anion had any effect on the potential at a given  $p_H$ , experiments were made with concentrations of  $N/100$ - and of  $4.2N$ -potassium chloride [points A and B, respectively, Fig. 1(a)]. In both cases the equilibrium values are seen to be practically on the curve, although peculiarities were noticeable in their establishment.

(b) *In solutions not rendered air-free.* The behaviour of electrodes in such solutions was so complicated that no standard quantitative work was attempted. Certain large-scale effects were observed, however, which seem to be of importance. In phosphate solutions, a definite critical  $p_H$  exists (between 7.5 and 8.5) on the alkaline side of which the equilibrium potential of a freshly-ground electrode starts at about  $-0.31$  (saturated calomel scale) but falls in about 10 mins. to about  $-0.3$ , at which it remains constant; on the acid

side, however, the potential rises rapidly to the neighbourhood of  $-0.8$  and then remains constant. In chloride solutions no such critical  $p_H$  for equilibrium potentials exists: for solutions as alkaline as  $p_H 9$  the potential very slowly drifts to a value near  $-0.7$ .

### *Discussion of Results.*

(a) *Air-free Experiments.*—The following tentative theory is advanced to explain the results shown in Fig. 1. The steeper straight line on the acid side of the curve represents the deposition of hydrogen by direct replacement of iron, the electrode in this region behaving directly as a hydrogen electrode with high negative potential due to overvoltage. This theory views the deposition of hydrogen as similar to its electrolytic deposition. The stream of ferrous ions leaving the metal and balancing the positive current caused by the hydrogen is thought to have no effect on the overpotential. Experiments on the simultaneous deposition of metal and hydrogen ions suggest that this should be the case (McAulay and Bowden, *Phil. Mag.*, 1926, **1**, 1282).

This theory immediately accounts for the fact that the slope of the line is less than  $0.057$  volt per  $p_H$  unit, for hydrogen evolution is more rapid the higher the concentration of the acid. It also accounts for the different lines obtained with chloride and phosphate. In the first case, deposition takes place at a clean iron surface, and in the second, at a surface of insoluble ferrous phosphate, and the overvoltage would be expected to have a different value.

There seems considerable difficulty in explaining the less steep straight line representing the more alkaline part of the curve, where evolution of bubbles does not take place. It is thought that it is determined by hydrogen overpotential and that the iron is effectively a hydrogen electrode. If the potential were determined by ferrous ions depositing on a clean iron surface, it would be at least  $0.2$  volt more negative than that observed; while ferric ions would be deposited till a concentration of less than  $10^{-15}N$  was left in solution before they could be in equilibrium with an iron surface at this potential. The electrode cannot be acting as an oxidation-reduction electrode for ferrous and ferric ions, for the concentration of ferric ions at such a potential would have to be of the order  $10^{-20}$  of that of the ferrous ions. It is impossible to conceive of such minute traces of an ion in the electrolyte determining the potential of the electrode when there is nothing to prevent the solution of ferrous ions from the iron. It appears probable, therefore, that hydrogen determines the electrode potential.

Another possibility is that the electrode surface throughout this part of the curve is in a different condition from that in which

there is direct replacement of iron by hydrogen, and that it has not the character of a clean iron surface. Possibly, the observed potential is characteristic of the equilibrium between ferrous ions in the solution and ferrous ions in some oxide lattice on the electrode surface. It is hoped that experiments with other metals will afford information as to the reason for this different slope.

(b) *Experiments in Solutions not rendered Air-free.*—The explanation of the qualitative results observed with these solutions is believed to be as follows. In the case of the phosphate, the definite positive potential obtained at  $p_H$  values greater than 8.5 is due to the formation of an oxide skin which the feeble disintegrating powers of the phosphate ion are unable to destroy. The negative potential obtained at smaller  $p_H$  values is believed to be due to the formation of a film of insoluble ferrous phosphate. The chloride ions, on the other hand, have a powerful disintegrating effect on the oxide film, and the final potential observed in aerated solutions is the result of the opposing effects of destruction of the film by chloride ions and its repair by dissolved air. Experiments with potassium sulphate indicated a much less energetic disintegration of the film by sulphate ions than by chloride ions.

#### *Summary.*

Examination of the electrode potentials of pure iron in air-free solutions of various  $p_H$  containing potassium chloride or phosphate has led to results of a standard and reproducible nature, which should provide a foundation for work of a more directly practical nature where conditions are necessarily more complicated. The curves showing the relation between  $p_H$  and equilibrium potential split up into two straight lines of different slope, and a discussion of these is attempted.

Experiments have also been made with solutions not rendered air-free, and a very marked discontinuity of the curves has been observed in the case of the phosphate solutions.

In conclusion, our best thanks are due to the Commonwealth Council for Scientific and Industrial Research for the generous grant that we have received from them which has made it possible to carry out the work described in this paper. In addition, attention is drawn to an oversight in a previous paper on this subject (J., 1929, 85), where it was intended to make a similar acknowledgment of an earlier grant made for the same purpose by the C.S.I.R.

## XXVII.—*The Pyrophosphate Method for the Determination of Magnesium.*

By STANKO STANKOV MIHOLIĆ.

It is known that in the determination of magnesium as pyrophosphate great care is necessary to obtain a precipitate of the composition  $\text{MgNH}_4\text{PO}_4$  (Epperson, *J. Amer. Chem. Soc.*, 1928, **50**, 321) and that it is necessary to ensure that ignition yields pure magnesium pyrophosphate free from organic matter. Various devices for obtaining the product white have been suggested (McNabb, *ibid.*, p. 301; Hillebrand, *Bull. Geol. Survey, U.S.A.*, 1919, **700**, 151), but Epperson has shown that these expedients are of little value. Since platinum crucibles are expensive and may be damaged, it is desirable to utilise porcelain or sintered-glass crucibles. In this case, however, lower temperatures of ignition must be used. Theoretical considerations lead to the conclusion that the temperature necessary for a complete dissociation of  $\text{MgNH}_4\text{PO}_4$  cannot be so high as hitherto used, viz., 900—1200°. Most ammonium salts dissociate below 500°, and ortho- is transformed into pyro-phosphoric acid at or below 250°. Moreover, it is a common experience that the charring of organic material is the more complete, and the ash the whiter, the lower the temperature used. Further, McNabb (*J. Amer. Chem. Soc.*, 1927, **49**, 1451) has shown that the analogous dissociation of magnesium ammonium arsenate is complete at 500—600°. An attempt was therefore made to ignite magnesium ammonium phosphate at as low a temperature as possible, and 480° was chosen as being probably the most suitable.

### EXPERIMENTAL.

For filtration, the sintered Jena-glass crucibles used (No. 3, with an average pore diameter of 20—30  $\mu$ ) were very satisfactory: one of them was used 50 times, and is still in use, showing only a slight corrosion and having lost only 0.021 g. owing to repeated cleaning with concentrated hydrochloric acid.

The tests were made with *N*/20-solutions of magnesium chloride or sulphate as standard. The magnesium content of the former was checked by evaporation with yellow mercuric oxide, ignition, and weighing as magnesium oxide, or by evaporation with sulphuric acid and weighing as magnesium sulphate; for the latter standard, only the second method was used, the other method being impracticable. As the magnesium sulphate solution was slightly too concentrated, corrected values for the calculated amount of pyrophosphate were substituted in Tables II and III.

The details of the estimation were as follows. To a measured amount of the solution, diluted with 200 c.c. of water, were added 3 drops of concentrated hydrochloric acid and then a filtered solution of 0.5 g. of ammonium chloride and 1 g. of ammonium phosphate in 20 c.c. of water containing 2 or 3 drops of a 1% alcoholic solution of phenolphthalein. The mixture was heated to boiling, and aqueous ammonia was added slowly drop by drop until the colour remained pink after prolonged stirring, followed by 50 c.c. of ammonia solution ( $d$  0.96) while the mixture was still hot. After standing over-night, the liquid was filtered through a sintered-glass crucible, the precipitate washed with about 50 c.c. of 2½% ammonium hydroxide solution, heated in an electric oven at 480° for 2 hours, and weighed. Subsequent heatings at the same temperature and weighings showed that the precipitate had attained constant weight in the first heating: it was a light snow-white powder. The results are in Tables I, II, and III.

Average error, +0.21%.

Tables II and III show that scarcely any alteration is effected by reprecipitation of the double phosphate.

In order to ascertain whether the conversion into pyrophosphate was complete at  $480^\circ$ , 0.2 g. samples of the pyrophosphate obtained were heated for  $\frac{1}{2}$  hour in a platinum crucible by a blast burner; the powder sintered to a hard crumbly mass, but the losses in four cases were 1.7, 1.7, 1.3 and 1.4 mg., giving an average of 1.5 mg. or 0.75%.

The method described above proved satisfactory in a long series of determinations of magnesium in mineral waters.

## XXVIII.—*The Absorption Spectra of Diphenyl and Some Derivatives.*

By THOMAS C. C. ADAM and ALFRED RUSSELL.

IN connexion with the relations between the constitution of organic compounds and their absorption spectra, it was shown (Baly, Edwards, and Stewart, J., 1908, **93**, 1902) that the seven-banded absorption spectrum of benzene can be explained by Collie's oscillation theory (J., 1897, **71**, 1013) for the structure of the benzene molecule on the assumption that each band corresponds to a make-and-break of valency. The spectrum of naphthalene was discussed in a similar manner (Baly and Tuck, J., 1906, **89**, 514) and found to be in agreement.

In the course of the following work, the resemblance manifest between the spectra of diphenyl and of its derivatives has led to a corresponding theory for this hydrocarbon. Since one carbon atom of each nucleus is bound, no valency oscillation involving only two carbon atoms can take place, nor is an oscillation

involving all six carbon atoms possible. Three types of pulsation remain :

FIG. 1.

If the appearance of a band in the spectrum is to indicate a make-and-break of valency, then only one of these is possible. The same band is shown by the 4-derivatives as by diphenyl itself, an indication that the pulsation of the molecule does not include the carbon atom in the 4-position; that is, the oscillation of valency is taking place as in (II). The spectroscopic evidence thus points to the existence of a virtual para bond in the diphenyl molecule making the

4-carbon atom the stable member of the ring. The spectra obtained for the 2-derivatives bear out the theory in the following respects:

(1) The 4-carbon atom being partially bound by a virtual bond, any electronic disturbance which includes this atom will be small compared with the typical disturbance, and the resulting band will

be absorbed in the typical band.

(2) If the main pulsation is suppressed by a 2-substituent, then selective absorption will be eliminated, except in so far as the 4-carbon atom is free to oscillate. In practice, 2-nitrodiphenyl shows one shallow band, and the heavily substituted 2-2''-diphenyldiphenyl shows a band still shallower.

#### EXPERIMENTAL.

The solvent employed was, in most cases, spectroscopically pure ethyl alcohol. For 4-diphenyldiphenyl and 4'-nitro-4-diphenyldiphenyl, it was necessary to employ redistilled A. R. chloroform owing to the low solubility in alcohol.

The spectra were photographed with a Hilger Model 3 all-quartz ultra-violet spectrograph with rotating sector attachment. The persistence of the band is taken as being the difference between the extinction coefficients of the head of

the band and of that frequency, towards the violet end, where complete transmission is obtained.

*Diphenyl*, m. p. 70.5°. The spectrum shows a deep well-defined band with its head at  $\nu$  4063 (see Fig. 1), in good agreement with the measurement of Baly and Tryhorn (J., 1915, 107, 1058), who examined the spectrum of a thin film of diphenyl.

*4-Nitrodiphenyl*, m. p. 113°. Substitution of a nitro-group for hydrogen has moved the head of the band towards the red to  $\nu$  3259.

FIG. 2.

*4-Aminodiphenyl*, m. p. 53°. The amino-substituent has the effect of broadening the band. The size and mass of the group being less than in the previous instance, the band head has not been shifted to the same extent, maximum absorption occurring at  $\nu$  3590.

*4-Aminodiphenyl hydrochloride*. The reduction of reactivity consequent on the formation of the hydrochloride brings about a considerable decrease in the persistence of the absorption, in this case from 224 to 64 units. The head of the band has also moved back towards the ultra-violet to  $\nu$  3720.

*4-Fluorodiphenyl*, m. p. 74.5°. As might be expected, the entry into the diphenyl molecule of a small light atom such as fluorine has no appreciable effect on the absorption (see Fig. 2).

*4-Chlorodiphenyl*, m. p. 75.5°. In this case, the greater size and mass of the chlorine atom has shifted the position of maximum absorption to  $\nu$  3979. The band is also more persistent, although the configuration of the curve is unaltered.

*4-Bromodiphenyl*, m. p. 89°. Replacement of chlorine by bromine has the effect of moving the head of the band to  $\nu$  3892.

*4-Diphenyllyldiphenyl*, m. p. 260°. Spectroscopically, at least, this compound acts as a heavily substituted diphenyl. The band, while retaining the characteristics of the diphenyl band, is shallower with a persistence of 172. The head has moved well up towards the red, occurring at  $\nu$  2965.

*4'-Nitro-4-diphenyllyldiphenyl*, m. p. 274°. Although no definite band is shown, there is evidence of a very shallow band about  $\nu$  3050.

*2-Nitrodiphenyl*, m. p. 36°. The feeble valency oscillation per-

FIG. 3.

*4-Diphenyllyldiphenyl*

*4'-Nitro-4-diphenyllyldiphenyl*

*2-Nitrodiphenyl*

*2-2''-Diphenyllyldiphenyl*

missible in a 2-substituted diphenyl is demonstrated in this case by the appearance of a very shallow band at  $\nu$  3350.

2-2''-Diphenylaldiphenyl, m. p.  $185^\circ$ . In conformity with the theory, the selective absorption shown by this compound is small, a very shallow band with its head at  $\nu$  3550 being obtained.

We are grateful to Messrs. Imperial Chemical Industries for a grant defraying the cost of the work.

XXIX.—*Studies in Keto-lactol Tautomerism. Part IV. Chemistry of 5-Acetyl-1:1:2-trimethylcyclopentane-2-carboxylic Acid. Observations on the Constitutions of the Acid Esters of Camphoric Acid, and a Synthesis of Homoepicamphor.*

By MUHAMMAD QUDRAT-I-KHUDA.

IN extending the study of ring-chain tautomerism of the keto-lactol type (I and II) to keto-monocarboxylic acids, it was suggested (J., 1929, 205) that the evidence of the existence of the hydroxy-phase of such acids would be obtained more readily by an investigation of  $\delta$ -keto-monocarboxylic acids having substituents at the  $\beta$ - and the  $\gamma$ -carbon atom. The  $\delta$ -keto-acids derived from the acid esters of camphoric acid fulfil this condition and their behaviour has been examined.

*ortho*-Methyl hydrogen camphorate (III) and *allo*-methyl hydrogen camphorate (IV), m. p.  $77^\circ$  and  $86^\circ$  respectively, when converted

into their acid chlorides and acted on by zinc methyl iodide under parallel conditions, gave, not methyl 2-acetyl-1:1:2-trimethyl-

cyclopentane-5-carboxylate (V, from III) and methyl 5-acetyl-1:1:2-trimethylcyclopentane-2-carboxylate (VI, from IV), but only one keto-ester; the semicarbazones obtained from specimens prepared from both sources melted, separately or mixed, at the same temperature.

The fact that only one keto-ester was obtained from the isomeric acid esters suggested that these were structurally identical and differed only in the spatial arrangement of the groups: this view was supported by the results obtained on brominating the acid chlorides produced from the two acid esters. Both chlorides absorbed bromine with almost equal ease and the products isolated after the reaction mixture had been poured into methyl alcohol were methyl camphanate (IX),  $\omega$ -bromocamphoric anhydride (X), and small quantities of the bromo-ester (VIII) and camphanic acid. These facts, particularly the production of the bromo-ester (VIII), suggest that the *allo*- and the *ortho*-acid ester both have the carboxyl group attached to a tertiary carbon atom and that the bromination proceeds in the normal way; the intermediate product ultimately loses methyl bromide and methyl chloride, giving the ester of camphanic acid and bromo-camphoric anhydride:

The structural identity of the two acid esters is rendered very probable by the fact that, when the *ortho*-acid ester (m. p. 77°) is converted into the acid chloride by heating with thionyl chloride and then treated with water, the product obtained melts at the same temperature as *allo*-methyl hydrogen camphorate; its crystalline structure is identical with that of the latter and there is no depression of the melting point of a mixture of the two compounds.

In view of these facts the work of Walker and his collaborators (Walker, J., 1893, **63**, 495; Walker and Henderson, J., 1895, **67**, 337; Walker and Cormack, J., 1900, **77**, 374), Noyes and Blanchard (*Amer. Chem. J.*, 1901, **26**, 285), and Haller and Blanc (*Compt. rend.*, 1905, **141**, 697) requires revision, which is being undertaken.

Camphoraldehydic acid (XI) (Bredt, *J. pr. Chem.*, 1917, **95**, 63), when heated with acetic anhydride, gives an acetoxo-derivative

(XIII), the reaction taking place with the isomeric hydroxy-lactonic form (XII) of the aldehydic acid.

The keto-acid (XIV) shows similar properties.

The ester (VI) on treatment with alcoholic potassium hydroxide gave a mixture of two solids, *viz.*, the *keto-acid* (XIV) and a *diketo*-compound (XVII), and a liquid substance, which was apparently the hydroxy-lactonic form (XVIII) of the keto-acid (XIV). The same keto-acid appears to have been obtained by Winzer (*Annalen*, 1890, 257, 298) from the product of hydrolysis of camphorylmalonic ester (XV). On treatment with semicarbazide acetate, the acid (XIV) gave a crystalline *semicarbazone* having the properties of the normal compound (XVI), whereas the liquid acid (XVIII) gave an

isomeric *substance*, of indefinite crystalline structure and very soluble in alcohol (compare the addition compound of Balbiano's acid and phenylhydrazine; Mahla and Tiemann, *Ber.*, 1895, 28, 2151), probably to be represented by the formula (XIX) :

When the keto-acid (XIV) or the hydroxy-lactone (XVIII) was treated with acetyl chloride, very little neutral product was obtained; the material was recovered in a *hydrated* form (XX), which was converted into the keto-acid (XIV) on drying. Both the keto-acid and the hydroxy-lactone, however, when treated with acetic anhydride, were converted into the same unsaturated *lactone* (XXI), which still exhibited optical activity although one of the two asymmetric carbon atoms had lost its asymmetry.

The keto-acid (XIX), on reduction with sodium and alcohol, gave *methylcampholide* (XXII): the introduction of the third asymmetric carbon atom changed the direction of rotation from dextro to lævo.

The keto-ester (VI), when heated with alcoholic sodium ethoxide, was converted into the diketo-compound (XVII), which, as already mentioned, was also obtained in small quantity by hydrolysis of the ester. The reduction of the diketo-compound by Clemmensen's method gave a waxy mass, with a strong camphoraceous odour, consisting of a ketone and a second substance. The ketone, produced in very small quantity, forms a *semicarbazone*, m. p. 220°, isomeric with the semicarbazone of homocamphor (XXIV), m. p. 250° (Lapworth and Royle, J., 1920, 117, 743), and is provisionally regarded as homocopicamphor (XXIII). The second substance is probably the keto-alcohol (XXV); it could not be obtained sufficiently pure for analysis.

Experiments are now in progress on the action of potassium cyanide on the lactone (XXII); it is also hoped to prepare the ketone (XXIII) and the keto-alcohol (XXV) in quantity in order to settle their constitutions.

#### EXPERIMENTAL.

*ortho*-Methyl hydrogen camphorate was prepared by Walker's method (*loc. cit.*). After crystallising twice from light petroleum (b. p. 40—60°), it melted at 77° and had  $[\alpha]_D^{25} + 53.94^\circ$  in 2.95% alcoholic solution.

*allo*-Methyl hydrogen camphorate was obtained by Walker's method (*loc. cit.*) by the partial hydrolysis of methyl camphorate, prepared by a method based on the one used by Frankland and Aston (J., 1901, 79, 517) for the esterification of tartaric acid and also by the method recommended by Haller and Blanc (*loc. cit.*). After crystallising twice from petroleum (b. p. 60—80°), the *allo*-ester melted at 86° and had  $[\alpha]_D^{25} + 45.1^\circ$  in 4.3% alcoholic solution.

*Bromination of the Chloride of the allo-Ester.*—The acid ester (42 g.) was mixed with phosphorus pentachloride (41 g.). When the vigour of the reaction had abated, the mixture was heated at 75—80° for an hour, 12 c.c. of dry bromine were gradually added, and

the heating was continued for 4—5 hours. The excess of bromine was then evaporated and the reaction mixture was poured into methyl alcohol (150 c.c.) and heated on the steam-bath for some time. After most of the alcohol had evaporated, the residue was poured into water and shaken with ether. The extract was washed with sodium carbonate solution and dried, and the solvent removed. The residue, consisting of crystalline material mixed with a little oil (A), was triturated with petroleum. The solid then remaining was partly soluble in hot petroleum (b. p. 60—80°); on cooling, the solution deposited methyl camphanate, m. p. 110° after recrystallisation (Found: C, 62.1; H, 7.5. Calc. for  $C_{11}H_{16}O_4$ : C, 62.3; H, 7.5%), hydrolysis of which gave camphanic acid, m. p. 201° (compare Bredt, *Annalen*, 1913, 395, 39). The portion of the solid insoluble in hot petroleum crystallised well from chloroform, melted at 215° (Found: Br, 30.8. Calc. for  $C_{10}H_{13}O_3Br$ : Br, 30.7%), and had all the properties of Wreden's bromocamphoric anhydride (*Annalen*, 1872, 163, 332).

The oil (A) was recovered from the petroleum solution and distilled in a vacuum: a little methyl camphorate came over and then methyl bromocamphorate distilled at 162—164°/12 mm. with slight decomposition. The yield was very small and the bromo-ester was not pure (Found: Br, 25.0.  $C_{12}H_{19}O_4Br$  requires Br, 26.0%).

The above sodium carbonate extract on acidification gave an oil which, when hydrolysed with caustic soda, yielded camphoric acid and a small quantity of camphanic acid.

The products obtained in a similar way from *ortho*-methyl hydrogen camphorate were essentially of the same nature as the above.

*Conversion of ortho- into allo-Methyl Hydrogen Camphorate.*—The *ortho*-ester (7 g.) was treated with thionyl chloride (4 c.c.) at 70—75° for an hour, the excess of thionyl chloride then removed under reduced pressure, and the residue diluted with dry benzene (50 c.c.) and decomposed with water. The acid was extracted with dilute sodium carbonate solution, precipitated by acidification with hydrochloric acid, and extracted with ether. After drying and removal of the ether, the oily residue obtained partly solidified on cooling. The solid was separated from the oily impurities by trituration with petroleum and crystallised from the same solvent; it then melted at 86° (Found: C, 61.5; H, 8.6. Calc. for  $C_{11}H_{18}O_4$ : C, 61.7; H, 8.4%).

The *allo*-ester, when similarly treated, was recovered unchanged.

*Methyl 5-Acetyl-1 : 1 : 2-trimethylcyclopentane-2-carboxylate* (VI).—*ortho*-Methyl hydrogen camphorate was mixed with thionyl chloride (15 c.c.) and the acid chloride obtained after the removal of the

excess of thionyl chloride as stated above was cooled, diluted with an equal volume of dry benzene, and added to a cold solution of zinc methyl iodide prepared from methyl iodide (35 c.c.), ethyl acetate (18 c.c.), and zinc-copper couple (35 g.) in benzene solution in the usual way. The *keto-ester* was isolated by treatment of the solution with water and dilute sulphuric acid and subsequent removal of the solvent and treated with a slight excess of semicarbazide acetate in aqueous-alcoholic solution. The *semicarbazone*, after crystallising several times from alcohol, melted at  $198^{\circ}$  (Found: C, 58.0; H, 8.8.  $C_{13}H_{23}O_3N_3$  requires C, 58.0; H, 8.6%). When it (36 g.) was heated with 50 c.c. of concentrated hydrochloric acid and 150 c.c. of water on the steam-bath for  $2\frac{1}{2}$  hours, the ester separated as an oil. After cooling, this was taken up in ether, washed with dilute caustic soda solution, dried, and distilled in a vacuum, the *keto-ester* being obtained as a mobile colourless liquid with a characteristic odour, b. p.  $135^{\circ}/11$  mm.,  $d_4^{17}$  1.04555,  $n_D^{17}$  1.4733 (whence  $[R_L]_D = 56.91$ . Calc., 57.08),  $[\alpha]_D^{25} + 21.3^{\circ}$  in 2.2% alcoholic solution (Found: 67.9; H, 9.6.  $C_{12}H_{20}O_3$  requires C, 67.9; H, 9.4%).

The same semicarbazone was obtained from the *keto-ester* produced from *allo-methyl hydrogen camphorate* by a similar series of reactions.

*Hydrolysis of the Keto-ester (VI). Preparation of the Keto-acid (XIV) and the Hydroxy-lactone (XVIII).*—The *keto-ester* (14 g., purified through the semicarbazone) was heated with aqueous-alcoholic potassium hydroxide (16 g.) on the steam-bath for 18–20 hours, the alcohol evaporated, the residue diluted with water and extracted with ether to remove any unchanged ester, and the alkaline solution acidified with hydrochloric acid. After a day or two, the oil that had separated partly solidified. The solid was drained on porous plate and crystallised from petroleum (b. p.  $60$ – $80^{\circ}$ ). Feathery needles of the *diketo-compound* (XVII) described below separated first, and then the *keto-acid* (XIV) in well-formed rhombic plates, m. p.  $96^{\circ}$  after two recrystallisations (Found: C, 66.7; H, 9.3; *M*, by titration, 197.  $C_{11}H_{18}O_3$  requires C, 66.7; H, 9.1%; *M*, 198).

*5-Acetyl-1:1:2-trimethylcyclopentane-2-carboxylic acid* is very soluble in the ordinary organic solvents except light petroleum. It has  $[\alpha]_D^{25} + 99.1^{\circ}$  in about 2.3% solution in chloroform. The *semicarbazone* (XVI), crystallised from methyl alcohol, melts at  $225^{\circ}$  (Found: C, 56.8; H, 8.5.  $C_{12}H_{21}O_3N_3$  requires C, 56.5; H, 8.2%).

The oil absorbed in the porous plate (above) was extracted with ether, dried, and distilled in a vacuum; the somewhat viscous mass

obtained, b. p. 186—187°/14 mm., showed no tendency to solidify (Found: C, 66.8; H, 9.1%). The oil was slowly attacked by dilute sodium bicarbonate solution. After treatment with semicarbazide acetate in dilute methyl alcohol, it gave on dilution a gummy mass which gradually solidified: by slow evaporation of a solution of the solid in hot dilute methyl alcohol, a substance of indefinite crystalline structure was obtained. This was dried in the air, washed with benzene to remove a small quantity of colouring matter, and dried over sulphuric acid in a vacuum desiccator; it then melted at 172° and decomposed at a higher temperature. The substance (? XIX) is isomeric with the semicarbazone (XVI) (Found: C, 56.8; H, 8.3%). It dissolves slowly in dilute sodium hydroxide solution and is recovered on acidification.

*Behaviour of the Keto-acid (XIV) and the Hydroxy-lactone (XVIII) towards Acetyl Chloride.*—Either of the acids (3 g.) was heated with excess of acetyl chloride (8 c.c.) on the steam-bath for a few hours, the acetyl chloride then evaporated, and the residue treated with water; the oil produced was dissolved in ether and shaken with dilute sodium carbonate solution. The neutral product gave only a trace of the unsaturated lactone described below. The alkaline extract on acidification gave an acid, which crystallised from hot water in shimmering plates, m. p. 73°; after being dried in the air for a day, it was analysed (Found: C, 60.9; H, 9.5; *M*, by titration, 215.5.  $C_{11}H_{20}O_4$  requires C, 61.1; H, 9.3%; *M*, 216). The acid is the hydrated form (XX) of the keto-acid (XIV) and is converted into this acid on being dried in a desiccator.

*Action of Acetic Anhydride on the Keto-acid (XIV) and the Hydroxy-lactone (XVIII).*—Either compound (5 g.) was refluxed with acetic anhydride (5 c.c.) for 2 hours, and the product distilled; the unsaturated lactone (XXI) passed over at 136°/22 mm. and solidified in the receiver. The lactone, m. p. 62°,  $[\alpha]_D^{25} + 77.7^\circ$  in a 3.3% solution in chloroform (Found: C, 73.1; H, 8.9.  $C_{11}H_{16}O_3$  requires C, 73.3; H, 8.8%), is extremely soluble in almost all organic solvents. It absorbs bromine very readily in chloroform solution.

*Methylcampholide (XXII).*—To a boiling solution of the keto-acid (XIV) (4.5 g.) in absolute alcohol (20 c.c.), sodium (5 g.) was added, followed by 75 c.c. of alcohol in three instalments during 2 hours' additional heating. The alcohol was evaporated on the steam-bath, and the residue diluted with water and acidified with concentrated hydrochloric acid. The oil obtained crystallised after the usual treatment with ether and dilute sodium carbonate solution. *Methylcampholide*, recrystallised from petroleum (b. p. 60—80°), melted at 100—101° (Found: C, 72.3; H, 9.9.  $C_{11}H_{18}O_2$  re-

quires C, 72.5; H, 9.8%) and had  $[\alpha]_D^{25} - 44.8^\circ$  in about 2.02% solution in chloroform.

1 : 8 : 8-*Trimethylbicyclo*[1 : 2 : 3]*octane-2 : 4-dione* (XVII).—The keto-ester (VI) (21 g.) was heated with alcoholic sodium ethoxide (sodium, 2.5 g.; alcohol, 55 c.c.) for 48 hours, the alcohol evaporated, and the residue diluted, extracted with ether, and acidified with concentrated hydrochloric acid. The oil obtained, which solidified, was dried and crystallised from petroleum, separating in slender short needles, m. p.  $220^\circ$  to a red liquid (Found: C, 73.2; H, 9.1.  $C_{11}H_{16}O_2$  requires C, 73.3; H, 8.8%). The *diketo*-compound was optically inactive, dissolved in dilute alkali solutions, gave a brown coloration with alcoholic ferric chloride, and absorbed bromine in chloroform with evolution of hydrogen bromide.

*Homoepicamphor* (XXIII) and the *Keto-alcohol* (XXV).—The compound (XVII) (5 g.) was heated under reflux with amalgamated zinc (25 g.), concentrated hydrochloric acid (100 c.c.), and water (50 c.c.); the reduction product partly distilled into the condenser. After cooling, the product was extracted with ether, the unchanged *diketo*-compound removed by dilute alkali solution, the ethereal solution dried, and the solvent removed. The residue was treated with semicarbazide acetate in methyl-alcoholic solution, and the mixture diluted with water and shaken with light petroleum. The residual *semicarbazone*, after crystallising from dilute methyl alcohol, melted at  $220^\circ$  (Found: C, 64.5; H, 9.8.  $C_{12}H_{21}ON_3$  requires C, 64.5; H, 9.4%). The quantity of it was very small and the ketone could not be regenerated. The petroleum solution gave a small quantity of a semi-solid substance which was probably the keto-alcohol (XXV).

The author wishes to express his grateful thanks to Professor J. F. Thorpe, C.B.E., F.R.S., for his interest in this work and for his many valuable suggestions, and to the Government of Bengal, India, for a foreign scholarship and a grant towards the purchase of chemicals.

### XXX.—*The cis-trans Ethenoid Transformation.*

By GEORGE ROGER CLEMO and STANLEY BROWN GRAHAM.

THE mechanism of the stereoisomeric transformation of ethylenic compounds has received considerable attention but remains far from clear. Several early workers noted that maleic acid and its

esters were converted into the fumaric form by minerals acids, and Tanatar (*J. Russ. Phys. Chem. Soc.*, 1911, **43**, 1742) and Pfeiffer (*Ber.*, 1914, **47**, 1592) describe the change of maleic to fumaric acid by means of ammonia and pyridine respectively. Recently, Meerwein and Weber (*Ber.*, 1925, **58**, 1266) have stated that potassium in ether converts methyl maleate into methyl fumarate.

As methyl fumarate is a highly crystalline solid with a solubility of about 1% in methyl maleate at the ordinary temperature, the conversion of the latter into the former furnishes a convenient method for studying this reaction.

Apparently, the catalytic action of ammonia and organic bases has not been investigated in this connexion, but it has now been found that the former, and primary and secondary amines, effect the change. For instance, a trace of piperidine transforms methyl maleate in a few seconds into a crystalline mass of the fumarate, and since the former has much the greater energy content, the temperature rises very considerably. Dimethylamine, diethylamine, piperazine, methylamine, allylamine, benzylamine, *d*- and *l*- $\alpha$ -phenylethylamine,  $\beta$ -phenylethylamine, coniine, and aniline also effect the change, although some of them do not bring about a complete transformation. Tertiary amines such as triethylamine, dimethylaniline, diethylaniline, and pyridine, however, do not catalyse the inversion, although triethylamine is a much stronger base than many of the above primary and secondary ones. At first it seemed that triethylamine was an exception to the rule, as the base supplied by Kahlbaum effected some change; but after it had been freed from primary and secondary impurities by treatment with toluene-*p*-sulphonyl chloride (Clemo and Perkin, *J.*, 1921, **119**, 648), it caused no conversion after a year at the ordinary temperature.

The mechanism usually favoured for the ethenoid inversion is that the catalyst adds itself in some way to the double bond, thus allowing free rotation with formation of the *trans*-form and regeneration of the catalyst. Even if it is assumed that a newly formed molecule may have enhanced activity, there still appears to be no adequate reason why some of the additive complexes should not reach a stable maturity.

Our experiments have shown that organic bases are only effective as catalysts when they contain amino- or imino-hydrogen, and this suggested the following mechanism for the inversion, in which the first stage is the formation of a co-ordinate link between the hydrogen atom of the base and the carbonyl oxygens of the ester. This would produce a mobility in the, at present, uncertain electronic system constituting the double bond, and lead to a very unstable complex

in which both the ethylenic carbon atoms would become positive and surrounded by only seven electrons.

The well-known catalytic action of primary and secondary bases in the Knoevenagel reaction (*Annalen*, 1894, **281**, 25) may be explained as being due to the formation of two ionised systems such as

give the reaction products.

Walden (*Z. physikal. Chem.*, 1896, **20**, 379) states that methyl maleate can be made from either maleic acid or anhydride, but no details are given, and recent workers have used the silver salt-methyl iodide method of preparation. It has now been found that methyl maleate can be easily prepared in good yield from maleic anhydride, methyl alcohol, and sulphuric acid.

#### EXPERIMENTAL.

*Methyl Maleate*.—Maleic anhydride (60 g.) was added to methyl alcohol (100 c.c.) and concentrated sulphuric acid (4 c.c.), and the mixture refluxed for 3½ hours on the water-bath. The bulk of the excess of alcohol was then distilled off and water added, followed by solid sodium carbonate to neutralise the sulphuric acid. The ester, when extracted with ether, dried over sodium sulphate, and fractionated, gave (a) 6 g., b. p. 200–204°, (b) 65 g., b. p. 204–206°, and (c) 1–2 g., b. p. above 206°. Fraction (a) alone contained traces of methyl fumarate, as shown by the silver nitrate test after hydrolysis with baryta [Found for (b): C, 49.7; H, 5.4. Calc. for C<sub>6</sub>H<sub>8</sub>O<sub>4</sub>: C, 50.0; H, 5.55%].

The methyl fumarate formed by the inversion of the above was identified by the method of mixed m. p. with an authentic specimen.

XXXI.—*The Methylation of the Oximes of Benzil.*  
*Part II. The Monomethyl Ethers of the Benzildioximes.\**

By OSCAR L. BRADY and MORRIS MARCUS MUERS.

THE preparation of the monomethyl ethers of the benzildioximes was undertaken with a view to the study of their metallic complexes, which will be described in a subsequent paper. In addition it was hoped that it might be possible to prepare, through these compounds, the hitherto unknown dimethyl ethers of  $\gamma$ -benzildioxime and the *NN*-dimethyl- $\beta$ -benzildioxime (Brady and Perry, J., 1925, 127, 2874).

*O*-Methyl- $\alpha$ -benzilmonoxime (I) on oximation gives a mixture of *O*-monomethyl- $\alpha$ -benzildioxime (II) and  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzildioxime (III). (The symbols  $\alpha'$  and  $\beta'$  are used to indicate the oximino-group methylated in the  $\gamma$ -dioxime,  $\alpha'$  being applied when the methylated hydroxyl group is vicinal and  $\beta'$  when it is remote from the phenyl group.)

$\alpha$ -Benzildioxime (IV) on monomethylation gives a mixture of the former compound (II) and *N*-monomethyl- $\alpha$ -benzildioxime (V). *O*-Monomethyl- $\alpha$ -benzildioxime (II) on further methylation yields *OO*-dimethyl- $\alpha$ -benzildioxime (VI) and *ON*-dimethyl- $\alpha$ -benzildioxime (VII).  $\alpha'$ -Monomethyl- $\gamma$ -benzildioxime (III) on further methylation gives *OO*-dimethyl- $\alpha$ -benzildioxime (VI) and *OO*-dimethyl- $\gamma$ -benzildioxime (VIII), and *N*-monomethyl- $\alpha$ -benzildioxime (V) yields *ON*-dimethyl- $\alpha$ -benzildioxime (VII) and *NN*-dimethyl- $\alpha$ -benzildioxime (IX).

The dimethyl ethers of  $\alpha$ -benzildioxime, described in Part I (Brady and Perry, *loc. cit.*), establish the configuration of the monomethyl ethers from which they can be prepared. *O*- and *N*-Ethers were distinguished by heating with hydriodic acid, methyl iodide and methylamine, respectively, being obtained. The configuration of  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzildioxime will be discussed later.

*O*-Monomethyl- $\alpha$ -benzildioxime (II) was converted by boiling with aniline for 30 seconds into  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzildioxime (III), the change being analogous to that of  $\alpha$ -benzildioxime to  $\beta$ -benzildioxime under similar conditions (J., 1925, 127, 2880); in the present case, however, brief treatment caused isomerisation of the unmethylated group only; more prolonged boiling with aniline or with hydrogen chloride in glacial acetic acid resulted in isomerisation of the methylated group also, giving *O*-monomethyl- $\beta$ -benzildioxime (XII).

\* The new configurations of Meisenheimer (*Ber.*, 1921, 54, 3206) are used throughout this paper.

*O*-Methyl- $\beta$ -benzilmonoxime (XI) does not react readily with hydroxylamine, it being necessary to heat it to 175–185° with hydroxylamine hydrochloride in alcohol; *O*-monomethyl- $\beta$ -benzildioxime (XII) is then formed exclusively. If any of the  $\beta'$ -*O*-monomethyl- $\gamma$ -benzildioxime (XVI) were formed, it would certainly undergo isomeric change under these conditions. The dichloride  $\text{PhC}(\text{NOMe})\cdot\text{CCl}_2\text{Ph}$ , which might react more readily, could not be prepared, since phosphorus pentachloride was without action on *O*-methyl- $\beta$ -benzilmonoxime.

The monomethylation of  $\beta$ -benzildioxime (X) leads to the formation of *O*-monomethyl- $\beta$ -benzildioxime (XII) and *N*-monomethyl- $\beta$ -benzildioxime (XIII). *O*-Monomethyl- $\beta$ -benzildioxime on further methylation gave *ON*- and *OO*-dimethyl- $\beta$ -benzildioxime (XIV and XV), and *N*-monomethyl- $\beta$ -benzildioxime gave *O*-methyl- $\beta$ -benzilmonoxime (XI), formed probably by the hydrolysis of *ON*-dimethyl- $\beta$ -benzildioxime.

From the monomethylation of  $\gamma$ -benzildioxime (XXII), only *N*-monomethyl- $\beta$ -benzildioxime (XIII) could be isolated, isomeric change occurring. From the other liquid products of the reaction, no *O*- or *N*-monomethyl- $\gamma$ -benzildioximes could be isolated.

When *N*-monomethyl- $\alpha$ -benzildioxime was boiled with aniline, the *N*-methyloximino-group was eliminated and replaced by the anil group, but if dimethylaniline was used, isomerisation occurred and *N*-monomethyl- $\beta$ -benzildioxime was formed: this is the first example of such isomerisation of an *N*-ether.

The results so far described are summarised in the diagram.

Unlike the *OO*-dimethyl ethers, the *O*-monomethyl ethers undergo the Beckmann rearrangement. *O*-Monomethyl- $\alpha$ -benzildioxime gives *N*-benzoyl-*O*-methylbenzamidoxime (XVII) at 0° and 3:5-diphenyl-1:2:4-oxadiazole (XVIII) at room temperature, methyl alcohol being eliminated in the latter case.

At room temperature, either the phosphorus pentachloride causes the isomerisation of the methylated oximino-group or *trans*-ring formation must take place; in the latter case, the usual explanation of salt formation between the two groups seems inadmissible,

$\begin{array}{c} \text{MeO} \cdot \text{NH} \cdot \text{O} \cdot \text{CPh} \\ \text{PhC} \text{---} \text{N} \end{array}$ , since *O*-methyl ethers are destitute of basic properties.

*O*-Monomethyl- $\beta$ -benzildioxime in the Beckmann rearrangement gives  $\beta$ -*O*-methylphenylglyoxyylanilideoxime (XIX), which has been synthesised by the methylation of phenylglyoxyylanilideoxime (XX), whose orientation is known by its conversion into oxanilide in the Beckmann rearrangement.

$\alpha'$ -*O*-Monomethyl- $\gamma$ -benzildioxime undergoes the Beckmann rearrangement with the formation of  $\alpha$ -*O*-methylphenylglyoxyylanilideoxime (XXI).

It has not been possible to synthesise this compound, but the production of aniline by hydrolysis fixes the relative positions of hydroxyl and phenyl in the oximino-group and the formation of  $\beta$ -*O*-methylphenylglyoxyylanilideoxime (XIX) from *O*-monomethyl- $\beta$ -benzildioxime eliminates the possibility of the methoxyl group being on the opposite side of the nitrogen atom in  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzildioxime. Moreover,  $\beta$ -*O*-methylphenylglyoxyylanilideoxime (XIX) is readily converted by boiling concentrated hydrochloric acid (a reagent which commonly causes isomerisation of an NOME group) into the  $\alpha$ -isomeride (XXI).

#### EXPERIMENTAL.

*O*-Methyl- $\alpha$ -benzilmonoxime.— $\alpha$ -Benzilmonoxime was prepared by a modification of the method of Auwers and Meyer (*Ber.*, 1889, 22, 540). A suspension of benzil (200 g.) in alcohol (700 c.c.), obtained by rapid cooling of the boiling solution, was cooled to 10° and treated below 15° with alternate small quantities of sodium hydroxide (100 g. in 100 c.c. of water) and hydroxylamine hydrochloride (66 g. in 100 c.c. of water). After being kept for 24 hours at room temperature, the mixture was diluted to 4 litres, a small quantity of benzil removed, and the oxime precipitated with concentrated hydrochloric acid or saturated ammonium chloride solution. The washed and dried precipitate was crystallised from benzene, which gave a much better separation of the  $\alpha$ - and  $\beta$ -benzilmonoximes than the 30% alcohol used by Auwers and Meyer. Yield, 70%. The oxime was converted into *O*-methyl- $\alpha$ -benzilmonoxime by the method of Brady and Perry (*loc. cit.*).

*Oximation of O-Methyl- $\alpha$ -benzilmonoxime.*—Finely divided *O*-methyl- $\alpha$ -benzilmonoxime (20 g.) was suspended in alcohol (60 c.c.) and sodium hydroxide (8 g.) and hydroxylamine hydrochloride (7 g.), each dissolved in 8 c.c. of water, were added in small portions. The mixture became hot and the *O*-methyl- $\alpha$ -benzilmonoxime dissolved to give a dark yellow solution. After 2 hours, small crystals filled the liquid, and on the next day these were collected and washed with a little alcohol (A). The filtrate when diluted to 200 c.c. gave a crystalline precipitate (B) and saturation of the mother-liquor with carbon dioxide gave a further precipitate (C).

The precipitate A, consisting of a sparingly soluble sodium salt, was dissolved in hot 2*N*-sodium hydroxide, some unchanged *O*-methyl- $\alpha$ -benzilmonoxime removed, and the solution cooled and saturated with carbon dioxide; the precipitate, after crystallising three times from acetone, gave *O*-monomethyl- $\alpha$ -benzildioxime (II) in flat needles, m. p. 181—182° (Found: N, 11.4; OMe, 9.2.  $C_{15}H_{14}O_2N_2$  requires N, 11.0; OMe, 12.2%). Low methoxyl values are usual with compounds of this type (compare Brady and Perry, *loc. cit.*).

When the above compound was boiled for 15 minutes with acetic anhydride, the mixture treated with water, and the product crystallised from alcohol, *acetyl-O*-monomethyl- $\alpha$ -benzildioxime was obtained in small plates, m. p. 107—108° (Found: N, 9.5.  $C_{17}H_{16}O_3N_2$  requires N, 9.4%). *Benzoyl-O*-monomethyl- $\alpha$ -benzildioxime, prepared by the Schotten-Baumann reaction, crystallised from glacial acetic acid in needles, m. p. 167° (Found: N, 7.8.  $C_{22}H_{18}O_3N_2$  requires N, 7.7%).

Fractions B and C when crystallised from various solvents gave a product, m. p. 157—160°, which was seen under the microscope to consist of approximately equal quantities of flat needles and small octahedra. When the mixture was dissolved in hot 2*N*-sodium hydroxide, and the solution cooled, the sodium salt of most of the *O*-monomethyl- $\alpha$ -benzildioxime separated; the mother-liquor, on saturation with carbon dioxide, gave a pasty solid which soon set to a brittle mass. Two crystallisations of this from glacial acetic acid gave a product, m. p. 165—167°: in later preparations, the separation was greatly assisted by seeding the acetic acid solution with these crystals and filtering the liquid before crystallisation was complete, whereby the bulk of the new compound was removed before the *O*-monomethyl- $\alpha$ -benzildioxime separated. Further crystallisation from acetic acid did not increase the purity of the product, as this treatment brought about partial conversion into a third isomeride, but crystallisation from chloroform and light

petroleum gave  $\alpha'$ -O-monomethyl- $\gamma$ -benzildioxime (III) in small octahedra, m. p.  $172^\circ$  (Found: N, 10.9; OMe, 9.6%).

*Acetyl- $\alpha'$ -O-monomethyl- $\gamma$ -benzildioxime* crystallised from alcohol in needles, m. p.  $80^\circ$  (Found: N, 9.6%), and *benzoyl- $\alpha'$ -O-monomethyl- $\gamma$ -benzildioxime* from glacial acetic acid in prisms, m. p.  $79^\circ$  (Found: N, 7.9%). Both compounds were prepared by the methods described above.

In the above oximation the final yields averaged 40–50% of the  $\alpha$ - and 7–10% of the  $\gamma$ -benzildioxime derivative with about 25% of inseparable mixture. Many unsuccessful attempts were made to obtain larger yields of  $\alpha'$ -O-monomethyl- $\gamma$ -benzildioxime: oximation in hot solution with free hydroxylamine gave but a small yield of the mixture; in hot acid solution, or with hydroxylamine hydrochloride alone in alcohol, much of the product was converted into O-monomethyl- $\beta$ -benzildioxime; in alkaline solution as above but at a higher temperature, much hydroxylamine was destroyed and a poor yield of the mixture obtained.

*Oximation of O-Methyl- $\beta$ -benzilmonoxime.*—O-Methyl- $\beta$ -benzilmonoxime, prepared by boiling O-methyl- $\alpha$ -benzilmonoxime with concentrated hydrochloric acid (Brady and Perry, *loc. cit.*), is unaffected by treatment with hydroxylamine in acid, alkaline, or neutral solution even at  $100^\circ$ . When, however, the compound (5 g.) was heated under pressure with hydroxylamine hydrochloride (1.8 g.) in alcohol (25 c.c.) at  $175$ – $185^\circ$  for 10 hours, and the solution cooled, a solid separated on scratching which, after crystallising three times from glacial acetic acid, gave O-monomethyl- $\beta$ -benzildioxime (XII) in stout prisms, m. p.  $177^\circ$  (Found: N, 11.1; OMe, 10.9%).

Mixtures of any two of the isomeric monomethylbenzildioximes obtained melted between  $130^\circ$  and  $150^\circ$ .

*Acetyl-O-monomethyl- $\beta$ -benzildioxime* crystallised from alcohol in prisms, m. p.  $81^\circ$  (Found: N, 9.5%), and *benzoyl-O-monomethyl- $\beta$ -benzildioxime* from glacial acetic acid in prisms, m. p.  $162^\circ$  (Found: N, 7.8%).

In this oximation no indication of  $\beta'$ -O-monomethyl- $\gamma$ -benzildioxime was obtained. This result was, however, to be expected owing to the instability of the derivatives of  $\gamma$ -benzildioxime, which at high temperatures change to the  $\beta$ -isomerides.

*Monomethylation of  $\alpha$ -Benzildioxime.*—A solution of  $\alpha$ -benzildioxime (10 g.) in 4*N*-sodium hydroxide (200 c.c.) and methyl alcohol (5 c.c.) was cooled in ice, and methyl sulphate (15 g.) added slowly. The precipitate which formed was collected, washed with cold 2*N*-sodium hydroxide, and extracted with hot *N*/5-sodium hydroxide; a small quantity of oil remained consisting of dimethyl

ethers. The alkaline extract on saturation with carbon dioxide gave *O*-monomethyl- $\alpha$ -benzildioxime. The mother-liquor from the methylation was saturated with carbon dioxide, the precipitate obtained was extracted with hot alcohol, some undissolved  $\alpha$ -benzildioxime removed, and the solid which separated on cooling was crystallised from alcohol, *N*-monomethyl- $\alpha$ -benzildioxime (V) being obtained in prisms, m. p.  $168^{\circ}$  (Found: N, 11.4.  $C_{15}H_{14}O_2N_2$  requires N, 11.0%). This compound gave no methyl iodide on treatment with hydriodic acid, but methylamine was detected in the solution by Valton's method (J., 1925, 127, 40).

*Monomethylation of  $\beta$ -Benzildioxime.*—This was carried out in the same way as that of  $\alpha$ -benzildioxime. The pasty precipitate of dimethyl ethers was removed and the filtrate diluted and saturated with carbon dioxide; the semi-solid precipitate obtained slowly hardened and after three crystallisations from alcohol gave a small yield of *O*-monomethyl- $\beta$ -benzildioxime. The mother-liquors from the crystallisation were evaporated to dryness at room temperature and the residue was extracted several times with boiling light petroleum and once with hot benzene, a further quantity of the *O*-methyl ether thus being removed; the undissolved part, crystallised from alcohol, gave *N*-monomethyl- $\beta$ -benzildioxime (XIII) in hexagonal prisms, m. p.  $205^{\circ}$  (decomp.) (Found: N, 11.2%). Hydriodic acid produced no methyl iodide from this compound, but methylamine was detected.

*Monomethylation of  $\gamma$ -Benzildioxime.*—The dioxime (5 g.) was dissolved in 2*N*-sodium hydroxide (100 c.c.), and a concentrated solution of sodium hydroxide (7 g.) added with cooling, followed by a little methyl alcohol (2.5 c.c.); the suspension of sodium salt obtained was cooled in ice, and methyl sulphate (4 g.) added. After 30 minutes, the mixture was diluted until solution was attained and an excess of a saturated solution of ammonium chloride was then added. The precipitate obtained, on crystallising twice from alcohol, gave *N*-monomethyl- $\beta$ -benzildioxime (2 g.). The mother-liquors from the crystallisation were evaporated at room temperature and the residue was extracted with hot benzene; some *N*-ether remained undissolved. The benzene solution on evaporation yielded a considerable quantity of oil, but no pure compound could be obtained therefrom.

*Methylation of *O*-Monomethyl- $\alpha$ -benzildioxime.*—A solution of the compound (5 g.) in hot 2*N*-sodium hydroxide (120 c.c.) was quickly cooled and methyl alcohol (5 c.c.) added, followed by methyl sulphate (10 g.) in small portions with cooling in ice. After some hours, the pasty solid was collected and crystallised first from glacial acetic acid and then from acetone; the *OO*-dimethyl- $\alpha$ -benzil-

dioxime obtained was identified by comparison with a specimen prepared by Brady and Perry's method. When the acetic acid mother-liquor was diluted somewhat with water, more of the above compound separated; this was removed, excess of water added to the filtrate, the precipitate formed dissolved in the minimum quantity of glacial acetic acid, and concentrated hydrochloric acid added until no further precipitate was formed. The precipitated hydrochloride (m. p. 157—161°) was washed with concentrated hydrochloric acid, then with hot benzene, and decomposed with concentrated aqueous ammonia. The solid obtained, after crystallisation from alcohol, was identified as *ON*-dimethyl- $\alpha$ -benzil-dioxime.

*Methylation of N-Monomethyl- $\alpha$ -benzildioxime.*—The compound (1 g.) was dissolved in 2*N*-sodium hydroxide, the solution cooled in ice, and methyl sulphate (2 g.) added. The oil formed slowly solidified; when it was crystallised from alcohol, *NN*-dimethyl- $\alpha$ -benzildioxime separated. The alcoholic mother-liquor was concentrated somewhat, a further quantity of the *NN*-ether removed, and concentrated hydrochloric acid added to the filtrate; the precipitated hydrochloride, after being washed with concentrated hydrochloric acid and with ether, was decomposed with ammonia, and the solid crystallised from alcohol, *ON*-dimethyl- $\alpha$ -benzil-dioxime being obtained.

*Methylation of O-Monomethyl- $\beta$ -benzildioxime.*—A solution of the compound (5 g.) in hot 2*N*-sodium hydroxide (120 c.c.) was cooled and treated with methyl sulphate (10 g.). The pasty precipitate was extracted with ether, and the solution dried with anhydrous sodium sulphate and saturated with dry hydrogen chloride. The oily hydrochloride precipitated was separated by decantation, united with a further quantity obtained by addition of light petroleum to the ethereal solution, and decomposed with concentrated aqueous ammonia. The oil obtained, after being kept in a vacuum over solid sodium hydroxide, solidified and then, on crystallising several times from light petroleum, gave *ON*-dimethyl- $\beta$ -benzildioxime. The ether-light petroleum solution from which the hydrochloride had been removed was evaporated, and the residue crystallised twice from alcohol, *OO*-dimethyl- $\beta$ -benzil-dioxime being obtained.

*Methylation of  $\alpha'$ -O-Monomethyl- $\gamma$ -benzildioxime.*—A mixture of the compound (2 g.), methyl iodide (1.5 g.), dry ether (20 c.c.), and dry silver oxide (2 g.) was boiled under reflux for 3 hours, cooled, and the liquid filtered. The solid was extracted with hot acetone; the extract on evaporation yielded *OO*-dimethyl- $\alpha$ -benzildioxime. The ethereal solution was evaporated at room temperature, and the

residue crystallised from acetone, a further quantity of the *OO*-ether being obtained. The acetone mother-liquor on evaporation at room temperature gave an oil which solidified when kept in an evacuated desiccator and scratched; crystallised from dilute alcohol and finally from 80% alcohol, this yielded *OO*-dimethyl- $\gamma$ -benzildioxime (VIII) in plates, m. p. 59° (Found: N, 10.3; OMe, 18.1.  $C_{16}H_{16}O_2N_2$  requires N, 10.4; OMe, 23.1%). The melting point of this compound was depressed by 30–40° by addition of an approximately equal quantity of *O*-methyl- $\alpha$ - or - $\beta$ -benzilmonoxime or *OO*-dimethyl- $\beta$ -benzildioxime, m. p.'s 61°, 62°, and 73° respectively.

Methylation of  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzilmonoxime with methyl sulphate as described for *O*-monomethyl- $\alpha$ -benzildioxime gave an oil which did not solidify after several months. When, however, the above compound had been obtained and was used to seed this oil, crystallisation occurred, and recrystallisation from alcohol gave a fair yield of *OO*-dimethyl- $\gamma$ -benzildioxime but no *OO*-dimethyl- $\alpha$ -benzildioxime.

*Isomeric Changes of the Methyl Ethers of the Benzildioximes.*—*O*-Monomethyl- $\alpha$ -benzildioxime (20 g.) was added to boiling, freshly distilled aniline (40 c.c.) and the mixture was boiled for 30 seconds and poured at once into ice-cold dilute hydrochloric acid. The precipitated mixture of the monomethyl ethers of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -benzildioximes, after being thoroughly washed with dilute hydrochloric acid, was separated by removal of unchanged *O*-monomethyl- $\alpha$ -benzildioxime as its sparingly soluble sodium salt and crystallisation of the remaining mixture from acetic acid and from chloroform and light petroleum (p. 220). About 5 g. of  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzildioxime were obtained (this is the easiest way of preparing this compound in quantity). If the time of contact with boiling aniline exceeds 30 seconds, a larger quantity of *O*-monomethyl- $\beta$ -benzildioxime is formed which is very difficult to separate. When *O*-monomethyl- $\alpha$ -benzildioxime (4 g.) was boiled for 5 minutes with aniline (10 c.c.) and cooled, a mass of crystals separated which gave 2 g. of *O*-monomethyl- $\beta$ -benzildioxime after being washed with dilute acid and crystallised from glacial acetic acid.

A suspension of *O*-monomethyl- $\alpha$ -benzildioxime (8 g.) in glacial acetic acid (30 c.c.) was saturated with dry hydrogen chloride and the mixture was boiled under reflux for 30 minutes, cooled and poured into water. The solid obtained, on crystallising from glacial acetic acid, gave 5 g. of *O*-monomethyl- $\beta$ -benzildioxime. Similarly  $\alpha'$ -*O*-monomethyl- $\gamma$ -benzildioxime gave *O*-monomethyl- $\beta$ -benzildioxime.

*OO*-Dimethyl- $\gamma$ -benzildioxime was boiled under reflux with con-

centrated hydrochloric acid for an hour and the solution was diluted with water and extracted with ether; the product, crystallised from acetone, gave *OO*-dimethyl- $\alpha$ -benzildioxime.

*N*-Monomethyl- $\alpha$ -benzildioxime (1 g.) was added to boiling aniline (3 g.) and boiled for 5 minutes. The solution was poured into cold dilute hydrochloric acid, and the resulting precipitate crystallised from alcohol; benzilmonoxime anil,  $\text{CPh}(\text{NOH})\cdot\text{CPh}\cdot\text{NPh}$ , thus obtained was identified by comparison with a specimen prepared by Auwers and Siegfeld's method (*Ber.*, 1893, 26, 794). The readily hydrolysable  $\text{NMe}\cdot\text{O}$  group was eliminated by this treatment, but when dimethylaniline was substituted for aniline *N*-monomethyl- $\beta$ -benzildioxime was obtained.

*Beckmann Rearrangement of O-Monomethyl- $\alpha$ -benzildioxime.*—The compound (5 g.) was suspended in dry ether (20 c.c.) cooled in ice, and phosphorus pentachloride (4 g.) added. After 8 hours' keeping at room temperature, all the oxime had dissolved; the ether was then decanted, washed with ice-cold water, and dried over potassium carbonate; on evaporation an oil was obtained which slowly solidified in a vacuum. The solid, crystallised twice from alcohol, gave 3 : 5-diphenyl-1 : 2 : 4-oxadiazole, identified by comparison with a specimen prepared by Günther's method (*Annalen*, 1889, 252, 48). The alcoholic mother-liquors from the crystallisation were diluted with water; the precipitate obtained, on crystallising twice from benzene, gave flat plates of *N*-benzoyl-*O*-methylbenzamidoxime (XVII), m. p.  $151^\circ$  (Found: N, 11.1; OMe, 11.9.  $\text{C}_{15}\text{H}_{14}\text{O}_2\text{N}_2$  requires N, 11.0; OMe, 12.2%). This compound (0.5 g.) was boiled under reflux with 30% sodium hydroxide solution (10 c.c.) for 1 hour: sodium benzoate separated; the alkaline solution, on extraction with ether, removal of the solvent, and crystallisation of the residue from light petroleum, gave *O*-methylbenzamidoxime, identified by comparison with a genuine specimen (Krüger, *Ber.*, 1885, 18, 1053). Hydrolysis of *N*-benzoyl-*O*-methylbenzamidoxime with concentrated hydrochloric acid gave benzamide and benzoic acid.

In later experiments the oxime-ether-phosphorus pentachloride mixture was kept at  $0^\circ$  until the reaction was complete; a larger proportion of *N*-benzoyl-*O*-methylbenzamidoxime was then formed which could be isolated by direct crystallisation from alcohol and benzene.

*Beckmann Rearrangement of  $\alpha'$ -O-Monomethyl- $\gamma$ -benzildioxime.*—The reaction was carried out as above, but the temperature was kept below  $0^\circ$  by means of a freezing mixture. The solid from the ether, after crystallising three times from alcohol, gave  $\alpha$ -*O*-methylphenylglyoxylanilideoxime (XXI) in long needles, m. p.  $118$ — $120^\circ$

(Found: N, 11.2.  $C_{15}H_{14}O_2N_2$  requires N, 11.0%). Hydrolysis of this compound with boiling concentrated hydrochloric acid and extraction with ether gave an oil, from which a solid (m. p. 57–60°) could be isolated, but in too small quantity for further investigation; the hydrochloric acid solution yielded aniline.

*Beckmann Rearrangement of O-Monomethyl-β-benzildioxime.*—The reaction was carried out at 0° as with the α-compound, the ether yielding a solid which, after crystallising twice from alcohol, gave β-O-methylphenylglyoxylanilideoxime (XIX) in needles, m. p. 152° (Found: N, 11.4%). Boiling concentrated hydrochloric acid converted it first into the α-isomeride; prolonged boiling gave results similar to those obtained with the latter compound. The constitution was proved by the following synthesis. A solution of phenylglyoxylanilide (2 g.), prepared from β-benzilmonoxime by the Beckmann rearrangement, in alcohol (15 c.c.) was cooled in ice, and hydroxylamine hydrochloride (0.7 g.) and sodium hydroxide (0.8 g.), each in 1 c.c. of water, were added slowly. After 2 hours, the whole was poured into water and the precipitated solid, after drying, was extracted with hot benzene, which removed a small quantity of benzanilide. The insoluble portion, together with the precipitate obtained by saturating the original alkaline filtrate with carbon dioxide was crystallised from alcohol, giving the β-phenylglyoxylanilideoxime of Beckmann and Köster (*Annalen*, 1893, 274, 9). This oxime (1 g.) was boiled under reflux with methyl iodide (1 g.), dry silver oxide (0.5 g.), and dry ether (15 c.c.) for 2 hours. After filtration and evaporation of the ether the residual solid was crystallised first from alcohol and then from benzene and light petroleum, β-O-methylphenylglyoxylanilideoxime being obtained.

### XXXII.—The Isomerism of the Oximes. Part XXXVII. Allyl-p-nitrobenzaldoximes, O- and N-Allylhydroxylamines, and Sulphime S-Ethers.

By OSCAR L. BRADY and FRANK HERBERT PEAKIN.

CLAISEN (*Z. angew. Chem.*, 1923, 36, 478; *Annalen*, 1925, 442, 210) has shown that unsaturated alkyl halides, acting upon sodium phenoxide, give O- or C-alkyl derivatives according as the reaction occurs in an ionising or a non-ionising solvent, and that saturated alkyl halides give only O-alkyl derivatives. Now, in the methylation

of aldoximes the formation of *O*- and *N*-methyl derivatives is probably due to an ionic and a non-ionic reaction respectively (Brady and Goldstein, J., 1926, 2403). It seemed likely, therefore, that the use of an unsaturated alkyl halide might give a greater proportion of *N*-ether. The allylation of aldoximes presented special difficulties: the compounds in many cases did not crystallise and there was a tendency for the formation of resinous polymerisation products; *p*-nitrobenzaldoxime, however, gave a crystalline *O*-allyl and *N*-allyl ether. The relative amounts of the two ethers obtained from the  $\alpha$ -oxime did not seem to differ materially from those of the methyl ethers, but a quantitative determination was impracticable, since extensive resinification occurred when attempts were made to hydrolyse the mixture of ethers in order to estimate the *N*-allylhydroxylamine (compare Brady and Goldstein, *loc. cit.*).

*O*-Allylhydroxylamine hydrochloride has been obtained by the hydrolysis of *O*-allylbenzhydroxamic acid, and a solution of *N*-allylhydroxylamine hydrochloride from *N*-allylbenzaldoxime.

Cinnamyl and styryl halides, reacting with aldoximes, gave only resinous products.

The sulphime *S*-ethers,  $R \cdot CH \cdot N \cdot SR'$ , of Zincke and Farr (*Annalen*, 1912, 391, 60, 74) are analogous to the oxime *O*-ethers and an attempt has been made to obtain them in stereoisomeric forms but without success. Only one ether is obtained by the action of *o*-nitrophenylsulphamine,  $NO_2 \cdot C_6H_4 \cdot S \cdot NH_2$ , on benzaldehyde and on *m*-nitrobenzaldehyde and no isomeric change is brought about by the action of ultra-violet light (compare Brady and Klein, J., 1927, 893).

#### EXPERIMENTAL.

*Allylation of  $\alpha$ -p-Nitrobenzaldoxime.*—Sodium (1.4 g.) was dissolved in alcohol (75 c.c.) and  $\alpha$ -*p*-nitrobenzaldoxime (10 g.) added, followed by allyl iodide (10 g.). After being heated under reflux for 3 hours, the mixture was kept over-night; yellow crystals (5 g.) then separated. Recrystallised from dilute alcohol, they gave  $\alpha$ -*O*-allyl-*p*-nitrobenzaldoxime in very pale yellow needles, m. p. 75° (Found: N, 13.7.  $C_{10}H_{10}O_3N_2$  requires N, 13.6%). This compound is volatile in steam, gives no hydrochloride, and, like other *O*-ethers, is very difficult to hydrolyse.

The mother-liquor from the above preparation was diluted with water; the brown solid precipitated (5 g.), on repeated crystallisation, gave more of the *O*-allyl ether. Concentration of the aqueous mother-liquor, followed by extraction with chloroform, gave a substance (1 g.) which after two crystallisations from benzene and light petroleum was found to be *N*-allyl-*p*-nitrobenzaldoxime, identical with the compound obtained from the  $\beta$ -oxime.

*Allylation of  $\beta$ -p-Nitrobenzaldoxime.*—If the above method be employed with the  $\beta$ -oxime, resinification occurs.

Sodium (0.7 g.) was dissolved in alcohol (20 c.c.),  $\beta$ -p-nitrobenzaldoxime (1.2 g.) added, the solution cooled to room temperature, and allyl iodide (0.7 c.c.) poured in; after 3 days a yellow crystalline material had separated and the whole was poured into water. The precipitate, after several crystallisations from benzene and light petroleum, gave *N*-allyl-*p*-nitrobenzaldoxime in pale yellow prisms, m. p.  $112^\circ$  (Found: N, 13.8.  $C_{10}H_{10}O_3N_2$  requires N, 13.6%). With dry hydrogen chloride in dry chloroform, this ether gave a slightly gummy, very hygroscopic precipitate of *N*-allyl-*p*-nitrobenzaldoxime hydrochloride, m. p.  $61$ – $64^\circ$  (Found: Cl, 14.1.  $C_{10}H_{10}O_3N_2 \cdot HCl$  requires Cl, 15.0%). The material was prepared for analysis by rapid pressure on porous tile, and the melting-point determination and the analysis were carried out at once.

*O-Allylhydroxylamine Hydrochloride.*—Benzhydroxamic acid (5 g.) in alcohol (16 c.c.) was treated with sodium hydroxide (1.5 g. in the minimum quantity of water) and allyl bromide (4 c.c.) in alcohol (10 c.c.), and the mixture heated under reflux for 30 minutes. The alcohol was removed on the water-bath, water (20 c.c.) added, and the oil extracted with chloroform. After removal of the solvent, cooling, and scratching, the residual oil solidified (5 g.), and crystallisation from benzene and light petroleum gave *O*-allylbenzhydroxamic acid in colourless needles, m. p.  $58^\circ$  (Found: N, 8.0.  $C_{10}H_{11}O_2N$  requires N, 7.9%). This compound (4 g.) was heated under reflux with alcohol (10 c.c.) and concentrated hydrochloric acid (4 c.c.) for 45 minutes; the product was diluted with water and extracted several times with chloroform. Evaporation of the aqueous solution on the water-bath left a deliquescent crystalline mass, which, after being pressed on porous tile and dried in a desiccator, consisted of colourless leaflets of *O*-allylhydroxylamine hydrochloride, m. p.  $172^\circ$  (decomp.) (Found: Cl, 33.6; N, 13.4.  $C_3H_7ON \cdot HCl$  requires Cl, 32.5; N, 12.8%). It had no reducing action on Fehling's solution and on treatment with *p*-nitrobenzaldehyde in alcohol gave  $\alpha$ -*O*-allyl-*p*-nitrobenzaldoxime.

*N-Allylhydroxylamine Hydrochloride.*— $\beta$ -Benzaldoxime (10 g.), suspended in alcohol (20 c.c.), was treated with sodium ethoxide (2 g. of sodium in 50 c.c. of alcohol), and allyl bromide (3 c.c.) added. After 12 hours, the alcohol was removed on the water-bath, water added, the oil extracted with chloroform, and the solvent removed. The crude *N*-ether could not be induced to crystallise, so it was heated under reflux with alcohol (20 c.c.) for 15 minutes, the odour of benzaldehyde soon being perceptible. The solution was evaporated on the water-bath, the aldehyde being carried off in the water

vapour. The semi-solid residue yielded nothing crystalline; in aqueous solution, however, it immediately reduced Fehling's solution in the cold, and on treatment with an alcoholic solution of *p*-nitrobenzaldehyde and aqueous sodium carbonate gave *N*-allyl-*p*-nitrobenzaldoxime.

*Sulphime S-Ethers*.—*o*-Nitrophenylsulphamine (1.4 g.; prepared by the method of Zincke and Farr, *loc. cit.*) in alcohol (25 c.c.) was heated under reflux for 10 minutes with *m*-nitrobenzaldehyde (1.3 g.). The solid which separated on cooling (2 g.), on crystallisation from benzene, gave *m*-nitrobenzylidene-*o*-nitrophenylsulphamine in lemon-yellow needles, m. p. 192° (Found: N, 13.9.  $C_{13}H_9O_4N_3S$  requires N, 13.9%). Examination of the mother-liquors from the preparation and from the crystallisation gave no indication of the presence of an isomeride: a similar result was obtained in the case of benzylidene-*o*-nitrophenylsulphamine (m. p. 161°) prepared by Zincke and Farr's method.

Both benzylidene- and *m*-nitrobenzylidene-*o*-nitrophenylsulphamine were exposed in benzene solution for 48 hours in silica tubes to the light of a quartz-mercury lamp, but were recovered unchanged on removal of the solvent.

UNIVERSITY COLLEGE, LONDON. [Received, November 28th, 1929.]

### XXXIII.—*The Parachor and Chemical Constitution.* *Part XIV. Tellurium Compounds.*

By FRANCIS HEREWARD BURSTALL and SAMUEL SUGDEN.

IN earlier papers of this series (Sugden, Reed, and Wilkins, J., 1925, 127, 1525; Henley and Sugden, J., 1929, 1058), a number of compounds of sulphur and selenium have been examined in which these elements exert a valency which is greater than the normal, *viz.*, 2. In every case the shell of eight electrons around the sulphur or selenium atom is not exceeded, and the parachors show the presence of the correct number of semipolar double bonds or singlet linkages which are necessary to maintain the octet. As a result of the work described below, this conclusion can now be extended to tellurium compounds. We have so far not found any telluroxides or other compounds containing semipolar double bond which are sufficiently stable in the fused state for parachor measurements; the dialkyl- and diaryl-tellurium dihalides are, however, remarkably stable substances, and measurements can be made for a considerable temperature interval above their melting points. In all but one of the substances examined, the parachor anomaly

predicted for the singlet linkages in the molecule has been realised experimentally.

It was necessary in the first place to determine the atomic constant for tellurium by measurements of the parachors of compounds in which this element exerts its normal valency of two. Data for such compounds are given in Table I. The figure recorded for diphenyl telluride is that obtained by Lowry and Gilbert (J., 1929, 2087). The ditelluride (6) began to decompose at its melting point,

TABLE I.  
*Atomic Parachor of Tellurium.*

Substance.	Formula.	[P] obs.	$\Sigma[P]$ .	Te.
(1) Diphenyl telluride	$\text{Ph}_2\text{Te}$	457.4	380.0	77.4
(2) Dianisyl telluride	$(\text{MeO}\cdot\text{C}_6\text{H}_4)_2\text{Te}$	575.2	498.0	77.2
(3) <i>Di-n-butyl telluride</i>	$(\text{C}_4\text{H}_9)_2\text{Te}$	426.8	346.2	80.6
(4) Phenoxtellurine*	$\text{C}_6\text{H}_4 < \overset{\text{Te}}{\text{O}} > \text{C}_6\text{H}_4$	452.9	371.9	81.0
(5) Di-2-chloro- <i>p</i> -phenetyl telluride†	$(\text{EtO}\cdot\text{C}_6\text{H}_3\text{Cl})_2\text{Te}$	731.2	650.4	80.8
(6) Di- <i>p</i> -phenetyl ditelluride	$(\text{EtO}\cdot\text{C}_6\text{H}_4)_2\text{Te}_2$	723.0	576.6	(73.2)
		Mean, excluding (6)		79.4

\* The heterocyclic 6-membered ring in this substance is assumed to have the normal value of 6.1 units.

† See p. 231.

so the value given for its parachor can only be regarded as approximate. The mean constant for tellurium, *viz.*, 79.4, is a little lower than the value 86 predicted from the parachors of adjacent elements (Henley and Sugden, *loc. cit.*), but lies satisfactorily between the constants for antimony (66.0) and iodine (91.0). The series, O = 20, S = 48.2, Se = 62.5, Te = 79.4, shows the same steady increase with atomic number which has been observed in other families of elements, *e.g.*, the halogens.

Table II gives the parachors of a number of tellurium compounds in which this element is quadrivalent, the data for compounds (3)—(5) being due to Lowry and Gilbert (*loc. cit.*). These substances are all of the type  $\text{R}_2\text{TeX}_2$ , where X is a halogen atom, and may be formulated electronically as salts (I) or as non-polar compounds (II); their properties, excepting those of (5), indicate a non-polar structure (compare Drew, J., 1929, 560; Lowry and Gilbert, *loc. cit.*),

so the parachor should indicate the presence of two singlet linkages by an anomaly of -24.8 units. All the substances, save (3), give an anomaly which is close to this value.

TABLE II.

*Quadrivalent Tellurium Compounds.*

Substance.	Formula.	[P] obs.	$\Sigma[P]$ .	Anomaly.
(1) Diphenyl telluridichloride	$(C_6H_5)_2TeCl_2$	547.3	568.0	-20.7
(2) Di- <i>p</i> -anisyl telluridichloride	$(MeO \cdot C_6H_4)_2TeCl_2$	663.2	686.0	-22.8
(3) $\alpha$ -Dimethyl telluridichloride	$Me_2TeCl_2$	282.5	300.2	-17.7
(4) $\alpha$ -Diethyl telluridi-iodide	$Et_2TeI_2$	425.0	451.6	-26.6
(5) $\beta$ -Diethyl telluridibromide	$Et_2TeBr_2$	377.3	405.6	-28.3

It has been shown by Drew (*loc. cit.*) that Vernon's  $\beta$ -compounds are probably dimerides with a polar structure, *i.e.*,  $(R_3Te)^+ (RTeX_4)^-$ . An electronic formula compatible with the octet rule may be written as in (III). Here both tellurium atoms have a complete octet and carry a positive charge; the anion contains four singlet-linked halogen atoms which give it a net charge of -1. On this view it will be seen that both the  $\alpha$ - and the  $\beta$ -compounds contain two singlet linkages per tellurium atom so that the parachors will give no distinction between the two series. The parachor found by Lowry and Gilbert for the last substance (see Table II) shows, as would be expected, much the same anomaly as the other quadrivalent tellurium compounds.

The substance described by Morgan and Drew (J., 1925, 127, 2307) as bis-*p*-phenetyl telluridichloride (IV) was also examined but proved to have very different properties from the corresponding anisyl compound (No. 2, Table II). The observed parachor, 731.2, is considerably lower than the value calculated for formula (IV), *viz.*, 739.2, but agrees well with the predicted value for formula (V), 729.8. The physical and chemical properties of this substance also

indicate that it is not a quadrivalent tellurium derivative but a nuclear-substituted diphenetyl telluride (V). Its melting point, 108°, is much lower than those of the diphenyl and dianisyl telluridichlorides, *viz.*, 160° and 182° respectively. Unlike the latter substance, the phenetyl compound is readily soluble in ligroin and cannot be reduced by zinc dust to the corresponding telluride. Furthermore, the phenyl and anisyl compounds are readily converted into telluroxides by aqueous alkali, but the phenetyl compound only gives up its chlorine slowly to boiling potash (Morgan and Drew, *loc. cit.*). We understand that further work on this and similar substances is now proceeding in Prof. Morgan's laboratory; meanwhile, from the evidence set out above we consider that formula

(V) gives the most probable structure of Morgan and Drew's phenetyl derivative.

### EXPERIMENTAL.

Surface tensions were determined by the method of maximum bubble pressure (Sugden, J., 1922, 121, 158; 1924, 125, 27) and densities by means of a U-shaped pyknometer (J., 1924, 125, 1171). The tables below are set out in our usual manner; the parachors are calculated by the formula  $P = M\gamma^{\frac{1}{2}}/D$ , where  $\gamma$  is the surface tension in dynes/cm., and  $D$  the density of the liquid, the density of the vapour being negligible.

*Diphenyl telluridichloride* ( $M = 352.5$ ). We are indebted to Prof. G. T. Morgan for a specimen of this substance. M. p. 160—161° (corr.). Densities determined:  $D_4^{62.8^\circ}$  1.618,  $D_4^{70^\circ}$  1.611,  $D_4^{77.5^\circ}$  1.603,  $D_4^{84.5^\circ}$  1.596, whence  $D_4^\circ = 1.785 - 0.00103t$ .

$t$ .....	167.5°	179°	189°	
$\gamma$ .....	39.47	38.23	37.17	
$D$ .....	1.613	1.601	1.591	
$[P]$ .....	547.6	547.4	547.0	Mean 547.3

*Di-p-anisyl telluridichloride* ( $M = 412.5$ ), prepared as described by Morgan and Kellett (J., 1926, 1085) and purified by several crystallisations from chloroform, was colourless and melted sharply at 182° (corr.). Densities determined:  $D_4^{186^\circ}$  1.544,  $D_4^{195.5^\circ}$  1.533,  $D_4^{206^\circ}$  1.523,  $D_4^{216^\circ}$  1.512, whence  $D_4^\circ = 1.734 - 0.00102t$ . The substance showed little sign of decomposition even at these high temperatures.

$t$ .....	186.5°	198.5°	211.5°	
$\gamma$ .....	37.82	36.49	35.57	
$D$ .....	1.543	1.530	1.517	
$[P]$ .....	663.0	662.5	664.0	Mean 663.2

*Di-p-anisyl telluride* ( $M = 341.6$ ) was obtained by Morgan and Kellett from the foregoing dichloride by reduction with zinc dust in benzene. A better yield (90%) was obtained by heating the dichloride in the water-bath with excess of zinc dust and glacial acetic acid; the filtered solution was poured into water and the precipitated telluride crystallised repeatedly from methyl alcohol; m. p. 53—54° (corr.). Densities determined:  $D_4^{92.5^\circ}$  1.515,  $D_4^{72^\circ}$  1.502,  $D_4^{52.5^\circ}$  1.492,  $D_4^{32.5^\circ}$  1.481, whence  $D_4^\circ = 1.582 - 0.00109t$ .

$t$ .....	76.5°	88.5°	100.5°	111°	121°	
$\gamma$ .....	40.60	38.84	38.75	36.68	35.63	
$D$ .....	1.499	1.486	1.473	1.461	1.450	
$[P]$ .....	575.1	574.0	576.1	575.4	575.5	Mean 575.2

*Dichlorodiphenetyl telluride* ( $M = 438.5$ ) was prepared as described by Morgan and Drew (*loc. cit.*) and crystallised from alcohol; m. p.

108° (corr.). Densities determined:  $D_4^{13.5^\circ}$  1.493,  $D_4^{14.5^\circ}$  1.482,  $D_4^{15^\circ}$  1.472,  $D_4^{16^\circ}$  1.462, whence  $D_4^\circ = 1.604 - 0.000979t$ .

$t$ .....	124.5°	136°	147.5°	157.5°	
$\gamma$ .....	37.52	35.93	35.12	34.12	
$D$ .....	1.482	1.471	1.459	1.450	
$[P]$ .....	732.1	729.9	731.7	731.0	Mean 731.2

*Phenoxtellurine* ( $M = 295.5$ ), prepared as described by Drew (J., 1926, 230), melted at 79° (corr.). Densities determined:  $D_4^{8.5^\circ}$  1.662,  $D_4^{10^\circ}$  1.645,  $D_4^{13.5^\circ}$  1.615,  $D_4^{14.5^\circ}$  1.602, whence  $D_4^\circ = 1.770 - 0.00117t$ .

$t$ .....	120.5°	132°	147°	
$\gamma$ .....	38.32	37.62	36.71	
$D$ .....	1.630	1.616	1.599	
$[P]$ .....	451.0	452.9	454.8	Mean 452.9

*Di-p-phenetyl ditelluride* ( $M = 497.1$ ), prepared by reduction of *p*-phenetyl telluritrichloride with aqueous bisulphite (Morgan and Drew, *loc. cit.*), crystallised from ligroin in orange-brown needles, m. p. 108° (corr.). As appreciable decomposition occurred when the substance was heated above its melting point, only one observation of the parachor was made. At  $t = 118^\circ$ ,  $\gamma = 34.44$ ,  $D = 1.666$ , whence  $[P] = 723.0$ .

*Di-n-butyl telluride* ( $M = 241.6$ ). This new substance was prepared as follows. The Grignard compound (2 mols.) from *n*-butyl bromide was added slowly to tellurium tetrachloride (1 mol.) suspended in dry ether. The mixture was heated for 2 hours on the water-bath, the ether distilled off, and the residue extracted with chloroform. The extract was shaken with water to decompose the excess of reagents and dried over calcium chloride, and the solvent removed. The residual red gum was dissolved in glacial acetic acid, and zinc dust added in slight excess. After a few minutes' heating on the water-bath, the solution was filtered and poured into water. The *telluride* then separated as a dark oil, which was dried over calcium chloride and distilled under diminished pressure in a stream of carbon dioxide. The product was a yellow oil, b. p. 132—135°/99 mm. (Found: Te, 52.5.  $C_8H_{18}Te$  requires Te, 52.8%); it possessed an unpleasant odour and oxidised on exposure to air. Exposure to light caused the yellow colour to deepen to a reddish tint.

Densities determined:  $D_4^{30^\circ}$  1.302,  $D_4^{35^\circ}$  1.294,  $D_4^{41^\circ}$  1.289,  $D_4^{46^\circ}$  1.284, whence  $D_4^\circ = 1.334 - 0.00109t$ .

### XXXIV.—*The Photochemical Interaction of Acetaldehyde and Oxygen.*

By EDMUND JOHN BOWEN and EDMUND LAGESEN TIETZ.

IN 1835 Liebig (*Annalen*, **14**, 139) observed that acetaldehyde absorbed oxygen at the ordinary temperature, giving, according to him, acetic acid. Later, several investigators, working on "autoxidation," found that benzaldehyde and some other aldehydes gave peroxides with oxygen, but there seems to be no reference in the literature to the formation of a peroxide of acetaldehyde under these conditions. Chastaing (*Ann. Chim. Phys.*, 1877, **11**, 145) found that acetic acid was formed in the photochemical reaction.

The experiments now described show that a peroxide of acetaldehyde is quantitatively formed, and that it is a moderately stable substance; moreover, it is formed thermally as well as photochemically when liquid acetaldehyde is shaken with oxygen (*Nature*, 1929, **124**, 914). There are two possible peroxides, *viz.*, peracetic acid,  $\text{CH}_3\cdot\text{CO}\cdot\text{O}\cdot\text{OH}$ , and diacetyl peroxide,  $\text{CH}_3\cdot\text{CO}\cdot\text{O}\cdot\text{O}\cdot\text{CO}\cdot\text{CH}_3$ , both of which have been prepared in other ways. The latter is hydrolysed to the former by water (Clover and Richmond, *Amer. Chem. J.*, 1903, **29**, 179). Bäckström (*Medd. K. Vetenskapsakad. Nobel-Inst.*, **6**, No. 16) has recently investigated the formation of a peroxide from benzaldehyde, and shown that the thermal and photochemical changes are chain reactions.

#### EXPERIMENTAL.

*Apparatus.*—A quartz mercury lamp contained in a water-cooled box served as a light source, and the light passed through a quartz window into a thermostat which contained the reaction vessel. This was made of clear fused quartz, joined to glass where necessary by mercury-sealed ground joints.

The purest specimens of acetaldehyde obtainable from Kahlbaum and Harrington were used, and the results were the same with either specimen.

1. *The Photochemical Oxidation of Gaseous Aldehyde by Air*.—A current of air, dried with sulphuric acid and filtered through glass wool, was drawn by a water-pump through a bubbler containing acetaldehyde at  $0^{\circ}$ , then through the quartz reaction bulb, and finally through potassium iodide solution. Iodine was liberated, showing that a peroxide had been formed by exposure of the gases to ultra-violet light. Control experiments showed that air alone passing through the reaction vessel did not liberate iodine, and that the excess aldehyde caught in the potassium iodide solution did not absorb any of the iodine liberated. The peroxide formed partly condensed in the reaction vessel, but by turning off the light and continuing the gas flow for several minutes the whole of it could be carried over. The temperature of the thermostat was  $20^{\circ}$  in the first experiments; it was later raised to  $30^{\circ}$  to diminish the time for "washing out" the peroxide after the light had been turned off. Experiments were made with rates of gas flow between 1000 and 20,000 c.c./hour, and it was found that at rates above 4000 c.c./hour the amount of peroxide formed was independent of the rate of flow, and linearly proportional to the time of exposure. The peroxide must be formed by a chain reaction, for the number of g.-mols. produced in these experiments per minute was about  $10^{-3}$ , whereas the energy in the light absorbed, calculated from an approximate knowledge of the energy distribution of the lamp and the absorption spectrum of acetaldehyde, was about  $10^{-6}$  g.-mol. quantum per minute. The chain length under these conditions was therefore about 1000 molecules, but the exact value of this is unimportant, as will be clear from section 2.

2. *Effect of Wave-length and Intensity of the Light*.—The above experiments were made with the full light of the mercury lamp. Experiments were next performed using screens to cut down the light intensity, in conjunction with filters. The screens were metal sheets with small perforations, and their transmissions were calibrated with a thermopile and an electric lamp. The following filters were used :

	Mercury lines transmitted.
(1) Vita-glass .....	>2900 Å.
(2) Auramine-O in aqueous solution (1 cm. of 0.0125%) .....	3135—2700
(3) Chlorine-bromine filter .....	2900—2485

The results are in Table I, where  $I$  represents the light intensity,  $y$  the titre against  $N/100$ -thiosulphate of the iodine liberated, and the filters used are denoted by their respective numbers in the foregoing scheme.

Table II gives the ratio of the mean titres to the square root of the light intensity, and shows clearly that the reaction is essentially

the same throughout the ultra-violet absorption band of acetaldehyde, the rate being proportional to the square root of the light intensity. This is a rather surprising result.

3. *Effect of Acetaldehyde and of Oxygen Concentration.*—The aldehyde concentration was changed by introducing a variable by-pass and a flow-meter across the acetaldehyde bubbler, and the oxygen concentration was varied by using oxygen-nitrogen mixtures from cylinders, a large bottle being interposed to ensure mixing of the gases. The composition of the mixtures was obtained from flow-meter readings.

Table III gives the variation of the rate (as measured by the iodine titre,  $y$ ) with the relative aldehyde concentration,  $[A]$ , and Table IV the variation with oxygen concentration in the oxygen-nitrogen mixture.

24.1	40.2	53.3	35.0
34.2	39.0	62.3	35.7
41.5	39.0	74.0	36.4
47.8	34.8	100.0	38.3

From these results it appears that the reaction rate is proportional to the aldehyde concentration and independent of the oxygen concentration.

Before the mechanism of the reaction could be explained, it was necessary to know whether the variation of the rate with aldehyde concentration was due to variations in the amount of light absorbed. This was therefore examined at different wave-lengths by means of a quartz spectrograph of a new type, designed by Mr. J. H. Jeffree, in which a quartz sodium photoelectric cell and Lindemann electrometer are used to measure the light in the spectrum formed by the instrument, which had also been used to investigate the transmissions of the filters described above. Between 3200 and 2800 Å., the absorption of gaseous acetaldehyde in the photochemical cell was about 90%, and between 2700 and 2400 Å. about 74%. The absorption was almost independent of the aldehyde concentration, showing that most of the mercury lines in the above regions were totally absorbed, the others being transmitted.

The kinetics of the reaction are  $dx/dt = k\sqrt{L}[A]$ , where  $L$  is the light absorbed, and  $[A]$  the aldehyde concentration. An explanation of this result can be given by the following chain mechanism :

	Rate.
1. $A + h\nu \longrightarrow A^*$	$k_1 L$
2. $A^* + O_2 \longrightarrow AO_2^*$	$k_2 [A^*][O_2]$
3. $AO_2^* + A \longrightarrow A^* + AO_2$	$k_3 [AO_2^*][A]$
4. $2AO_2^* \longrightarrow ?$	$k_4 [AO_2^*]^2$

Reactions 2 and 3, by repetition, produce chains, which are broken by reaction 4. For the steady reaction, we have

$$\begin{aligned} d[A^*]/dt = 0 &= k_1 L + k_3 [AO_2^*][A] - k_2 [A^*][O_2] \\ \text{and } d[AO_2^*]/dt = 0 &= k_2 [A^*][O_2] - k_3 [AO_2^*][A] - k_4 [AO_2^*]^2 \\ \text{whence } k_1 L &= k_4 [AO_2^*]^2 \end{aligned}$$

$$\text{Then } d[AO_2]/dt = k_3 [AO_2^*][A] = k_3 \sqrt{L} \sqrt{k_1/k_4} [A]$$

When peracetic acid reacts with potassium iodide the solution should become alkaline :

Experiments showed, however, that after the iodine titration the

solution was always slightly acid. This point is referred to again in section 4.

4. *Oxidation in the Liquid and the Dissolved State.*—The apparatus used for these experiments consisted of a small quartz tube to contain the liquid, mounted in a shaking machine in a thermostat, and connected by flexible tubing to a gas burette containing oxygen. As solvents, water, acetic acid, and hexane were tried, as they are transparent to the light absorbed by acetaldehyde. The peroxide was estimated by adding the liquid to potassium iodide solution as before, and was found to be formed very rapidly in liquid aldehyde and in its solutions in the above three solvents, and once formed, to be very stable, showing no decomposition in one hour, except in the aqueous solutions, in which it almost all reacted in 20 seconds. This latter fact was utilised to determine the nature of the peroxide. Liquid aldehyde was shaken with oxygen to produce some peroxide. One portion (a) was added at once to neutral potassium iodide solution, the liberated iodine titrated with *N*/100-thiosulphate, and the remaining acidity estimated with *N*/100-baryta solution. The other portion (b) was added to water, and the peroxide allowed to react with the excess aldehyde to give acetic acid. The acidity of this solution was then estimated. The following table gives some results:

Portion.	Expt. 1.		Expt. 2.	
	Iodine titre.	Acid titre.	Iodine titre.	Acid titre.
(a) .....	24.97	8.28	25.32	7.56
(b) .....	0.0	45.77	0.0	46.68

These figures can be explained by assuming that the peracetic acid first formed partly reacts with aldehyde to give acetic acid, but that the reaction is limited by the combination of the acetic acid with peracetic acid to give diacetyl peroxide, according to the equations

Diacetyl peroxide reacts with potassium iodide to give a neutral solution:  $(\text{CH}_3\cdot\text{CO}\cdot\text{O})_2 + 2\text{KI} \longrightarrow 2\text{CH}_3\cdot\text{CO}_2\text{K} + \text{I}_2$ , and the average iodine titre value above (25.15 c.c.) represents 12.57 c.c. of *N*/100-peroxide. The average acid titre after the iodine titration (7.92 c.c.) probably represents a little excess acetic acid. The increase in acidity on standing in aqueous solution should then be represented by  $46.22 - 7.92 = 38.3$  c.c. of *N*/100-acid. The reaction of the peroxide on standing in water must be  $(\text{CH}_3\cdot\text{CO}\cdot\text{O})_2 + \text{CH}_3\cdot\text{CHO} \longrightarrow 3\text{CH}_3\cdot\text{CO}_2\text{H}$ , representing an acidity of  $3 \times 12.57 = 37.71$  c.c. of *N*/100-acid, in close agreement with the calculated figure, 38.3 c.c.

It seems necessary to assume the formation of diacetyl peroxide to account for the approximate neutrality of the solutions after titration of the iodine liberated. The results given in Table VI for hexane-aldehyde mixtures show an even greater approach to neutrality than the figures just given.

Although the peroxide was found to be quite stable when formed in pure liquid aldehyde, the reaction rates were very irregular, due to the high vapour pressure, which, by producing a buffer of vapour, prevented the oxygen from freely dissolving in the liquid. The absorption of oxygen also took place rapidly in the dark. Very reproducible results were obtained for solutions of acetaldehyde in glacial acetic acid and in hexane. The thermal reaction in these solvents was small. Table V gives some results for acetic acid solutions, the amounts of oxygen absorbed (as given by gas-burette readings), and of peroxide formed ( $\text{AO}_2$ , as deduced from the iodine titre) being recorded as g.-mols.  $\times 10^{-4}$ .

TABLE V.

Ratio, by vol., $\text{C}_2\text{H}_4\text{O} : \text{C}_2\text{H}_4\text{O}_2$ .	Time, mins.	$\text{O}_2 \times 10^4$ .	$\text{AO}_2 \times 10^4$ .
1 : 1	1	1.72	1.45
	2	3.08	2.51
	3	4.27	3.36
	4	4.87	3.89
(Dark reaction	15	0.35	0.28)
1 : 2	1	1.64	1.51
	3	4.85	4.43
	5	7.56	6.30
(Dark reaction	15	0.39	0.39)
1 : 5	1	1.20	1.44
	2	2.34	2.54

	15	6.77	6.01
(Dark reaction nil.)			
1 : 10	2.5	0.89	0.99
	5	2.15	2.13
	7	2.72	2.56
	10	3.78	3.50
	15	6.30	5.33
(Dark reaction nil.)			

These results show that the amount of peroxide formed increases linearly with time, and that the rate is proportional to the aldehyde concentration when it is below 20%. The most important result, however, is the agreement between the number of molecules of oxygen absorbed and of peroxide produced. In acetic acid solutions,

diacetyl peroxide formation can occur without the preliminary decomposition of some of the per-acid by reaction with aldehyde.

Table VI gives results for hexane solutions. The light intensity was varied with screens as previously described, and its relative values are denoted by  $I$ . The iodine titre  $y$  (c.c. $N$ /100-thiosulphate) is a measure of the peroxide produced.

TABLE VI.

Ratio, by vol., $C_2H_4O : C_6H_{14}$ .	$I$ .	$y$ .	$y/\sqrt{I}$ .	Excess acidity after iodine titre (c.c. $N$ /100).
1 : 2	48.5	69.1	9.93	4.5
	23.3	45.0	9.32	2.5
	16.0	41.6	10.4	2.0
	7.5	26.8	9.77	2.0
1 : 3	48.5	42.3	6.08	2.5
	23.3	28.7	5.94	2.0
	16.0	27.3	6.82	2.0
	7.5	21.4	7.81	2.0
1 : 5	48.5	25.6	3.68	0.3
	23.3	18.4	3.81	0.0
	16.0	14.6	3.65	0.0
	7.5	10.8	3.94	0.0

These results are in complete agreement with those of Tables I and II, and show that the rate of peroxide formation is proportional to the square root of the light intensity and to the aldehyde concentration. The amount of free acid found after the iodine titre is small, showing that diacetyl peroxide is probably formed.

5. *The Inhibition by Ethyl Alcohol*.—The introduction of an inhibitor into the system will alter the chain-breaking mechanism from the bimolecular reaction  $2AO_2^* \longrightarrow ?$  to one of the type  $AO_2^* + X \longrightarrow ?$ . The rate of reaction will then become proportional to the light intensity instead of to its square root. That this is actually the case is shown in Table VII, which gives results for the rate when alcohol was added.

TABLE VII.

Ratio by volume. Aldehyde:hexane:alcohol = 2 : 4 : 1.						
$I$ .....	4.85	4.85	2.33	2.33	1.60	1.60
$y$ .....	33.9	34.1	16.4	16.6	11.5	11.3
$y/\sqrt{I}$ .....	6.99	7.03	7.04	7.19	7.19	7.07

From this result it is apparent that the effectiveness of an inhibitor at a given concentration must depend on the light intensity in this reaction. Assuming that the mechanism of inhibition is that described above, it can be shown that for fixed light intensity and aldehyde concentration the rate should vary according to the equation  $y^2 + \alpha Xy = \beta$ , where  $y$  is the rate and  $X$  the inhibitor con-

centration; whereas for fixed light intensity and inhibitor concentration, the ratio of rate to aldehyde concentration should be constant. These conclusions are tested by the results given in Tables VIII and IX, for solutions in hexane. The former table gives  $X$  as the percentage of alcohol,  $y$  as the iodine titre, and the value of  $\alpha$  as calculated from the above equation with  $\beta = 5242$ .

TABLE VIII.

Aldehyde concentration, 33%.

$X$ .	$y$ .	$\alpha$ .
0	72.4	—
1.33	55.5	29.3
6.67	29.1	22.6
12.5	11.3	36.3

TABLE IX.

Alcohol concentration, 14.3%.

$[A]$ .	$y$ .	$[A] - 14.3$ .
14.3	1.9	0
21.42	6.1	7.1
28.56	10.5	14.3
35.7	22.0	21.4

Although the variation of velocity with inhibitor concentration is approximately as expected, yet its variation with aldehyde concentration can only be made to agree with the theory if the inhibitor concentration is subtracted from the aldehyde concentrations (see Table IX). The interpretation of this is that the alcohol first combines with activated aldehyde molecules to give a compound which is the actual inhibitor, thereby reducing the effective aldehyde concentration. These experiments are being continued.

6. *Static Measurements on Gaseous Mixtures.*—It was suggested to us by Mr. A. C. Egerton that, as peroxides are formed as intermediate compounds in the oxidation of hydrocarbons, experiments on the effect of "anti-knock" substances on this reaction would be interesting. For this purpose, gaseous mixtures of acetaldehyde and oxygen at total pressures between 60 and 20 cm. of mercury were introduced into a quartz bulb connected to a mercury manometer, and the reaction was followed by the diminution of pressure which occurs when the mixture is exposed to ultra-violet light. The pressure change-time curves for the complete reaction were found to begin with a long linear portion. When the ratio of acetaldehyde to oxygen was greater than 3:2, the rate after the initial period fell off gradually to an end-point, while when the ratio was less than this, the end-point was approached abruptly. Tables of results for these measurements are not given because a complete explanation depends on the nature of the final products, which were found by analysis to be complex, and to contain carbon dioxide, monoxide, and acetic acid. The initial rate of reaction was found to be approximately proportional to the square root of the light intensity and to the aldehyde pressure, and independent of the oxygen pressure, in agreement with the results derived from estimation of the peroxide.

The effect of introducing small quantities (0.1—5 mm.) of the vapour of anti-knock substances was as follows.

*Iron carbonyl.* A dense white mist was formed when the light was turned on. The oxidation of the aldehyde was inhibited for a long period, proportional to the amount of iron carbonyl present. At the end of the induction period the mist practically disappeared, and the reaction suddenly began at a rate almost equal to its value in the absence of the inhibitor. A red powder ( $\text{Fe}_2\text{O}_3$ ?) was left in the reaction vessel.

*Nickel carbonyl.* The quantity introduced, owing to the higher vapour pressure, was about ten times that of iron carbonyl. A dense mist was formed, and a white solid deposited, and the reaction was inhibited completely.

*Selenium diethyl.* A dense mist was again formed, but no induction period was produced; instead, the reaction proceeded at a slow rate which gradually increased as the mist disappeared. Great difficulty was experienced in removing the last traces of selenium compounds from the reaction vessel after these experiments.

*Lead tetraethyl.* The vapour of this substance had no effect on the reaction rate.

*Ethyl iodide.* The introduction of this substance decreased the rate of reaction greatly, without producing any induction period.

These results show that anti-knock substances do not all act as inhibitors for this reaction. Lead tetraethyl does not affect the reaction at all. The results for ethyl iodide can be explained as an inner filter effect. It is uncertain whether iron and nickel carbonyls act as direct inhibitors or whether the mist formed merely scatters the light. The most that can be said is that an apparently equally heavy mist is formed with selenium diethyl, without the production of an induction period. The inhibiting effect of iron carbonyl is inversely proportional to the aldehyde pressure, which is some evidence that it acts as a direct chain breaker.

#### *Summary.*

1. A peroxide is formed when gaseous, liquid, or dissolved acetaldehyde is exposed in presence of oxygen to ultra-violet light. The reaction has been examined in different spectral regions. In the liquid and the dissolved state the peroxide is also formed in the dark.

2. The rate of reaction is proportional to the square root of the light intensity and to the aldehyde concentration, but independent of the oxygen concentration. This can be explained by a chain mechanism involving the formation of peracetic acid as the first product.

3. Reasons are given to show that diacetyl peroxide is formed by further reactions of the peracetic acid.

4. Alcohol acts as an inhibitor when added to hexane solutions of aldehyde. As expected, the rate becomes directly proportional to the light intensity, instead of to its square root.

5. Anti-knock substances do not all act as inhibitors of the photochemical reaction between acetaldehyde and oxygen.

We are indebted to Mr. Egerton for the anti-knock substances, and to the Royal Society for a grant to purchase the quartz spectrograph used in this work.

### XXXV.—*Extinction of Methane Flames by Water Vapour.*

By HUBERT FRANK COWARD and JOHN JEBSON GLEADALL.

THE limits of inflammability of methane in air are narrowed by the progressive addition of an inert gas to the air. Data for the effect of carbon dioxide, nitrogen, argon, and helium have been published (Coward and Hartwell, J., 1926, 1522). To these is now added a series of results obtained with water vapour, for which no data of any moment have hitherto been recorded.

#### EXPERIMENTAL.

For observations on the limits of inflammability of gas mixtures, it is desirable to use a vessel which is both wide enough to avoid errors due to cooling by its walls and long enough to show whether flame travels independently of the initial impetus of the source of ignition. Constant pressure should be maintained during inflammation, if the observations are to have any precise significance. Experience has shown ("Limits of Inflammability of Gases and Vapors," by H. F. Coward and G. W. Jones, *U.S.A. Bureau of Mines*, Bull. 279, 1928) that a vertical tube 2 inches in diameter, 4—6 feet long, and opened at the end behind the flame at about the moment of ignition, meets these requirements; it gives results nearly the same as those obtained in very much larger apparatus. The source of ignition is preferably near the lower end of the tube, for certain weak mixtures, although capable of indefinite propagation of flame upwards, are unable to burn downwards.

These requirements are met readily when gases alone are under examination, but not so easily when the temperature of the con-

tainer has to be above the normal to avoid condensation of vapours. Fig. 1 shows the arrangement which has proved satisfactory with mixtures of methane, air, and water vapour up to the temperature (just above  $67^{\circ}$ ) necessary to maintain enough water vapour to extinguish flame in any mixture of methane and air.

The glass tube A was surrounded by a stream of hot water from a gas heater. The water jacket was covered, save for a vertical observation slit, with asbestos cloth, and the water was stirred by

air bubbles from the perforated tube B. The difference in temperature between the top and bottom of the water jacket was never more than  $0.2^{\circ}$ .

For an experiment, the tube A was filled with water and water-sealed by the beaker C. The jacket and the beaker were brought to a predetermined temperature which was then maintained constant. The air bubble which had appeared at the top of A was sucked off, and the prepared mixture of methane and air admitted through the tap and finally bubbled through the water in C until about twice the volume of A had passed. A piece of tape, held by thin stainless-steel springs against the inner

wall of A, maintained liquid water in contact with the gas throughout the length of the tube.

The inflammability of the mixed methane, air, and water vapour was tested, when it had been heated by the constant-temperature jacket for 10 minutes, by passing a "fat" spark from an induction coil across the 5 mm. gap at D.\* At the same moment the beaker C was withdrawn to permit ready escape of the expanded products of combustion. An inflammable mixture propagated a blue flame with

\* Such a spark is strong enough to ensure ignition of any methane-air mixture which is capable of propagating flame—its energy much exceeds the minimum for ignition.

a convex front throughout the whole tube above the spark gap; if the mixture were outside the limits of inflammability, a cap of flame appeared above the spark gap, but did not assume the characteristic shape of the flame in a mixture which is inflammable *per se*, nor did it extend far up the tube. The distinction was clear.

In calculating the composition of the mixture, the ratio of methane to air was obtained by analysis of a sample from the gas holder. The total pressure of the mixture was atmospheric, and the partial pressure of the water vapour was assumed equal to the saturation pressure of water at the temperature of the jacket. The only place where the temperature of the tube A might have been somewhat lower was in and just below the rubber stopper, but, as the mixture at that place would be heavier than the rest, its influence on the composition of the mixture near and above the spark would be inappreciable.

It was possible that radiation from the advancing flame might evaporate some moisture from the tape and from the walls of the tube, just ahead of the flame, and thus produce a mixture of greater water content than we had calculated. To test this point, the tape was removed and a lower-limit mixture was passed through until only a few large drops of water, and (in one experiment) one patch of smaller drops, remained. The mixture was kept until it was saturated, and then ignited; the flame which travelled up the tube showed no change in width or shape as it passed the wet places. In other tests a small length of tape was inserted in the tube. The tape remained wet during the test, but the flame was not affected as it approached or passed the tape. It is concluded that evaporation of water by the flame was without appreciable influence on the limits.

*Results.*—The limits of inflammability of methane in dry air, in the 3-foot tube of the apparatus described, the water in the vessel C being replaced by mercury, were 5.24 and 14.08%. These agree sufficiently well with the previous observations in a 6-foot tube, *viz.*, 5.24 and 14.02%.

The results which serve to define the limits of mixtures of water vapour, methane, and air are in Table I. As the method of experiment is by trial and error, the range between inflammable and non-inflammable mixtures being narrowed in successive experiments, only the last few results of each series are quoted. When the figures of the first four columns of the tables are plotted on a large-scale diagram, the choice of the figures for the limit mixtures, shown in cols. 5 and 6, becomes clear. The concentration of water vapour is expressed as a percentage on the "original atmosphere" of air water vapour; whereas that of methane is expressed as

a percentage of the whole, *i.e.*, methane *plus* air *plus* water vapour.

TABLE I.

Propagated flame.		Failed to propagate flame.		Limit mixture.		Temp. (approx.).

19.4	9.36	19.6	9.42			

\* These five mixtures are scarcely distinguishable one from another, analytically. We estimate the accuracy of the water figure as within 0.2 unit and of the methane figure as within 0.02 unit.

Fig. 2 contains a graph of the limits given in Table I, with lower and higher limits for mixtures saturated with water vapour at laboratory temperature (see Coward and Hartwell, *loc. cit.*, footnote p. 1523). The curves for carbon tetrachloride (Coward and Jones, *Ind. Eng. Chem.*, 1926, 18, 970) and other diluent gases are included. The broken line is the locus of mixtures in which the molecular ratio CH<sub>4</sub> : O<sub>2</sub> is 1 : 2.

Most of the points on the water-vapour curve were necessarily obtained at temperatures higher than that of the laboratory. The points nearest the "nose" of this curve, for example, were obtained at 67°. For comparison, therefore, the position of the "nose" of the carbon dioxide curve was determined at the same temperature, and found to lie at 27.1% of carbon dioxide, instead of 24.5% at 17°. The "nose" of the nitrogen curve would doubtless be extended similarly by the same increase of temperature. Water vapour therefore lies between carbon dioxide and nitrogen in its extinctive action on methane flames, and is very nearly as effective, volume for volume, as the former.

#### Discussion.

The extinctive action of five of the six diluent gases runs in the order of their molecular heat capacities, which are (*C<sub>p</sub>*, 0—1200°):

Carbon tetrachloride, 22 (estimated); carbon dioxide, 10.90; water vapour, 9.20; nitrogen, 7.21; argon, 5.0. Helium is exceptional, for its heat capacity is equal to that of argon, but its extinctive effect on flame is relatively much greater. This is ascribed to its abnormally high thermal conductivity.

FIG. 2.

The extinctive action of water vapour is rather greater than would be inferred from its specific heat. The actual heat capacity of the water vapour present in the limit mixtures is, however, relatively greater than the figure 9.20 would suggest; for, according to Bose (*Z. Elektrochem.*, 1908, 14, 269), saturated water vapour is about 8.5% associated at 67°. Allowance being made for this and for the heat of dissociation of the complex water molecules ( $\text{H}_4\text{O}_2 = 2\text{H}_2\text{O} - 9640$  cal.; Bose, *loc. cit.*), the relative heat capacity of water vapour would be nearly 10.0 in the series.

The incidence of the water-gas equilibrium, which is attained in the gases "snatched" from the centre of higher-limit flames of methane, oxygen, and nitrogen (Coward, *Fuel*, 1929, 8, 470), has but a small effect on the heat of reaction, the heat capacity, and the thermal conductivity of the mixture. The effects of alterations in these three factors, due to the water-gas reaction, may be shown nearly to cancel one another.

The conclusion is, therefore, that, in the relative extinctive effects on methane flames of diluent gases which take no important part in the flame reactions, the chief factor is the heat capacity of the diluent, but that helium stands in an exceptional position by virtue of its high thermal conductivity. Other factors have very little influence. Carbon tetrachloride, although it undergoes extensive reaction in the flame of a methane-air mixture, falls into line with the other diluent gases.

### XXXVI.—*Mobile Anion Tautomerism. Part IV. The Stability of Some $\alpha$ - and $\gamma$ -Alkylallyl Alcohols and their Esters. 2:4-Dimethylcinnamyl Alcohol.*

By HAROLD BURTON.

It has been emphasised in previous parts of this series that the migratory power of X in the simple three-carbon anionotropic system, (I)  $R\cdot CHX\cdot CH:CH_2 \rightleftharpoons R\cdot CH:CH\cdot CH_2X$  (II), depends on three factors: (i) the group R, (ii) some molecular property of the solvent closely related to the dielectric constant, and (iii) the anionic stability of X (i.e., strengths of the acids HX). With regard to factor (iii), the migratory power of X is in the order  $Br > O\cdot CO\cdot CCl_3 > O\cdot CO\cdot C_6H_4\cdot NO_2(p)$ ;  $OAc > OH$ , the position of the trichloroacetoxy-group following from the recent work of Prévost (*Ann. Chim.*, 1928, 10, 160). Prévost has shown that esterification of trichloroacetic acid with either methylvinylcarbinol,  $CHMe(OH)\cdot CH:CH_2$ , or crotyl alcohol,  $CHMe\cdot CH\cdot CH_2\cdot OH$ , gives in each case the same mixture of about 55% of methylvinylcarbinyl trichloroacetate and about 45% of crotyl trichloroacetate. Furthermore, the action of potassium trichloroacetate on crotyl bromide

( $\alpha$ -bromo- $\Delta^{\beta}$ -butene) also gives the same mixture of the isomeric trichloroacetates. The explanation advanced by Prévost to account for the formation of the same mixture is that "trichloroacetic acid esterifies solely by the effect of hydrogen ions in liberating the tri-polar ion  $\text{CH}_3\cdot\overset{+}{\text{CH}}\cdot\bar{\text{C}}\text{H}\cdot\overset{+}{\text{CH}}_2$ ; the trichloroacetoxy-group subsequently combining at one or other of the positive poles."

An alternative explanation is that the esters of types I and II are first formed and that these subsequently undergo interconversion to give an equilibrium mixture. It is probable that Prévost considered this aspect, since he states that the isomeric trichloroacetates are not isomerised even above  $100^\circ$ . No experimental details of the attempted interconversions are given and one may presume that Prévost merely heated the esters alone below their boiling points. Consideration of the experimental conditions under which esterification is carried out indicates that the mixture of either alcohol and trichloroacetic acid would have a moderately high dielectric constant; this would tend to decrease as reaction proceeded. In Prévost's experimental procedure, esterification is far from complete (yield of esters, 45–46%), so that rearrangement of the isomeric trichloroacetates would be expected to occur if such an explanation is the correct one. On the other hand, the dielectric constants of the pure esters would be relatively small and long heating would be necessary to effect any interconversion (see Burton, J., 1928, 1650).

The author's method (*loc. cit.*) being used, methylvinylcarbinyl and crotyl trichloroacetates were heated in acetic anhydride (dielectric constant = 20.5) for 6 hours at the boiling point; in each case the equilibrium mixture of about 55% of the former and 45% of the latter ester was obtained. This shows definitely that the explanation suggested above is probably the correct one, and that Prévost's failure to effect isomerisation was due to unsuitable experimental conditions.

It would be expected that esterification of trichloroacetic acid with butylvinylcarbinol would afford a mixture with the equilibrium displaced in the direction II. Unfortunately, this has not been capable of verification, as the attempted esterification gave rise to none of the expected esters.

In Part III (J., 1929, 455) it was pointed out that the influence of the  $n$ -alkyl group in activating the simple three-carbon anionotropic system should reach its maximum at about  $n$ -hexyl. It was also stated that "even then the activation may not be as great as that produced by the phenyl or by *gem*-dialkyl groups." It is now shown that the  $n$ -hexyl and *iso*amyl groups are very similar to the

methyl group in their activating power. For instance,  $\alpha$ -n-hexylallyl *p*-nitrobenzoate, like  $\alpha$ -methylallyl *p*-nitrobenzoate, is recovered unchanged when an acetic anhydride solution is boiled for 6 and 24 hours; and acetylation of  $\alpha$ -isoamylallyl alcohol with an excess of acetic anhydride gives the corresponding acetate, as does methylvinylcarbinol. The pronounced difference in activating power of the alkyl and the phenyl group is again emphasised in experiments with  $\alpha$ -m-4-xylylallyl alcohol, which are described in the experimental portion. The conversion of this alcohol into 2:4-dimethylcinnamyl alcohol is of interest in view of the very limited methods available for the synthesis of cinnamyl alcohols.

#### EXPERIMENTAL.

Methylvinylcarbinol and butylvinylcarbinol were prepared by Delaby's method (*Compt. rend.*, 1922, 175, 967).

Butylvinylcarbinyll *p*-nitrobenzoate, prepared by the pyridine method, crystallises from cold alcohol in colourless plates, m. p. 24—25° (Found: C, 63.8; H, 6.5.  $C_{14}H_{17}O_4N$  requires C, 63.9; H, 6.5%).

*Esterification of Trichloroacetic Acid with Methylvinylcarbinol.*—This was carried out in the manner described by Prévost (*loc. cit.*). The yield of mixed esters, b. p. 70—90°/10 mm., was 45—46%. Fractionation of the mixture in a vacuum, by means of a Dufton column (50 cm.), gave approximately equal amounts of two well-defined fractions, the mid-piece being rejected. Further distillation under reduced pressure and collection of the middle fractions only, afforded methylvinylcarbinyll trichloroacetate, b. p. 69.5—70.5°/8 mm.,  $n_{D_{461}}^{18}$  1.46390 (Found: C, 33.4; H, 3.0. Calc.: C, 33.1; H, 3.2%), and crotyl trichloroacetate, b. p. 86—86.5°/9 mm.,  $n_{D_{461}}^{18}$  1.47596 (Found: C, 33.4; H, 3.4%). The refractive indices were measured with a Pulfrich instrument, the green line of the mercury arc being used, with an auxiliary slit to increase the accuracy of setting. The drum of the instrument was used, so the differences between the observed indices are more accurate than the absolute values. The pure esters and mixtures were measured rapidly one after another at the same temperature. The mixtures obtained from three similar experiments showed  $n_{D_{461}}^{18}$  1.46947, 1.46947, and 1.46932 respectively; hence content of methylvinylcarbinyll trichloroacetate = 54, 54 and 55% respectively.

*Conversion of the Esters into the Equilibrium Mixture.*—Either of the esters (10 g.) was boiled with acetic anhydride (20 c.c.) for 6 hours. The yellow solution was poured into water and extracted with ether, and the extract was washed repeatedly with sodium

\* The values for C are all somewhat high owing to the large chlorine content of the esters.

carbonate solution until free from acid and dried. The residue from the ethereal extract gave, in addition to a main fraction, b. p. 70—90°/10 mm., high-boiling material, showing that some decomposition had taken place. The mixed esters were redistilled three times and analysed (Found: C, 33.6, 33.5; H, 3.1, 3.5%). The refractive indices of the mixtures were 1.46916 and 1.46932; hence content of methylvinylcarbinyl trichloroacetate = 56 and 55%.

*α-n-Hexylallyl Alcohol* ( $\Delta^a$ -Nonen- $\gamma$ -ol),  $C_6H_{13}\cdot CH(OH)\cdot CH\cdot CH_2$ .—The Grignard reagent prepared by the method of Gilman and McCracken (*J. Amer. Chem. Soc.*, 1923, 45, 2463) from magnesium (12 g.), *n*-hexyl bromide (82 g.), ether (200 c.c.), and a trace of iodine was cooled below 0°, and a solution of acraldehyde (33 c.c.) in ether (150 c.c.) added during 2 hours. The mixture was stirred for a further 4 hours and then decomposed with ice and saturated ammonium chloride solution. Distillation of the oil from the ethereal extract gave 36 g. of a mobile oil, b. p. 88—95°/16 mm., which gave high values for carbon and hydrogen and was not purified by further fractionation. When the oil was heated with *p*-nitrobenzoyl chloride (50 g.) and pyridine (350 c.c.) on the water-bath for 2 hours, and the mixture poured on ice, a solid (35 g.) was obtained. This was collected, washed with cold light petroleum, drained on porous earthenware, and crystallised from a concentrated alcoholic solution at 0—5°; *α-n-hexylallyl p-nitrobenzoate*, m. p. 36—37°, then separated in almost colourless plates (Found: C, 65.8; H, 7.2.  $C_{16}H_{21}O_4N$  requires C, 66.0; H, 7.2%).

Hydrolysis of the *p*-nitrobenzoate (14.5 g.) by boiling with 5% alcoholic potassium hydroxide solution (100 g.) for 2 hours, the product being worked up in the usual way, gave *α-n-hexylallyl alcohol* as a colourless mobile oil, b. p. 89°/12 mm. (Found: C, 75.7; H, 12.8.  $C_6H_{13}O$  requires C, 76.05; H, 12.7%).

When the *p*-nitrobenzoate (5 g.) was boiled with acetic anhydride (10 c.c.) for 6 and for 24 hours, and the solutions were poured into water, unchanged material was obtained in each case.

*α-isoAmylallyl Alcohol*,  $CHMe_2\cdot CH_2\cdot CH_2\cdot CH(OH)\cdot CH\cdot CH_2$ .—The Grignard reagent prepared from magnesium (12 g.), *isoamyl* bromide (76 g.), ether (300 c.c.), and a trace of iodine was treated during 2 hours with a solution of acraldehyde (30 c.c.) in ether (150 c.c.) as for the hexyl analogue. Decomposition of the product with ice and ammonium chloride and careful fractionation of the product obtained afforded 14 g. of the *alcohol*, b. p. 73—74°/16 mm., as a colourless mobile oil (Found: C, 75.05; H, 12.6.  $C_8H_{16}O$  requires C, 75.0; H, 12.5%). A crystalline *p*-nitrobenzoate could not be prepared by the pyridine method.

*α-isoAmylallyl acetate*,  $CHMe_2\cdot CH_2\cdot CH_2\cdot CH(OAc)\cdot CH\cdot CH_2$ , was

obtained by boiling a mixture of the above alcohol (14 g.) and acetic anhydride (20 c.c.) for 9 hours and working up the product in the usual way. The ester is a colourless mobile oil, b. p. 83—84°/18 mm. (Found: C, 70·5; H, 10·6.  $C_{10}H_{18}O_2$  requires C, 70·6; H, 10·6%). Hydrolysis with an excess of boiling 5% alcoholic potassium hydroxide solution regenerated the above alcohol.

*α-m-4-Xylylallyl Alcohol*,  $C_6H_3Me_2\cdot CH(OH)\cdot CH:CH_2$ .—To the well-cooled Grignard reagent prepared from magnesium (12 g.), *m-4*-iodoxylylene (116 g.), ether (200 c.c.), and a trace of iodine, a solution of acetaldehyde (33 c.c.) in ether (150 c.c.) was added during 2 hours. The mixture was stirred for a further 3 hours, and the very gummy product decomposed with ice and ammonium chloride solution. Distillation of the residue from the ethereal extract afforded a fraction (12 g.), b. p. 130—140°/15 mm., which on redistillation gave the impure *alcohol*, b. p. 129—131°/12 mm., as a colourless mobile oil (Found: C, 80·1; H, 8·8.  $C_{11}H_{14}O$  requires C, 81·5; H, 8·6%). The *phenylurethane*, m. p. 105—106°, crystallises from light petroleum in clusters of colourless fine needles (Found: C, 77·0; H, 6·8.  $C_{18}H_{19}O_2N$  requires C, 76·9; H, 6·8%).

*2:4-Dimethylcinnamyl Alcohol*,  $C_6H_3Me_2\cdot CH:CH\cdot CH_2\cdot OH$ .—A mixture of *α-m-4*-xylylallyl alcohol (8 g.) and acetic anhydride (10 c.c.) was boiled for 6 hours and then fractionated. The 2:4-dimethylcinnamyl acetate, b. p. 168—170°/17 mm., obtained was hydrolysed with a slight excess of 5% alcoholic potassium hydroxide solution, giving 2:4-dimethylcinnamyl alcohol, which was obtained as a pleasant-smelling, straw-coloured, viscous liquid, b. p. 162—164°/19 mm. (Found: C, 80·8; H, 8·6.  $C_{11}H_{14}O$  requires C, 81·5; H, 8·6%). The *phenylurethane* separated from light petroleum in colourless needles, m. p. 82—83° (Found: C, 77·0; H, 6·9.  $C_{18}H_{19}O_2N$  requires C, 76·9; H, 6·8%).

The author is indebted to Professor C. K. Ingold, F.R.S., for his interest in this work and to Mr. A. Rumfitt for carrying out the majority of the analyses recorded. The cost has been partly defrayed with a grant from the Government Grant Committee of the Royal Society, to whom the author's thanks are due.

THE UNIVERSITY, LEEDS.

[Received, December 20th, 1929.]

## XXXVII.—Some Trinitroethylbenzenes.

By JAMES NELSON EDMUND DAY.

AN account is here given of the preparation of 3:4:5-, 2:3:4-, and 2:4:5-trinitroethylbenzenes, together with some of their reactions. One of the difficulties in the study of derivatives of

ethylbenzene has been a suitable initial material of undoubted purity; this has been overcome by using *p*-aminoethylbenzene, prepared from pure *p*-aminoacetophenone by the reduction method of Clemmensen (*Ber.*, 1913, 46, 1837; 1914, 47, 51, 681).

On acetylation of *p*-aminoethylbenzene the acetyl derivative described by Paucksch (*Ber.*, 1884, 17, 769) was obtained, and this on nitration gave 3:5-dinitro-4-acetamidoethylbenzene (m. p. 182—183°) identical with that previously described (Paucksch, *loc. cit.*; Brady, Day, and Allam, J., 1928, 982). These experiments were carried out to make certain that the compound described by Paucksch was the *p*- and not the *o*-amino-compound, as it was obtained by separation of the *o*- and *p*-acetamidoethylbenzenes by crystallisation, a process which it had been found difficult to repeat satisfactorily.

3:5-Dinitro-4-aminoethylbenzene, on diazotisation and treatment with sodium nitrite and copper sulphate, gave 3:4:5-trinitroethylbenzene.

*p*-Aminoethylbenzene, on nitration in presence of excess of sulphuric acid, gave 2-nitro-4-aminoethylbenzene identical with the compound prepared by reduction of crude 2:4-dinitroethylbenzene (compare Cline and Read, *J. Amer. Chem. Soc.*, 1927, 49, 3150, who have shown that some 4-nitro-2-aminoethylbenzene is also produced in this reaction; compare also Brady, Day, and Allam, *loc. cit.*). Nitration of 2-nitro-4-acetamidoethylbenzene gave a mixture of 2:3-dinitro- and 2:5-dinitro-4-aminoethylbenzenes which on oxidation with Caro's acid gave respectively 2:3-dinitro-4-nitrosoethylbenzene and 2:5-dinitro-4-nitrosoethylbenzene. Oxidation of the latter compounds with nitric acid gave the required 2:3:4- and 2:4:5-trinitroethylbenzenes.

2:3:4-Trinitroethylbenzene has also been prepared by the direct nitration of 2:3-dinitroethylbenzene.

These trinitroethylbenzenes are very similar to the corresponding

trinitrotoluenes, but their melting points are lower. They form well-defined *methylamine* and *hydrazine* derivatives by replacement of the mobile nitro-group. Their alcoholic solutions give colorations with dilute sodium hydroxide solution. 2:3:4-Trinitroethylbenzene gives a bright green-yellow colour, changing to brown and brownish-red; the corresponding trinitrotoluene gives a green and then a brown colour. 2:4:5-Trinitroethylbenzene gives a bright green, changing to dark green and red; the corresponding trinitrotoluene gives blue, green, and then brown colours. 3:4:5-Trinitroethylbenzene and the corresponding trinitrotoluene both give a bright pink colour, changing to brown.

#### EXPERIMENTAL.

*p-Aminoethylbenzene*.—A mixture of granulated zinc (100 g., left in contact with mercuric chloride, 20 g., in water, 400 c.c., for 12 hours and then washed with water), concentrated hydrochloric acid (200 c.c.), and water (200 c.c.) was gently heated while *p*-aminoacetophenone (25 g.), dissolved in concentrated hydrochloric acid (200 c.c.), was added slowly through an upright condenser, followed by concentrated hydrochloric acid (100 c.c.). After being heated for 5 hours, the mixture was cooled and, a slight excess of a concentrated solution of sodium hydroxide having been added, submitted to steam distillation. The *p*-aminoethylbenzene was extracted from the distillate with ether (average yield, 19.5%; varying the time of boiling or the amount of hydrochloric acid did not greatly affect the yield).

On acetylation with acetic anhydride, the amine gave *p*-acet-amidoethylbenzene, identified by its m. p. and mixed m. p. with a specimen prepared from ethylbenzene.

On nitration with ten times its weight of nitric acid (*d* 1.5), the acetyl compound gave 3:5-dinitro-4-acetamidoethylbenzene, m. p. 182—183° after crystallisation from alcohol. Addition of this substance did not lower the melting point of the 3:5-dinitroacet-amidoethylbenzene previously prepared (Brady, Day, and Allam, *loc. cit.*). This experiment supplied the direct evidence required, that the amino-group in the dinitroacetamidoethylbenzene, m. p. 183°, previously isolated from the nitrated mixture of *o*- and *p*-acet-amidoethylbenzenes, was in the 4-position.

3:4:5-Trinitroethylbenzene.—Sulphur dioxide was passed into nitric acid (*d* 1.5) (5.7 g.) at 0° until the gain in weight was 0.6 g. The solution was cooled to — 12°, 3:5-dinitro-4-aminoethylbenzene (1.4 g.) dissolved in it, the solution poured on ice (20 g.), and the whole added to a mixture of copper sulphate (5.7 g.) and sodium nitrite (1.6 g.) in water (25 c.c.) containing ice (50 g.). After 12

hours, the precipitate was collected, washed, and heated with nitric acid ( $d$  1.42) on the water-bath for 30 minutes, the mixture cooled and diluted, and the product crystallised from nitric acid ( $d$  1.42). A final crystallisation from alcohol containing a little acetic acid gave 3:4:5-*trinitroethylbenzene* in white needles, m. p. 92.5° (Found: C, 39.8; H, 2.9; N, 17.3.  $C_8H_7O_6N_3$  requires C, 39.8; H, 2.9; N, 17.4%).

3:4:5-Trinitroethylbenzene (0.2 g.) in alcohol (6 c.c.) was warmed with 33% methylamine solution (0.3 g.) in alcohol (2 c.c.) on the water-bath for 5 minutes, and the solution diluted with an equal volume of water and cooled. Crystallisation of the precipitate from dilute alcohol gave 3:5-dinitro-4-methylaminoethylbenzene in orange needles, m. p. 73° (Found: C, 47.9; H, 5.0.  $C_9H_{11}O_4N_3$  requires C, 48.0; H, 4.9%).

Similarly, from 3:4:5-trinitroethylbenzene (0.2 g.) in alcohol (6 c.c.) and 50% hydrazine hydrate solution (0.2 g.) in alcohol (4 c.c.), 3:5-dinitro-4-hydrazinoethylbenzene was obtained; it formed copper-red plates, m. p. 85°, on crystallisation from alcohol (Found: C, 42.5; H, 4.5.  $C_8H_{10}O_4N_4$  requires C, 42.5; H, 4.5%).

2-Nitro-4-aminoethylbenzene.—Sulphuric acid ( $d$  1.84) (55 c.c.) was cooled to 0°, and *p*-aminoethylbenzene (5 g.) added slowly. The solution was cooled to -8°, and stirred while a mixture of nitric acid ( $d$  1.5) (3.3 g.) and sulphuric acid ( $d$  1.84) (8 c.c.) was added drop by drop. After being kept at 0° for 30 minutes, the mixture was poured on ice. The precipitated sulphate was decomposed with 2*N*-sodium hydroxide, and the amine extracted with ether. Crystallised from light petroleum, the product melted at the same temperature (45°) as the compound described by Cline and Read (*loc. cit.*).

2:3-Dinitro-4-nitrosoethylbenzene.—2:3-Dinitro-4-aminoethylbenzene (1.58 g.) (Brady, Day, and Allam, *loc. cit.*) was dissolved in sulphuric acid ( $d$  1.84) (5 c.c.) at 0°. Sulphuric acid ( $d$  1.84) (5 c.c.) was cooled in a freezing mixture, finely powdered ammonium persulphate (5.13 g.) added in small quantities at a time, and the solution kept at 0° for an hour and then poured on ice (12 g.) in a stoppered bottle. The sulphuric acid solution of the amine was added, and the mixture shaken occasionally during the following 5 days. The precipitate, after being washed with water and crystallised from alcohol, gave 2:3-dinitro-4-nitrosoethylbenzene in fine yellow crystals, which melted at 80–81° to a dark green liquid (Found: N, 18.5.  $C_8H_7O_5N_3$  requires N, 18.7%). The dark green hot alcoholic solution of this compound became yellow on cooling.

2:3:4-Trinitroethylbenzene.—2:3-Dinitro-4-nitrosoethylbenzene was heated on the water-bath for 30 minutes with an excess of

nitric acid (*d* 1.42), the solution diluted, and the precipitate crystallised from benzene–light petroleum, 2 : 3 : 4-*trinitroethylbenzene* being obtained in pale yellow plates, m. p. 80° (Found : C, 39.7; H, 2.9; N, 17.2.  $C_8H_7O_6N_3$  requires C, 39.8; H, 2.9; N, 17.4%). This compound was also obtained by adding 2 : 3-dinitroethylbenzene (1 g.) slowly to a mixture of nitric acid (*d* 1.5) (1 g.) and sulphuric acid (*d* 1.84) (12 c.c.) and heating the whole at 100° for 2 hours; it separated on cooling and was crystallised as before.

Treated with methylamine as was 3 : 4 : 5-trinitroethylbenzene, it gave 2 : 4-dinitro-3-methylaminoethylbenzene, which crystallised from dilute alcohol in yellow plates, m. p. 92–93° (Found : C, 48.2; H, 4.8.  $C_9H_{11}O_4N_3$  requires C, 48.0; H, 4.9%).

Treated with hydrazine hydrate as described above, it gave 2 : 4-dinitro-3-hydrazinoethylbenzene, which separated from alcohol in bright orange-red needles, m. p. 149° (Found : C, 42.5; H, 4.5.  $C_8H_{10}O_4N_4$  requires C, 42.5; H, 4.5%).

2 : 5-Dinitro-4-nitrosoethylbenzene.—2 : 5-Dinitro-4-aminoethylbenzene (Brady, Day, and Allam, *loc. cit.*) was oxidised with persulphuric acid in the same way as 2 : 3-dinitro-4-aminoethylbenzene. The precipitate was collected after 4 days and crystallised from alcohol, 2 : 5-dinitro-4-nitrosoethylbenzene being obtained in small, deep yellow prisms, m. p. 111–112° (Found : N, 18.4.  $C_8H_7O_5N_3$  requires N, 18.7%). The hot alcoholic solution was dark yellowish-green and the pure substance melted to a dark green liquid.

2 : 4 : 5-Trinitroethylbenzene.—2 : 5-Dinitro-4-nitrosoethylbenzene, on oxidation with nitric acid (*d* 1.42), gave 2 : 4 : 5-trinitroethylbenzene, which separated from benzene–light petroleum in light yellow crystals, m. p. 40° (Found : C, 40.0; H, 3.0; N, 17.6.  $C_8H_7O_6N_3$  requires C, 39.8; H, 2.9; N, 17.4%).

With methylamine, it gave 2 : 4-dinitro-5-methylaminoethylbenzene, which crystallised from alcohol in yellow needles, m. p. 149° (Found : C, 48.2; H, 5.0.  $C_9H_{11}O_4N_3$  requires C, 48.0; H, 4.9%). With hydrazine, it gave 2 : 4-dinitro-5-hydrazinoethylbenzene, which crystallised from alcohol in yellow-brown needles, m. p. 141° (Found : C, 42.7; H, 4.6.  $C_8H_{10}O_4N_4$  requires C, 42.5; H, 4.5%).

The author wishes to thank Dr. O. L. Brady for his interest in this work.

XXXVIII.—*The Reactions of Malonic Esters with Formaldehyde. Part I.*

By KENNETH NORMAN WELCH.

DURING the course of a research requiring large quantities of ethyl methylenedimalonate, it was found that the product prepared by Knoevenagel's method (*Ber.*, 1894, **27**, 2345) varied considerably in yield and contained a substance which decomposed with evolution of formaldehyde during distillation. Although Gault (*Bull. Soc. chim.*, 1912, [iv], **11**, 381) showed that better yields could be obtained by employing an excess of ethyl malonate, it was felt that a more thorough investigation of the reaction would be justified.

Ethyl malonate condenses with formaldehyde in the presence of dilute sodium hydroxide solution to give a solid addition compound, *ethyl di(hydroxymethyl)malonate* (I). The presence of two hydroxyl groups was proved by the preparation of a *diphenylcarbamate* and a neutral *sulphite*. Further, the ester (I) was converted into  $\alpha$ -iodomethylacrylic acid,  $\text{CH}_2\text{:C}(\text{CH}_2\text{I})\cdot\text{CO}_2\text{H}$ , by the action of hydriodic acid, and this unsaturated acid, which gave the iodoform reaction, was reduced to isobutyric acid by the action of hydriodic acid and red phosphorus. The readiness with which ethyl di(hydroxymethyl)malonate loses formaldehyde forms an interesting comment on a paper by Earl, Ellsworth, Jones, and Kenner (*J.*, 1928, 2697).

When formaldehyde was condensed with a larger excess of ethyl malonate in the presence of dilute sodium hydroxide solution, a saturated compound, probably ethyl hydroxymethylmalonate (II), was produced as an oil: this could not be distilled owing to the ease with which it lost water to give ethyl methylenemalonate. This substance is responsible for the more complex condensation products obtained by the action of formaldehyde on ethyl malonate: the production of ethyl methylenedimalonate (III) and ethyl pentane- $\alpha\alpha\gamma\gamma\gamma$ -hexacarboxylate (IV) (compare Bottomley and Perkin, *J.*, 1900, **77**, 294) is explained as follows:

The above reactions take place independently under the conditions employed in the condensation of formaldehyde and ethyl malonate.

For instance, ethyl di(hydroxymethyl)malonate reacts with ethyl malonate in the presence of piperidine, triethylamine, or potassium hydroxide (*a*; p. 260) to give a mixture of (III) and (IV), and the yield of the latter is decreased when a larger excess of ethyl malonate is used (*b*; p. 260): experiment (*c*) (p. 260) shows that the last result is not due to the action of ethyl malonate on (IV). Further, ethyl methylenemalonate condenses readily with ethyl malonate and with ethyl methylenedimalonate (III) in the presence of piperidine to give (III) and (IV) respectively.

Although ethyl hydroxymethylmalonate (II) is incapable of isolation in the pure state, its alkyl substitution products, for example, *ethyl (hydroxymethyl)ethylmalonate*, can be distilled in a vacuum without decomposition.\* This ester reacts with ethyl malonate in the presence of piperidine to give ethyl methylenedimalonate and ethyl ethylmalonate, but no facile reaction occurs between ethyl (hydroxymethyl)ethylmalonate and ethyl ethylmalonate.

#### EXPERIMENTAL.

*Ethyl Di(hydroxymethyl)malonate* (I).—Ethyl malonate (100 g.), 40% formalin (180 g.), and a few drops of B.D.H. Universal Indicator were mixed and 10% sodium hydroxide solution was gradually added. Reaction began at  $p_H$  7.5 and was rapid at  $p_H$  8.5. Owing to slight hydrolysis of the ester the  $p_H$  was apt to fall, and sodium hydroxide was added during 48 hours to maintain it between 8 and 9. The mixture became homogeneous and the temperature was kept below 50°. The mixture was then diluted with water (2 vols.), shaken with the smallest quantity of ether necessary to remove insoluble impurities, saturated with sodium chloride, and extracted five times with ether. The dried extracts, on removal of the ether, left a residue, which was heated in a vacuum at 50–60°. The glycerol-like substance remaining solidified after some months or more quickly on generous seeding. After being drained on porous plate and recrystallised from benzene–petroleum (b. p. 100–120°) or, better, from ether–amyl ether, *ethyl di(hydroxymethyl)malonate* was obtained in colourless elongated prisms, m. p. 52–53° (Found: C, 49.1, 48.9; H, 7.1, 7.2; OEt, 40.1.  $C_9H_{16}O_6$  requires C, 49.1; H, 7.3; OEt, 40.9%). This ester has an intensely bitter taste and is very soluble in water, alcohol, ether, and benzene and slightly soluble in light petroleum and amyl ether. It is decomposed by heat into formaldehyde, water, alcohol, carbon dioxide, small

\* Such condensations appear to be general and experiments with formaldehyde and ethyl butane- $\alpha\beta$ -tricarboxylate are in progress with a view to the synthesis of pilocarpic acid (Jowett, J., 1901, 79, 1331).

quantities of ethyl acrylate and ethyl methylenemalonate and a large quantity of high-boiling tar.

The *diphenylcarbamate*, prepared by the action of phenylcarbamide (5 g.) on ethyl di(hydroxymethyl)malonate (5 g.) during one week at the room temperature, crystallised from alcohol in needles (8 g.), m. p. 161° (Found: C, 60.0; H, 5.8; N, 6.3.  $C_{23}H_{26}O_8N_2$  requires C, 60.3; H, 5.7; N, 6.1%). *Ethyl di(hydroxymethyl)malonate sulphite*, prepared by the action of thionyl chloride (11.8 g.) on ethyl di(hydroxymethyl)malonate (22 g.) in anhydrous ether for 6 hours, distilled as a colourless oil (19 g.), b. p. 166°/20 mm. (Found: C, 40.6; H, 5.3.  $C_9H_{14}O_7S$  requires C, 40.6; H, 5.2%).

*$\alpha$ -Iodomethylacrylic Acid*.—Ethyl di(hydroxymethyl)malonate (10 g.) and hydriodic acid (*d* 1.71; 66 g.) were boiled for 45 minutes, ethyl iodide and carbon dioxide being evolved. After cooling and standing for 1 hour, the solid (7 g., m. p. 95–100°) was collected, washed with a little water, and rapidly recrystallised from boiling water; it separated in cream-coloured plates, m. p. 104–106° (slight decomp.). A somewhat purer specimen (m. p. 106–107°) of the same substance was obtained by subjecting ethyl di(hydroxymethyl)malonate to a preliminary hydrolysis with 3% sulphuric acid at 120–140°, and treating the crude acid (which rapidly polymerises) with cold hydriodic acid (Found: C, 22.6; H, 2.4; *M*, ebullioscopic in ether, 220.  $C_4H_5O_2I$  requires C, 22.6; H, 2.4%; *M*, 212).  *$\alpha$ -Iodomethylacrylic acid* rapidly turns brown on exposure to light and air.

*Reduction of  $\alpha$ -Iodomethylacrylic Acid*.—Ethyl di(hydroxymethyl)malonate (25 g.) was converted into iodomethylacrylic acid by heating with hydriodic acid as described above. Red phosphorus (7 g.) and hydriodic acid (30 g.) were then added and the mixture was boiled for 10 hours. After dilution with an equal volume of water, the mixture was steam-distilled; the distillate was neutralised with sodium hydroxide and evaporated to dryness. Excess of 50% sulphuric acid was added; the liberated acid, isolated by extraction with ether, boiled at 150–160°. It was converted into the chloride by the action of the theoretical quantity of boiling thionyl chloride for 20 minutes, and the product poured into an excess of aniline (6 g.). After being heated on the water-bath for 20 minutes, the product was poured into an excess of dilute hydrochloric acid; the solid obtained, after recrystallisation from dilute alcohol, melted at 103–105°, alone or in admixture with authentic isobutyranilide.

*Ethyl (Hydroxymethyl)malonate (II)*.—Formalin (10 g.), ethyl malonate (60 g.), and enough alcohol to give a homogeneous mixture were mixed with a few drops of B.D.H. Universal Indicator, and

sodium hydroxide solution added to produce  $p_H$  9. After 24 hours, the mixture was rendered faintly acid, diluted with water, and extracted with ether. After drying and removal of the solvent, the excess of ethyl malonate was distilled off in a vacuum, leaving ethyl (hydroxymethyl)malonate as an oil, which was almost without action on dilute potassium permanganate solution. Treated with phenylcarbimide, the ester gave diphenylurea, m. p.  $238^\circ$ .

*Condensation of Ethyl Di(hydroxymethyl)malonate with Ethyl Malonate.*—(a) Ethyl di(hydroxymethyl)malonate (10 g.), ethyl malonate (20 g.), and piperidine, triethylamine or alcoholic potassium hydroxide (a few drops) were heated for 6 hours in the water-bath. On cooling and standing over-night, crystals separated. The whole was then fractionated, giving: (i) ethyl methylenedimalonate (10 g.), b. p.  $140\text{--}180^\circ/5$  mm., which on hydrolysis gave glutaric acid, m. p.  $95\text{--}97^\circ$ , not depressed by admixture with an authentic specimen; (ii) ethyl pentane- $\alpha\gamma\gamma\gamma$ -hexacarboxylate (10 g.), b. p.  $180\text{--}240^\circ/5$  mm., which solidified and, after being drained and recrystallised from alcohol, melted at  $52\text{--}53^\circ$  (Found: C, 54.9; H, 7.0. Calc. for  $C_{23}H_{36}O_{12}$ : C, 54.8; H, 7.1%).

(b) A similar experiment with 60 g. of ethyl malonate instead of 20 g. yielded ethyl methylenedimalonate (27 g.) but no pentane derivative (IV).

(c) The condensation (a) was repeated, but, after the preliminary heating, the product was mixed with ethyl malonate (35 g.) and a few drops of piperidine and heated for a further 6 hours. Ethyl pentane- $\alpha\gamma\gamma\gamma$ -hexacarboxylate (10 g.) was isolated after removal of the excess of ethyl malonate.

*Ethyl (hydroxymethyl)ethylmalonate*, prepared by condensing ethyl ethylmalonate (20 g.) and formalin (30 g.) for 48 hours under the conditions employed for the condensation of formalin with ethyl malonate, was obtained as an oil (15 g.), b. p.  $105\text{--}107^\circ/4$  mm. (Found: C, 54.8; H, 8.3.  $C_{10}H_{18}O_5$  requires C, 55.0; H, 8.3%). The *phenylcarbamate* crystallised from dilute methyl alcohol in plates, m. p.  $63\text{--}64^\circ$  (Found: C, 60.5; H, 6.9.  $C_{17}H_{23}O_5N$  requires C, 60.5; H, 6.8%).

Ethyl (hydroxymethyl)ethylmalonate (2 g.), ethyl malonate (5 g.), and piperidine (1 drop) were heated on the water-bath for 5 days. Distillation then yielded ethyl ethylmalonate, b. p.  $90\text{--}100^\circ/12$  mm., and ethyl methylenedimalonate, b. p.  $190\text{--}200^\circ/12$  mm., which was hydrolysed to glutaric acid, m. p.  $94\text{--}96^\circ$ .

No apparent reaction took place on the water-bath between ethyl (hydroxymethyl)ethylmalonate and ethyl ethylmalonate in the presence of piperidine. At  $130\text{--}140^\circ$ , alcohol was eliminated, but nothing further could be isolated from the product.

*Condensation of Ethyl Methylenemalonate with Ethyl Malonate and with Ethyl Methylenedimalonate.*—Ethyl methylenemalonate (freshly distilled) (2 g.) and ethyl malonate were mixed and methyl-alcoholic potassium hydroxide (1 drop) was added; considerable heat was evolved. After standing in the cold for 1 hour, the product was unreactive to dilute potassium permanganate solution and on distillation gave ethyl methylenedimalonate (3 g.), as proved by conversion into glutaric acid.

Under the same conditions, the condensation with ethyl methylenedimalonate was complete after 1 hour's heating on the water-bath; the mixture solidified on cooling and was proved to be ethyl pentane- $\alpha\alpha\gamma\gamma$ -hexacarboxylate by the mixed m. p. method.

The author wishes to thank the Chemical Society for a grant which has partly defrayed the cost of the materials used in this research.

### XXXIX.—*Colloidal Phenoxides. Part II. Some Phenanthraxanthones.*

By WILSON BAKER.

A NUMBER of derivatives of 7-hydroxybenzo- $\gamma$ -pyrone containing aromatic groups in positions 2 and 3 dissolve in hot aqueous alkaline solutions and yield gels on cooling. The relationships existing between the chemical constitution and the capability of forming gels in these compounds was established in Part I (Baker and Eastwood, J., 1929, 2897), and the ultimate object of the work was indicated. Briefly, this was to prepare a substance which should give a gel in alkaline solutions and at the same time exhibit fluorescence, so that by examination in ultra-violet light the structure of the gel might be visible.

The simplest derivative of benzo- $\gamma$ -pyrone which gives a gel is 7-hydroxy-2:3-diphenylbenzo- $\gamma$ -pyrone (I), and the attempt to make the molecule fluoresce while retaining the colloidal properties is described in this paper. The work recorded in Part I showed that only minor changes could be made in the molecule (I) without destroying the desired physical properties of the alkali salts. Such changes as can be made within these limitations consist of alteration of the substituents in positions 2 and 3 (introduction of a *p*-methoxy-group, replacement of phenyl by styryl) and the intro-

duction of a further hydroxyl group in position 5. No such changes can be expected, nor are found, to increase appreciably the fluorescence of the substance (I), and it was obvious that some other type of simple alteration to the molecule was necessary. Attention was therefore directed to the synthesis of 10-hydroxyphenanthraxanthone\* (II), in which the two phenyl nuclei are united, so that the substance, being a phenanthrene derivative, might be expected to possess an enhanced fluorescence.

This synthesis has now been achieved, but both the physical and the optical properties of the alkali salts of the substance are such that it is very doubtful if it will serve the purpose for which it was intended. The gels are unstable and without appreciable fluorescence.

The ring closure between the two phenyl nuclei was effected by means of Pschorr's phenanthrene synthesis, and in order to study the conditions of the reaction use was made of the readily accessible 7-methoxy-3-phenyl-2-(6-nitro-3:4-dimethoxyphenyl)benzo- $\gamma$ -pyrone (III). This substance was prepared by the nitration of 7-methoxy-3-phenyl-2-(3:4-dimethoxyphenyl)benzo- $\gamma$ -pyrone (Part I, *loc. cit.*) in acetic acid solution, the position of the nitro-group being inferred from the great reactivity of the veratryl nucleus in position 6, and the success of the subsequent ring closure. Reduction with tin and hydrochloric acid gave 7-methoxy-3-phenyl-2-(6-amino-3:4-dimethoxyphenyl)benzo- $\gamma$ -pyrone, and a methyl-alcoholic solution of the sulphate of this base, when diazotised and subsequently boiled, deposited the very sparingly soluble 6:7:10-trimethoxyphenanthraxanthone (IV) in 70% yield. This compound was demethylated by boiling with hydrobromic acid and acetic acid, giving 6:7:10-trihydroxyphenanthraxanthone. The high yield of (IV) is doubtless to be attributed to the spatial arrangement of the *o*-nitrophenyl and

\* At the suggestion of the Editor the parent substance has received the name "phenanthraxanthone" with the numbering shown. The formula (II) should be inverted, but in order not to confuse the relation of the substance to the diphenylbenzo- $\gamma$ -pyrone from which it is prepared, the representation above is adopted in this paper.

the phenyl group, *cis-trans* isomerism about the ethylenic linkage being impossible.

The synthesis of (II) was effected as follows. When 2:4-dihydroxyphenyl benzyl ketone was heated under carefully defined conditions with *o*-nitrobenzoic anhydride and sodium *o*-nitrobenzoate and the product was hydrolysed with alcoholic potassium hydroxide, 7-hydroxy-3-phenyl-2-*o*-nitrophenylbenzo- $\gamma$ -pyrone (V) was obtained. The methyl ether of this compound was reduced with tin and hydrochloric acid to the base 7-methoxy-3-phenyl-2-*o*-aminophenylbenzo- $\gamma$ -pyrone, and diazotisation of this substance in the manner described above yielded 10-methoxyphenanthraxanthone, from which 10-hydroxyphenanthraxanthone (II) was obtained by demethylation with hydrobromic acid in acetic acid.

Owing to difficulties encountered in the preparation of (V), the synthesis of (II) was attempted in another way. *o*-Nitrophenylacetonitrile was condensed with resorcinol under the conditions of the Hoesch reaction, giving 2:4-dihydroxyphenyl *o*-nitrobenzyl ketone; this, when heated with benzoic anhydride and sodium benzoate, yielded a product which gave 7-hydroxy-2-phenyl-3-*o*-nitrophenylbenzo- $\gamma$ -pyrone (VI) on hydrolysis. The corresponding methyl ether, however, when reduced with tin and hydrochloric acid or with ferrous sulphate and ammonia, yielded, not a primary base, but an uncrystallisable substance showing some of the properties of a secondary amine. It is possible that ring closure may occur between the amino-group first produced and the carbonyl group, and that further reduction then takes place.

#### EXPERIMENTAL.

7-Methoxy-3-phenyl-2-(6-nitro-3:4-dimethoxyphenyl)benzo- $\gamma$ -pyrone (III).—7-Hydroxy-3-phenyl-2-(3:4-dimethoxyphenyl)benzo- $\gamma$ -pyrone (Part I, *loc. cit.*) (10 g.) was dissolved in warm glacial acetic acid (75 c.c.), and to the cooled solution was added a mixture of glacial acetic acid (50 c.c.) and concentrated nitric acid (50 c.c.; *d* 1.42). After 2 hours, the red solution was poured into water, and the precipitated nitro-compound collected; it crystallised from

alcohol, in which it was sparingly soluble, in light yellow, thick, diamond-shaped plates (or hexagonal plates), m. p.  $222^{\circ}$  (Found : C, 66.0; H, 4.6; N, 3.5.  $C_{24}H_{19}O_7N$  requires C, 66.5; H, 4.4; N, 3.2%). In contrast to the unnitrated substance, this compound shows no basic properties towards hydrochloric acid.

*7-Methoxy-3-phenyl-2-(6-amino-3:4-dimethoxyphenyl)benzo- $\gamma$ -pyrone.*—The finely powdered nitro-compound (III) (10 g.), alcohol (300 c.c.), finely divided granulated tin (25 g.), and concentrated hydrochloric acid (60 c.c.) were gently boiled for 6 hours; alcohol (100 c.c.) was then removed by distillation. The filtered solution deposited thick, hexagonal, light yellow plates of the *stannichloride*, which were collected after 12 hours and washed with a little alcohol (yield, 8.7 g.). The substance slowly darkens from  $200^{\circ}$  and melts with decomposition at about  $240^{\circ}$  [Found : C, 49.6; H, 4.2.  $(C_{24}H_{19}O_5NH_2, HCl)_2SnCl_4$  requires C, 50.5; H, 3.9%]. The *stannichloride* (2.5 g.) was dissolved in hot 50% alcohol (50 c.c.) containing concentrated hydrochloric acid (1 c.c.) and a rapid stream of hydrogen sulphide was passed through the hot solution. When the filtered, tin-free liquid was treated with an excess of concentrated aqueous ammonia, the free *amino*-compound separated in small, sulphur-yellow, diamond-shaped plates, m. p.  $208^{\circ}$  (Found : C, 71.3; H, 5.4; N, 3.7.  $C_{24}H_{21}O_5N$  requires C, 71.4; H, 5.3; N, 3.5%). Yield, 7 g. from 10 g. of the nitro-compound. The *hydrochloride* separates from 50% alcoholic hydrochloric acid in very pale yellow, hexagonal plates (Found : N, 3.2; Cl, 7.7.  $C_{24}H_{21}O_5N, HCl$  requires N, 3.2; Cl, 8.1%). It slowly becomes more yellow at  $100^{\circ}$  owing to loss of hydrogen chloride; the same change takes place on heating with water or organic solvents or in a vacuum over sodium hydroxide.

*6:7:10-Trimethoxyphenanthraxanthone* (IV).—The preceding *amino*-compound (1 g.) was dissolved in a warm mixture of methyl alcohol (120 c.c.) and concentrated sulphuric acid (2 g.) and cooled to  $-10^{\circ}$ . A 5% aqueous solution of sodium nitrite (13.9 c.c.) was then added during  $\frac{1}{2}$  hour, and the solution subsequently kept at  $0^{\circ}$  for 2 days. The liquid, which now contained a small amount of crystalline material, was boiled under reflux for  $\frac{1}{2}$  hour, colourless needles being deposited. These were separated from the hot liquid by filtration, washed with much alcohol and with water, and dried (yield, 0.7 g.); m. p.  $232-233^{\circ}$  (Found : C, 74.3; H, 4.8.  $C_{24}H_{18}O_5$  requires C, 74.6; H, 4.7%). *6:7:10-Trimethoxyphenanthraxanthone* is almost insoluble in most organic solvents. It separates from a large volume of boiling glacial acetic acid in hair-like needles. It dissolves in concentrated sulphuric acid to an orange-yellow solution which exhibits no fluorescence, and

shows feebly basic properties towards concentrated hydrochloric acid.

6:7:10-*Trihydroxyphenanthraxanthone*.—The attempted demethylation of the trimethoxyphenanthraxanthone (IV) with hydriodic acid, or hydriodic acid in acetic acid, was unsatisfactory, owing to the precipitation of an insoluble dark-green hydriodide of the methylated compound.

6:7:10-Trimethoxyphenanthraxanthone (0.5 g.) was boiled with glacial acetic acid (25 c.c.) and hydrobromic acid (25 c.c.;  $d$  1.5) for 8 hours. After  $2\frac{1}{2}$  hours, the solution began to deposit orange crystals of a hydrobromide, which gradually increased in amount, and were finally collected and washed with very dilute sodium bicarbonate solution and with water; the free trihydroxyphenanthraxanthone was then obtained as a pale yellow powder. By dissolving it in a large volume of boiling alcohol and filtering and concentrating the solution, it was obtained in small blunt-ended prisms, which when rapidly heated melted at  $318\text{--}319^\circ$  with much darkening. The substance contains alcohol of crystallisation which is lost at  $110^\circ$ , the crystals becoming opaque (Found: C, 70.9; H, 5.3. Found in material dried at  $110^\circ$ : C, 72.9; H, 3.9.  $C_{21}H_{12}O_5 \cdot EtOH$  requires C, 70.8; H, 4.7%.  $C_{21}H_{12}O_5$  requires C, 73.3; H, 3.5%). 6:7:10-*Trihydroxyphenanthraxanthone* as a xanthone derivative with vicinal hydroxyl groups is a weak mordant dye. On cotton mordanted with iron, aluminium and tin, it gives greyish-brown, pale lemon-yellow, and bright yellow shades respectively. Its alcoholic solution develops an intense dull bluish-green colour with ferric chloride.

*o*-Nitrobenzoic Anhydride.—This was prepared by a modification of the method of D.R.-P. 201325 (compare Robinson and Venkataraman, J., 1929, 63). *o*-Nitrobenzoic acid (33.4 g.) was dissolved in a mixture of dry ether (50 c.c.) and pyridine (15.8 g.), and a solution of thionyl chloride (11.9 g.) in ether (50 c.c.) was added with vigorous shaking. After 24 hours, ice and dilute hydrochloric acid were added and the solid product was collected, washed successively with dilute hydrochloric acid, sodium bicarbonate solution, and much water, and dried at first in the air, then at  $100^\circ$ . The anhydride (24 g.) formed a white crystalline powder, m. p.  $126\text{--}128^\circ$ . Bischoff and Rach (*Ber.*, 1884, 17, 2789) state that the substance is explosive, but the author is unable to confirm this. The anhydride can be heated to  $200^\circ$  without decomposition, and when heated as rapidly as possible to very high temperatures in a small tube it decomposes suddenly but without explosion.

7-Hydroxy-3-phenyl-2-*o*-nitrophenylbenzo- $\gamma$ -pyrone (V).—The interaction of *o*-nitrobenzoic anhydride, 2:4-dihydroxyphenyl

benzyl ketone, and sodium *o*-nitrobenzoate under the ordinary conditions of the chromone synthesis ( $180^{\circ}$  for 10 hours) gives a negligible yield of the desired product. After many failures, the following method was found to give fairly satisfactory results and the *o*-nitrobenzoic acid was recoverable.

2:4-Dihydroxyphenyl benzyl ketone (4 g.), *o*-nitrobenzoic anhydride (16 g.), and sodium *o*-nitrobenzoate (4 g.) were heated at  $153^{\circ}$  (anisole vapour bath) for  $2\frac{1}{2}$  hours. The product was dissolved in hot 90% alcohol (60 c.c.) and boiled with potassium hydroxide (8 g.), dissolved in a little water, for 2 minutes. The solution was diluted with water (200 c.c.) and saturated with carbon dioxide and the precipitate was collected, washed, and crystallised from alcohol (charcoal) (yield, 1.1 g.). A further recrystallisation from alcohol yielded pale yellow prisms, m. p.  $268^{\circ}$  (Found: N, 3.9.  $C_{21}H_{13}O_5N$  requires N, 3.9%). The methyl ether, prepared quantitatively by the action of methyl sulphate and alkali upon a 50% acetone-alcohol solution of the compound, crystallised from alcohol in pale yellow, highly refracting, four-sided bi-pyramids, m. p.  $183^{\circ}$  (Found: C, 70.8; H, 4.1.  $C_{22}H_{15}O_5N$  requires C, 70.8; H, 4.1%).

7-Methoxy-3-phenyl-2-*o*-aminophenylbenzo- $\gamma$ -pyrone.—The preceding methyl ether (3.5 g.), alcohol (200 c.c.), granulated tin (20 g.), and concentrated hydrochloric acid (50 c.c.) were boiled for 6 hours. The solution was diluted with water and treated while hot with hydrogen sulphide and the tin-free filtrate was rendered alkaline with excess of ammonia solution and at once filtered from a small amount of flocculent material. The base crystallised completely on further dilution (yield, 3.2 g.); on recrystallisation from alcohol it formed thin, pale-yellow, diamond-shaped plates, m. p.  $213^{\circ}$  (Found: N, 4.4.  $C_{22}H_{17}O_3N$  requires N, 4.1%).

10-Methoxyphenanthraxanthone.—The preceding base (1 g.) was dissolved in warm methyl alcohol (120 c.c.) containing concentrated sulphuric acid (2 g.), cooled to  $-10^{\circ}$ , and diazotised by the gradual addition of 5% aqueous sodium nitrite (10.2 c.c.). The solution was kept for 24 hours at  $0^{\circ}$  and then boiled for  $\frac{1}{2}$  hour and the crystalline precipitate was collected, washed with water and alcohol, and recrystallised from glacial acetic acid, in which it was very sparingly soluble. It separated in very pale yellow prisms, m. p.  $248-249^{\circ}$  (Found: C, 80.8; H, 4.3.  $C_{22}H_{14}O_3$  requires C, 81.0; H, 4.3%). The solution in concentrated sulphuric acid is yellow and slowly develops a strong blue fluorescence.

10-Hydroxyphenanthraxanthone (II).—The preceding compound (0.4 g.) was boiled for 12 hours with glacial acetic acid (60 c.c.) and hydrobromic acid (20 c.c.; *d* 1.5). The product which separated on cooling was collected and acetylated by boiling for 1 hour with acetic

anhydride and a drop of pyridine. The acetyl derivative subsequently separated in colourless prisms, m. p. 234—235°. Hydrolysis of this compound was effected by boiling its alcoholic suspension with a few drops of aqueous sodium hydroxide; a yellow solution exhibiting a weak green fluorescence was then produced. Acidification threw down a gelatinous precipitate, which, after boiling with water, was collected and pressed on porous earthenware. The substance was now dissolved in a large volume of boiling glacial acetic acid (charcoal); after concentration to a small bulk, the solution deposited bunches of fine colourless needles, m. p. 325—326° with slight darkening (Found: C, 80·5; H, 3·9.  $C_{21}H_{12}O_3$  requires C, 80·8; H, 3·9%).

10-Hydroxyphenanthraxanthone dissolves in dilute aqueous sodium hydroxide to a yellow solution which sets to a turbid gel on cooling. The gel has no marked fluorescence and, unlike those described in Part I, is not very stable and shows a great tendency to deposit the alkali salt as a fibrous curd. The solution of 10-hydroxyphenanthraxanthone in concentrated sulphuric acid is yellow and slowly develops a greenish-blue fluorescence.

*o*-Nitrophenylacetonitrile.—*o*-Nitrophenylpyruvic acid was prepared by the modification of Reissert's method (*Ber.*, 1897, 30, 1036) suggested by Gulland and Haworth (*J.*, 1928, 585). The oxime of this acid (Reissert, *Ber.*, 1908, 41, 3813) was readily converted into *o*-nitrophenylacetonitrile by warming it with its own weight of acetic anhydride; a vigorous reaction rapidly occurred, after a few minutes water was added, and the crystalline nitrile, which separated on shaking, was collected, washed, and dried (yield, almost quantitative).

2:4-Dihydroxyphenyl *o*-Nitrobenzyl Ketone.—A mixture of *o*-nitrophenylacetonitrile (10 g.) and resorcinol (20 g.) in anhydrous ether (300 c.c.) was saturated with a rapid stream of hydrogen chloride without external cooling until all had dissolved. Powdered zinc chloride (10 g.) was then added and the solution was cooled to 0° and again saturated with hydrogen chloride. After 48 hours, water was added and the ketimine hydrolysed by heating on the steam-bath for 1 hour. The solid ketone (10·5 g.), which separated on cooling, was used directly for the preparation of the benzo- $\gamma$ -pyrone (VI). The pure substance separates from dilute alcohol (charcoal) in very pale yellow, prismatic needles, m. p. 159—161° (Found: N, 5·2.  $C_{14}H_{11}O_5N$  requires N, 5·1%). Its alcoholic solution gives a deep reddish-brown coloration with ferric chloride. The solution in aqueous sodium hydroxide is yellow.

7-Hydroxy-2-phenyl-3-*o*-nitrophenylbenzo- $\gamma$ -pyrone (VI).—The preceding ketone (10 g.), benzoic anhydride (75 g.), and sodium benzoate

(10 g.) were stirred and heated at 180—190° for 6 hours. The product was dissolved in alcohol (200 c.c.), heated for 20 minutes with potassium hydroxide (40 g.) in water (100 c.c.), diluted with a large volume of water, and saturated with carbon dioxide. The *pyrone* was used without further purification for the preparation of its methyl ether. The pure substance separates from a small amount of alcohol in very pale yellow octahedra, m. p. 267° (Found : N, 4.1.  $C_{21}H_{13}O_5N$  requires N, 3.9%).

The *methyl* ether, prepared in the same manner as the methyl ether of (V), crystallised from alcohol in colourless prismatic needles, m. p. 178° (Found : C, 70.7; H, 3.9.  $C_{22}H_{15}O_5N$  requires C, 70.8; H, 4.0%). The reduction of this compound in the manner described for the reduction of the methyl ether of (V) gave a light yellow powder, which could not be obtained in the crystalline state. The substance, which is very readily soluble in all the common organic solvents except light petroleum, develops a greenish tint on exposure to light, and cannot be diazotised. It gives a weak Liebermann's nitroso-reaction. A similar result was obtained by reduction with ferrous sulphate and ammonia.

The author wishes to record his thanks to Miss F. M. Eastwood, B.A., B.Sc., for carrying out the preliminary experiments with *o*-nitrobenzoic anhydride, and to Dr. J. M. Gulland for advice in connexion with the phenanthrene ring closure.

## XL.—*An Investigation into the Formation of 4(5)-Aminoglyoxalines. Part I.*

By ISIDORE ELKANAH BALABAN.

THE only evidence at present (Fargher, J., 1920, **117**, 668; Pyman, J., 1922, **121**, 2616) that 4(5)-aminoglyoxalines are true aromatic amines is the formation, after diazotisation, of coloured solutions with aqueous sodium  $\beta$ -naphthoxide. In order to submit examples of them to typical reactions characteristic of aromatic amines, it seemed desirable to commence a detailed study of their formation and stability. They have hitherto been prepared by the reduction of 4(5)-nitroglyoxalines and 4(5)-benzeneazoglyoxalines (Fargher and Pyman, J., 1919, **115**, 235; Windaus and Langenbeck, *Ber.*, 1923, **56**, 685).

Reduction of 4(5)-nitro-2-methyl- and of 4(5)-nitro-glyoxalines with iron and water (and a drop of acetic acid), ferrous sulphate

and sodium hydroxide, sodium sulphide, or activated aluminium or by West's method, (J., 1925, 127, 494) gave no basic material; the dark blue solutions mentioned by previous workers were, however, often obtained. (Catalytic hydrogenation is under investigation.)

The present communication deals mainly with the application of the Curtius synthesis of amines to ethyl glyoxaline-4(5)-carboxylate (I). When this ester is heated with hydrazine hydrate, *glyoxaline-4(5)-carboxyhydrazide* (II) is obtained, which is converted by treatment with nitrous acid into *glyoxaline-4(5)-carboxyazide* (III): this compound, heated with ethyl alcohol on the water-bath, yields 4(5)-*carbethoxyaminoglyoxaline* (IV). Similarly, with methyl alcohol, the *carbomethoxyamino*-derivative can be prepared.

Attempts to convert the azide by boiling with water into the *s*-carbamide failed: the solution gave an intense Pauly reaction, but an amorphous picrate only could be isolated. The carbomethoxy- and carbethoxy-amino-derivatives were recovered to the extent of about 30% and 50% respectively after boiling with hydrochloric acid, and attempts to obtain 4(5)-aminoglyoxaline by heating them with 2*N*-hydrochloric acid in a sealed tube at 150° or with concentrated sulphuric acid on the water-bath were likewise unsuccessful. Satisfactory hydrolysis also could not be effected with 10% aqueous sodium carbonate or boiling 2*N*-sodium hydroxide. The phthalimido-derivative, which might be quantitatively hydrolysed to the amine (compare Ing and Manske, J., 1926, 2348), could not be prepared. The *as*-carbamide was not formed when the carbethoxyamino-derivative was heated with 3.5% alcoholic ammonia at 150°. 4(5)-*Nitro-5(4)-carbethoxyaminoglyoxaline* (V), notwithstanding the presence of a nitro-group in the *o*-position with respect to the substituted amino-group, also could not be converted by hydrolysis with 10% aqueous sodium carbonate into the corresponding amine.

Balaban and Pyman (J., 1924, 125, 1565) and Sarasin and Wegmann (*Helv. Chim. Acta*, 1924, 7, 713) have shown that the halogen atom in 5-chloro-4-nitro-1-methylglyoxaline (VI) can be replaced by the sulpho- and the cyano-group. The compound does not react with aqueous ammonia or acetamide, but when it is heated

with 3.5% alcoholic ammonia at 140° 4-nitro-5-amino-1-methylglyoxaline (VII) is obtained in good yield. This amine does not form an acetyl or a benzylidene derivative, but after treatment with nitrous acid it gives with alkaline  $\beta$ -naphthol a greenish-blue insoluble dye and with alkaline resorcinol a violet solution, whereas with sodium hydroxide only a pale yellow colour is obtained. The amine is rapidly decomposed by 16% hydrochloric acid (or even 7%) at room temperature, nitrous acid being liberated and a compound, m. p. 140°, formed: this is presumably  $\alpha$ -methylamino- $\alpha$ -hydroxyacetamide (IX), because when it is boiled with aqueous sodium hydroxide it yields ammonia and methylamine. Owing to the

mild conditions of hydrolysis, fission occurs at the 1:2- and the 2:3-positions of (VII), formic acid being split off [compare the formation of dibenzoyldiaminoethylene from glyoxaline (Bamberger and Berle, *Ber.*, 1892, 25, 278) and of *DL*-alanine-*N*-methyldiamidine from 5-amino-1:4-dimethylglyoxaline (Pyman, *loc. cit.*)]. The substance (VIII) is then acted upon by the liberated nitrous acid, hydroxyl being substituted for the amino-group. The formation of glyoxylic acid on alkaline hydrolysis of the amide (IX), and its subsequent conversion into glycollic acid, must be presumed, for the only identifiable acid obtained was oxalic acid. As Böttinger (*Annalen*, 1879, 198, 217) has shown that ammonium  $\alpha$ -amino- $\alpha$ -hydroxyacetate is decomposed by boiling water, the possibility of obtaining the acid corresponding to (IX) and its conversion directly into methylamine and glyoxylic acid was very remote.

#### EXPERIMENTAL.

For the preparation of glyoxaline-4(5)-carboxylic acid (Fargher and Pyman, *loc. cit.*; Balaban and Pyman, *J.*, 1922, 121, 954) it is unnecessary to isolate the carboxyanilide. After removal of unchanged glyoxaline-4:5-dicarboxylic acid, the acid solution is concentrated to 25 c.c. and treated with concentrated hydrochloric acid (250 c.c.); 50 g. of the dicarboxylic acid give about 20 g. of glyoxaline-4(5)-carboxylic acid.

*Glyoxaline-4(5)-carboxylhydrazide* (II).—When a mixture of 5.6 g. of ethyl glyoxaline-4(5)-carboxylate and hydrazine hydrate (4.0 c.c.; 2 mols.) was heated on the water-bath, solution took place in 15

minutes; after a further 15 minutes, when the solution was cooled, the *hydrazide* (5.0 g.), m. p.  $210^{\circ}$ , separated in almost quantitative yield. It crystallised from boiling water, in which it was fairly readily soluble, in long, colourless, silky needles containing  $1\text{H}_2\text{O}$ , m. p.  $213^{\circ}$  (Found for air-dried substance: loss at  $100^{\circ}$ , 12.5, 12.8.  $\text{C}_4\text{H}_6\text{ON}_4 \cdot \text{H}_2\text{O}$  requires  $\text{H}_2\text{O}$ , 12.5%. Found in dried material: N, 45.1, 43.6; C, 37.9; H, 4.9.  $\text{C}_4\text{H}_6\text{ON}_4$  requires N, 44.4; C, 38.1; H, 4.8%). The hydrazide is moderately easily soluble in alcohol but insoluble in benzene, chloroform, and ether. It reduces ammoniacal silver nitrate slowly, but not Fehling's solution.

The *picrate* crystallises from water (1 in 85 parts of boiling water) in anhydrous yellow needles, m. p.  $223^{\circ}$  (decomp.) (Found in air-dried salt by nitron estimation: picric acid, 64.8.

requires picric acid, 64.5%).

*Glyoxaline-4(5)-carboxyazide* (III).—A mixture of the hydrazide (6.3 g.), concentrated hydrochloric acid (7.0 c.c.), and a little ice was treated at  $0^{\circ}$  with sodium nitrite (7.0 g. in 15 c.c. of water). After 15 minutes, the *azide* was collected and washed with ice-water, 8.0 g. of slightly moist material, decomp.  $137^{\circ}$  (explosively), being obtained [Found in material dried at  $100^{\circ}$ : N (Dumas), 51.1.  $\text{C}_4\text{H}_3\text{ON}_5$  requires N, 51.0%]. It crystallised from 95% alcohol in minute stout rods.

When the azide is heated with water on the water-bath, gas is evolved and a dark green solution is produced, from which a *picrate* can be obtained; this chars at  $230^{\circ}$  after previous darkening (Found in dried material: picric acid, 66.4.  $\text{C}_7\text{H}_8\text{ON}_6 \cdot 2\text{C}_6\text{H}_3\text{O}_7\text{N}_3$  requires picric acid, 69.4%). Attempts to regenerate the base from the *picrate* were unsuccessful.

*4(5)-Carbethoxyaminoglyoxaline* (IV).—The azide (6.3 g.) was heated under reflux with absolute ethyl alcohol (50 c.c.) for 4 hours, the solvent removed, the residue dissolved in a little dilute hydrochloric acid and treated with charcoal, and the filtered solution concentrated to a few c.c. and basified with anhydrous sodium carbonate; the *carbethoxyamino*-derivative (3.0 g.; yield, 42.2%) obtained crystallised from boiling water, in which it was readily soluble, in anhydrous, colourless, hexagonal plates, m. p.  $180^{\circ}$  (Found in dried material: N, 27.2.  $\text{C}_6\text{H}_5\text{O}_2\text{N}_3$  requires N, 27.1%). It is very soluble in alcohol, moderately easily soluble in benzene, sparingly in chloroform, but insoluble in ether. With Pauly's reagent it gives a deep red solution. The hydrochloride regenerated from the *picrate* was obtained as a gum, which did not crystallise.

The *picrate* crystallises from boiling water (1 in 60 parts) in anhydrous, golden, hexagonal, prismatic needles, decomp.  $210^{\circ}$

(sintering from  $203^{\circ}$ ) (Found in substance dried at  $100^{\circ}$ : picric acid, 59.6, 59.8.  $C_6H_5O_2N_3, C_6H_3O_7N_3$  requires picric acid, 59.6%).

The *nitrate* crystallises from water, in which it is moderately easily soluble, in anhydrous, colourless, hexagonal prisms, decomp.  $143^{\circ}$  (Found in salt dried at  $100^{\circ}$ : nitric acid, by nitron method, 29.1.  $C_6H_5O_2N_3, HNO_3$  requires nitric acid, 28.9%).

4(5)-*Carbomethoxyaminoglyoxaline*, similarly prepared from the azide and methyl alcohol (yield, about 50%), crystallises from water (1 in 8 parts, boiling) in anhydrous diamond-shaped plates, m. p.  $175^{\circ}$  (Found in material dried at  $100^{\circ}$ : N, 30.3.  $C_5H_7O_2N_3$  requires N, 29.8%). It is very soluble in alcohol, sparingly soluble in ether, and insoluble in benzene and chloroform. With Pauly's reagent, a rich port-wine colour is produced. The *picrate* crystallises from water, in which it is sparingly soluble, in anhydrous irregular prisms, which blacken at about  $240^{\circ}$  and decompose at  $243^{\circ}$  (Found: picric acid, 61.4, 61.6.  $C_5H_7O_2N_3, C_6H_3O_7N_3$  requires picric acid, 61.9%).

5(4)-*Nitro-4(5)-carbomethoxyaminoglyoxaline* (V).—The preceding nitrate (1 g.) was added to concentrated sulphuric acid (2 c.c.) at  $0^{\circ}$  during 10 minutes and then warmed on the water-bath until effervescence began (10 minutes). The *nitro*-derivative, which separated (yield, 58%) when the mixture was poured on ice, crystallised from water in large, anhydrous, rhomboidal plates, m. p.  $234^{\circ}$  (decomp.) (Found in material dried at  $100^{\circ}$ : N, 28.3.  $C_6H_5O_4N_4$  requires N, 28.0%). It is soluble to the extent of 1 in 400 parts of boiling water and also in hot alcohol, but insoluble in benzene, chloroform, and ether. No colour reaction is given with Pauly's reagent.

4-*Nitro-5-amino-1-methylglyoxaline* (VII).—5-Chloro-4-nitro-1-methylglyoxaline (6.6 g.) and alcoholic ammonia (3.5%; 90 c.c.) were heated together at  $140^{\circ}$  for 4 hours. The *nitro*-compound, which had separated (3.7 g.; yield, 63.7%), crystallised from water (solubility, 1 part in 170 parts, boiling) in yellow, anhydrous, rectangular plates, m. p.  $303^{\circ}$  (decomp.) (Found in material dried at  $100^{\circ}$ : C, 33.7; H, 4.3; N, 39.8.  $C_4H_6O_2N_4$  requires C, 33.8; H, 4.2; N, 39.4%). It is soluble in concentrated hydrochloric acid, but not in dilute acid, alcohol, chloroform, or ether. It dissolves in boiling glacial acetic acid, forming apparently an acetate, for when the diluted solution is treated successively with sodium nitrite and alkaline  $\beta$ -naphthol a greenish-blue colour is obtained. The *nitro*-compound does not give a *picrate* when treated with aqueous picric acid.

*Action of cold 16% hydrochloric acid.* When the *nitro*-compound (2.6 g.) was added to 16% hydrochloric acid (10.4 c.c.) and stirred,

the solution darkened considerably and after some minutes much heat was evolved, the temperature rose from  $21^{\circ}$  to  $47^{\circ}$ , effervescence ensued, nitrous acid was liberated, and crystals immediately separated (1.1 g.), leaving a mother-liquor (M). The solid did not give a Pauly reaction, or a coloured solution with sodium  $\beta$ -naphthoxide after treatment with nitrous acid. When it was recrystallised from a little water (10 c.c.; charcoal), a small crop (0.1 g.), m. p.  $140^{\circ}$ , was obtained; the mother-liquor on concentration gave only a dark brown gum. The mother-liquor (M) on concentration gave 0.3 g., m. p.  $140^{\circ}$ . The combined mother-liquors were mixed with an excess of aqueous sodium hydroxide, and the volatile amines distilled into hydrochloric acid. After evaporation, the residue gave 0.5 g. insoluble in absolute alcohol (Found: Cl, 64.8. Calc. for  $\text{NH}_4\text{Cl}$ : Cl, 66.4%) and 0.6 g., m. p.  $195\text{--}200^{\circ}$ , soluble in absolute alcohol (Found: Cl, 53.5. Calc. for  $\text{NH}_2\text{Me}, \text{HCl}$ : Cl, 52.6%). The alkaline solution yielded, after acidification and treatment with calcium chloride in ammoniacal solution, 0.4 g. containing 97% of calcium oxalate.

$\alpha$ -Methylamino- $\alpha$ -hydroxyacetamide (IX) is moderately easily soluble in hot water, but much less so in cold, and crystallises in long, anhydrous, pale brown needles, m. p.  $140^{\circ}$ . Its aqueous solution is neutral to litmus (Found in material dried at  $100^{\circ}$ : C, 34.0; H, 7.8; N, 26.7, 27.0.  $\text{C}_3\text{H}_8\text{O}_2\text{N}_2$  requires C, 34.6; H, 7.7; N, 26.9%).

The author is indebted to Mr. R. H. Klein, F.I.C., for making some of the analyses recorded in this paper.

## XLI.—*Internal Equilibrium in Sulphur. Part II. Amorphous Sulphur ( $\text{S}_\mu$ ) as a Gel, and the Tyndall Effect in Liquid Sulphur.*

By DALZIEL LLEWELLYN HAMMICK and MICHAEL ZVEGINTZOV.

It has long been recognised (Krøyt, *Z. physikal. Chem.*, 1909, 65, 486; Hammick and Holt, J., 1926, 1995) that as molten sulphur is heated, it becomes richer in one or more forms which are less miscible with other liquids and give rise to the peculiar properties of liquid sulphur. It also appears to have been generally assumed, with Smith and his co-workers, that the insoluble, amorphous solid obtained when molten sulphur is chilled, allowed to harden, and

then extracted with carbon disulphide, is identical with one of the constituents present in the melt. As is well known, the familiar allotropic line (Smith and Carson, *Z. physikal. Chem.*, 1907, 57, 685) giving the percentages of  $S_\mu$  present in liquid sulphur at various temperatures is constructed from data derived from estimates of the amount of insoluble sulphur present in specimens of sulphur chilled from these temperatures.

In the course of our experiments on equilibria in the system sulphur-sulphur chloride (J., 1928, 1785), we noticed that in the presence of even quite small proportions of its chloride the element could be heated to 160–180° without any great increase in viscosity. For instance, mixtures of pure sulphur (98%) with sulphur chloride (2%) heated in sealed tubes for various periods ( $\frac{1}{2}$ –2 hours) at 140° and 180° gave quite mobile, dark-coloured liquids. Most of these mixtures on sudden chilling solidified almost completely, and it was found that a considerable proportion of the solid separating was insoluble in carbon disulphide, *i.e.*, the solid contained  $S_\mu$ . In many of the tubes, however, solidification did not occur on chilling, and in some cases it was possible to open them and treat the contents with carbon disulphide while the latter were still metastable and fluid. The supercooled mixture was completely miscible with this solvent. It would thus appear that  $S_\mu$ , insoluble in carbon disulphide, does not exist in the fluid sulphur-sulphur chloride mixtures that have been chilled from high temperatures, but makes its appearance when such mixtures deposit solid. Only when the concentration of sulphur chloride was not more than 2% was it possible to demonstrate this distinction between two specimens of sulphur which had been treated in exactly the same way in respect to heating and chilling, but differed by the circumstance that in one case the separation of solid had been avoided and with it the production of  $S_\mu$ . Nevertheless, the fact that the mere heating of sulphur and chilling does not by itself yield sulphur insoluble in carbon disulphide (or  $S_\mu$ ) was confirmed in numerous cases where solutions of sulphur in sulphur chloride and in other solvents, such as xylene, pyridine, and quinoline, were chilled from temperatures between 150° and 180° without solid separating and found to be completely miscible with carbon disulphide.

In the light of the above observations it becomes necessary to account for the insolubility in carbon disulphide of chilled sulphur by a hypothesis that does not postulate the pre-existence of the insoluble  $S_\mu$  in the liquid from which it is produced on chilling, and we have therefore come to the conclusion that insoluble amorphous sulphur is probably a gel. The plasticity of freshly chilled sulphur obviously accords with this supposition; the "setting" of plastic

sulphur to the hard amorphous  $S_{\mu}$  is, we suggest, analogous to the hardening of gels such as those of hydrated oxides (silica gels, etc.). In further support of our view we adduce the following observations.

(i) *The solubility of  $S_{\mu}$  in various solvents.* "Chilled" sulphur, prepared by distilling pure sulphur into cold water, was found to be insoluble in cold carbon disulphide, sulphur chloride, pyridine, quinoline, and xylene, whether it was in the rubber-like, plastic condition or had been kept until it had set to a hard mass. Rapid solution occurred, however, in the above solvents at temperatures above (roughly)  $120^{\circ}$ . For instance, 50% by weight of amorphous sulphur added to boiling sulphur chloride ( $138^{\circ}$ ) liquefied and dissolved completely in 5 seconds. A similar result was observed in quinoline at  $130^{\circ}$ ; 10% of amorphous sulphur also dissolved readily and rapidly in liquid benzoic acid at  $123^{\circ}$ . In pyridine (b. p.  $115^{\circ}$ ), dissolution was much slower and the amorphous sulphur did not liquefy completely: 10 g. dissolved completely, however, in 100 g. of solvent in 1 minute.

That amorphous sulphur (or  $S_{\mu}$ ) dissolves in hot solvents has, of course, long been known; but the fact that it does so has been ascribed to the effect of temperature in promoting its rapid change into soluble  $S_{\lambda}$ . It does not seem to be generally realised, however, that even at  $140^{\circ}$  it takes about 3 hours for "internal equilibrium" to be set up in liquid sulphur, and that "amorphous sulphur" kept at the natural f. p. of sulphur ( $114.5^{\circ}$ ) for 10 hours still contains 50% of insoluble sulphur (Smith and Carson, *loc. cit.*). Further, the authors (*loc. cit.*) found that in sulphur chloride solution at  $148^{\circ}$ ,  $1\frac{1}{2}$  hours were required to establish equilibrium. On the other hand, if  $S_{\mu}$  is really a gel, it might be expected, like other gels such as rubber, gelatin, resins, etc., to show a more or less abrupt change in properties at and above the temperatures at which the gel structure is destroyed. It is significant that rapid dissolution of  $S_{\mu}$  in solvents begins at about  $120^{\circ}$ , i.e., at about the melting point of crystalline sulphur, which may possibly be the continuous phase in the gel.

(ii) *The Tyndall effect in liquid sulphur.* The hypothesis that chilled sulphur or  $S_{\mu}$  is a gel led to the expectation that the liquid from which it is produced might show the properties of a sol. Liquid sulphur was therefore examined for the Tyndall effect. It is well known that the production of liquids in a state of optical purity is a matter of considerable difficulty. The sulphur used was therefore carefully purified by crystallisation from pure carbon disulphide and then by distillation, first under ordinary pressure and finally in a vacuum. It was then introduced into the side bulb of an apparatus of Pyrex glass, consisting of a cylindrical observation

tube with flat top and bottom, the apparatus was exhausted with a mercury pump and sealed, and the sulphur distilled into the observation tube, remelted, and tipped back into the distillation bulb.\* This was done six times, in order to wash out the observation tube, which was then surrounded by a small electric resistance furnace. A beam of light from a 500-watt lamp was focused through a window in the side of the furnace into the melted sulphur, which was observed through the top. A well-defined Tyndall beam of polarised scattered light was observed at all temperatures from the melting point up to  $200^{\circ}$ , at which the deep colour of the liquid sulphur prevented further observations.

Having obtained this characteristic indication of the presence of colloidal particles in liquid sulphur, we attempted to measure the intensity of the scattered light over a range of temperature in order to find out whether there was any correlation between the concentration of colloidal particles and the increase of viscosity of liquid sulphur that occurs at about  $160^{\circ}$ . The exciting beam was caused to enter the observation vessel as near to the bottom as possible, and at the same time light from a small electric-light bulb (3-watt) was passed vertically up through the base. By varying the resistance in circuit with the small bulb, it was possible roughly to match, by observation through the top of the tube, the intensity of the light transmitted from the control lamp through the liquid sulphur with the intensity of the Tyndall light. Both the direct and the scattered light had to traverse very nearly the same depth of liquid (about 8 cm.). The current flowing through the "control" lamp was measured on a milliammeter, and the temperature of the sulphur was varied by altering the resistance in series with the electric heating furnace that surrounded the observation tube. No great precision can be claimed for the observations made; nevertheless, the rather surprising conclusion can be drawn from them that, as far as could be detected by the rough apparatus used, no appreciable alteration in the intensity of the scattered Tyndall light could be observed between  $125^{\circ}$  and  $200^{\circ}$ . A typical series of measurements was :

Temp. of furnace ...	$128^{\circ}$	$135^{\circ}$	$153^{\circ}$	$165^{\circ}$	$180^{\circ}$	$200^{\circ}$
Current in control lamp (amp.) ...	0.45	0.43	0.435	0.45	0.44	0.45

Before these experiments could be repeated with more refined apparatus, however, a private communication from W. L. Cousins

\* In order to test this method for obtaining liquids optically "pure," experiments were carried out in similar pieces of apparatus with carbon tetrachloride and phenol. In each case two washings of the observation tube with distillate were sufficient to give liquids in which no Tyndall effect could be observed.

and B. Lange in Berlin informed us of results, to be published shortly, which they had obtained in measuring the intensity of polarisation of the Tyndall light in molten sulphur, and further work on the matter was abandoned.

In conclusion, it may be noted that the view that insoluble sulphur ( $S_\mu$ ) is a gel removes the difficulty in accounting for the fact that, although it is metastable with respect to crystalline sulphur, the latter is vastly more soluble.

### *Summary.*

Experiments are described showing that insoluble sulphur (amorphous sulphur or  $S_\mu$ ) is not present as such in liquid sulphur but makes its appearance when the liquid solidifies. It is therefore suggested that  $S_\mu$  is in reality a gel, and in support of this hypothesis its ready solubility in certain solvents at temperatures above the m. p. of crystalline sulphur (possible continuous phase) is noted, and the presence of colloidal particles in pure molten sulphur is established by observations on the Tyndall effect.

## XLII.—*Nitrous Acid as a Nitrating Agent. Part I.* *The Nitration of Dimethyl-p-toluidine.*

By HERBERT HENRY HODGSON and ARNOLD KERSHAW.

NITROUS acid *nitrates* dimethyl-*p*-toluidine, giving at least 80% of 3-nitrodimethyl-*p*-toluidine (3-nitro-4-dimethylaminotoluene): nitric acid at the same dilution is practically inactive. *o*-Nitrosation analogous to the *p*-nitrosation of dimethylaniline does not appear to take place. Since 2-nitrodimethyl-*p*-toluidine is produced by the normal nitration process, the mechanism of the above reaction must differ from that of ordinary nitration.

Lapworth and Robinson (*Mem. Manchester Phil. Soc.*, 1928, **72**, 47) explain the apparently anomalous ortho-nitration of benzaldehyde and of acetophenone by assuming the formation of an additive complex (I) of nitric acid and the unsaturated group, which then favours nitration in the ortho-position. In the light of this conception it may be assumed that the nitrogen atom and the 3-carbon atom of dimethyl-*p*-toluidine, both strongly activated (II), produce a negative field which attracts the polarised nitrous acid,  $\text{H}\ddot{\text{O}}\text{N}^+\text{O}^-$ , and, by rendering its nitrogen\* less positive, makes it prone to oxidation: the free nitrous acid in the solution oxidises the nitrous

acid component of the complex (II) to nitric acid, with evolution of nitric acid and nitrous oxides and subsequent nitration at the activated 3-carbon atom.

The m. p.'s of the picrates of the two pairs of nitro-compounds studied show definitely that the lower m. p. is associated with the greater chelation (in the case of the 3-nitro-compounds) and conversely that the higher m. p. accompanies increased salt-formation (with the 2-nitro-compounds).

The brilliant red unstable compound formed when dimethyl-*p*-toluidine is mixed with picric acid may perhaps be due to temporary formation of the salt of the *aci*-form of picric acid (III), since such salts have a bright red colour.

#### EXPERIMENTAL.

*Preparation of Dimethyl-p-toluidine.*—A mixture of *p*-toluidine (72.7 g.), methyl iodide (96.5 g.), and water (100 c.c.) was heated under reflux (2–3 hours), and then exactly neutralised with aqueous sodium hydroxide. A further addition of methyl iodide (96.5 g.) was made, and after being again heated until the odour of the methyl iodide had vanished, the mixture was rendered faintly alkaline and steam-distilled. The oily layer of the distillate was treated with acetic anhydride (2–3 c.c. at a time) until no rise of temperature subsequently occurred, a further 5 c.c. were added (total addition, about 35 c.c.) and the mixture was heated on the water-bath for 1 hour, poured into water (200 c.c.), shaken well to decompose the acetic anhydride, neutralised with sodium hydroxide, and steam-distilled; pure dimethyl-*p*-toluidine (33 g.) passed over (b. p. 207°) (Found: N, 10.6. Calc.: N, 10.4%).

The *picrate*, prepared from equimolecular quantities of the base and picric acid in hot alcohol, separated on cooling in elongated prisms, m. p. 128° after recrystallisation from alcohol (Found: N, 15.2. C<sub>15</sub>H<sub>16</sub>O<sub>7</sub>N<sub>4</sub> requires N, 15.4%). When dimethyl-*p*-toluidine is mixed with solid picric acid, a very deep red compound is produced which soon changes into a bright yellow one. Cold alcoholic solutions when mixed give a red solution, from which the yellow *picrate* crystallises, although its alcoholic solution is yellow.

*Action of Nitrous Acid on Dimethyl-p-toluidine.*—The base (10 g.), dissolved in a mixture of concentrated hydrochloric acid (28 c.c.) and water (20 c.c.), was gradually treated at 0° with sodium nitrite (16 g. in 100 c.c. of water). Reaction began on addition of the first drop, the solution became red, and nitric oxide containing a detectable quantity of nitrous oxide was evolved; when about half the sodium nitrite had been added, the deep red solution became turbid owing to separation of the oily reaction product. After 1 hour, the mixture was treated with urea to remove any excess of nitrous acid, neutralised with sodium hydroxide, and steam-distilled, and the distillate (1200 c.c.) was extracted with ether. The extract, after being shaken three times with dilute hydrochloric acid (40 c.c.; 1 part of conc. acid and 2 parts of water), was evaporated and nitrosomonomethyl-p-toluidine (1.6 g.) was obtained from the residue by steam-distillation. The nitrosoamine gave a brilliant colour in the Liebermann reaction and crystallised from light petroleum in almost colourless prisms, m. p. 49.5° (Bamberger and Wulz, *Ber.*, 1891, **24**, 2081, give m. p. 52—53°) (Found: N, 18.8. Calc.: N, 18.7%).

The aqueous acid extract (above) was made faintly alkaline and steam-distilled; 3-nitrodimethyl-p-toluidine (10.5 g.) passed over as a red oil, which, after solidifying, crystallised from aqueous alcohol in red needles, m. p. 26° (Found: N, 15.3.  $C_9H_{12}O_2N_2$  requires N, 15.5%). The *picrate*, prepared as described above, crystallised from alcohol in bright yellow, elongated, rectangular plates, m. p. 129° to a red liquid after softening (Found: N, 17.0.  $C_{15}H_{15}O_9N_5$  requires N, 17.1%). The amine and its *picrate* were identified by comparison with the synthetic compounds (below).

Nitric acid of the same concentration as the nitrous acid employed above was practically inactive, showing that the above nitration could not have been due to nitric acid present in the nitrous acid as initially generated.

*Synthesis of 3-Nitrodimethyl-p-toluidine.*—4-Chloro-3-nitrotoluene (6 g., prepared from 3-nitro-p-toluidine) was heated under reflux with a solution of dimethylamine (in slight excess of the theoretical quantity) in alcohol (40 c.c.) for 20 hours. The alcohol was then removed by distillation, and the reaction product steam-distilled; 3-nitrodimethyl-p-toluidine, obtained in theoretical yield, crystallised from dilute alcohol in red needles, m. p. 26° (Found: N, 15.4%). The *picrate* melted at 129° (Found: N, 17.3%).

*Nitration of Dimethyl-p-toluidine.*—The amine (3 g.) in concentrated sulphuric acid (7 c.c.) was gradually treated at 0° with a mixture of nitric acid (1.4 c.c.; *d* 1.5) and sulphuric acid (2 c.c.). After 12 hours, the whole was poured on ice (200 g.), neutralised;

and submitted to steam-distillation; 2-nitrodimethyl-p-toluidine, which distilled in almost theoretical yield, crystallised from glacial acetic acid, on dilution with water, in large vermilion plates, m. p. 37° (Found: N, 15.4.  $C_9H_{12}O_2N_2$  requires N, 15.5%). The *picrate* crystallised from alcohol in elongated yellow prisms, m. p. 141—143° (Found: N, 17.2.  $C_{15}H_{15}O_9N_5$  requires N, 17.1%).

*o*-Nitrodimethylaniline was readily prepared in theoretical yield by heating an alcoholic solution (140 c.c.) of *o*-chloronitrobenzene (15g.) and dimethylamine (in slight excess of the theoretical quantity) under reflux for 6 hours (compare Weissenberger, *Monatsh.*, 1912, **33**, 821). The *picrate* crystallised from alcohol in greenish-yellow needles, m. p. 103° (Found: N, 18.0.  $C_{14}H_{13}O_9N_5$  requires N, 17.7%).

*Dimethylaniline picrate* crystallises from alcohol in greenish-yellow plates, m. p. 159° (Found: N, 16.2.  $C_{14}H_{14}O_7N_4$  requires N, 16.0%).

3-Nitrodimethylaniline *picrate* separates from alcohol in elongated yellow plates, m. p. 119° (Found: N, 17.4.  $C_{14}H_{13}O_9N_5$  requires N, 17.7%).

All the above nitro-bases give yellow solutions in non-dissociating solvents, whereas in dissociating media, and in particular in phenol, intense red solutions are formed.

The authors desire to thank Messrs. J. W. Leitch & Co. for gifts of some of the chemicals used in this investigation.

TECHNICAL COLLEGE, HUDDERSFIELD. [Received, November 30th, 1929.]

### XLIII.—*The Variation of Phenol Coefficients in Homologous Series of Phenols.*

By CHARLES EDWARD COULTHARD, JOSEPH MARSHALL,  
and FRANK LEE PYMAN.

THE introduction into medicine of the antiseptic, hexylresorcinol, was the outcome of work by Johnson and Lane (*J. Amer. Chem. Soc.*, 1921, **43**, 348) and Dohme, Cox, and Miller (*ibid.* 1926, **48**, 1688) in which the influence of alkyl substituents upon the germicidal value of resorcinol was studied. It was shown that the germicidal value of 4-*n*-alkylresorcinols rose to a maximum at 4-*n*-hexylresorcinol, which had a phenol coefficient of 50, the values for *n*-amyl- and *n*-heptyl-resorcinol being 33 and 30 respectively. It was further shown that the antiseptic values of the *n*-alkyl-resorcinols were greater than those of branched-chain alkylresorcinols having the same number of carbon atoms.

Exact information as to the effect of alkyl substituents upon the antiseptic value of phenol and its homologues is somewhat scanty and therefore it appeared to be of interest to make a systematic study of the variation of the phenol coefficients in the homologous series of *n*-alkylphenols, *n*-alkylcresols, and *n*-alkylguaiacols.

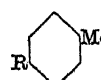

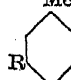

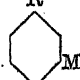

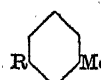

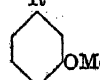

For the determination of phenol coefficients, the Rideal-Walker technique was closely followed, but owing to the sparing solubility of most of the compounds in water, solutions in dilute aqueous sodium hydroxide were employed, care being taken to keep the concentration of sodium hydroxide below lethal strength. In most cases, initial solutions of 0.1% of the compound in *N*/100-sodium hydroxide were used. The results are in Table I.

Comparing the vertical columns in this table, it will be seen that the phenol coefficients of the *p*-*n*-alkylphenols are, in general, considerably less than those of the corresponding *n*-alkylcresols, and the values of the *n*-alkylguaiacols are comparatively trivial. In comparing the horizontal columns, it will be noticed that the antiseptic value of the compounds increases generally with the number of carbon atoms in the side chain up to the *n*-amyl derivative and then diminishes.

Of the *n*-amylcresols, 4-*n*-amyl-*m*-cresol has been studied in some detail, and has been found to have high phenol coefficients (200 to 300), not only when tested against *Bacillus typhosus* (which is employed in the Rideal-Walker method), but also against various strains of *Streptococcus* and *Staphylococcus*. Since, in addition, its toxicity is comparatively low, it may prove to be of value in medicine.

TABLE I.

## Phenol coefficients.

\* The phenol coefficient of *o*-*n*-butylphenol was 75.

† The phenol coefficient of 6-ethyl-*m*-cresol (Me : OH : Et = 1 : 3 : 6) was 15.

*Preparation of n-Alkylphenols, n-Alkylcresols, and n-Alkylguaiacols.*

All the alkyl derivatives were prepared by reduction of the corresponding ketones by Clemmensen's method. The ketones were prepared by four methods: (1) the Nencki condensation of acid and phenol using zinc chloride, (2) the Fries isomerisation of phenyl esters by means of aluminium chloride, (3) the isomerisation of phenyl esters by zinc chloride, and (4) condensation of acids with phenols by means of phosphorus oxychloride.

(1) The Nencki reaction is well known to give good yields of 4-acylresorcinols or 2-acylquinols when resorcinol or quinol is condensed with fatty acids and zinc chloride. Goldzweig and Kaiser (*J. pr. Chem.*, 1891, **43**, 86) state that pyrocatechol does not react when employed in the Nencki reaction and it would appear that this statement has been accepted, although Neitzel (*Ber.*, 1891, **24**, 2863) mentions that acetylpyrocatechol is "apparently" produced by this method. He did not, however, obtain it in a pure state owing to the similarity in solubility of pyrocatechol and acetylpyrocatechol. We are able to confirm the formation of acetylpyrocatechol and other acylpyrocatechols by the Nencki method, and have separated them from unchanged pyrocatechol in each case by distillation under diminished pressure.

Attempts to apply the Nencki reaction to monoalkyl ethers of dihydroxybenzenes have given poor yields, but positive results were obtained in the formation of pæonol from resorcinol monomethyl ether and acetic acid, and in the preparation of acetovanillone and its homologues from guaiacol and fatty acids. Attempts to condense quinol monomethyl ether with acetic acid, however, gave a negative result. The Nencki reaction has been little used for the condensation of monohydric phenols with fatty acids, but Michael and Palmer (*Amer. Chem. J.*, 1885, **7**, 275) obtained *p*-acetylphenol in this manner, and Goldzweig and Kaiser (*loc. cit.*) obtained *p*-propionylphenol similarly, although the yield is not stated in either case. We have condensed a series of fatty acids with phenol by this method and have obtained the *p*-acylphenols in poor yield, *viz.*, 2–10% of the theoretical, and have observed that small quantities of the *o*-acylphenols are formed simultaneously. The sole products obtained from *m*-cresol in the Nencki reaction were the 4-acyl-*m*-cresols, as would be expected from the well-known fact that an alkyl group in the meta-position to the hydroxyl induces substitution in the neighbourhood of the hydroxyl (Auwers and Mauss, *Annalen*, 1928, **464**, 293), but here again the yields are poor.

(2) A considerable number of acylphenols and acylcresols have been made by the Fries isomerisation under the conditions described

by Rosenmund and Schnurr (*Annalen*, 1928, 460, 56), viz., heating the appropriate ester with 1.1 molecules of aluminium chloride. Attempts to prepare acylguaiacols similarly were unsuccessful, but the publication of a paper by Pfeiffer and Haack (*Annalen*, 1927, 460, 156) on the combination of aluminium bromide with ethers in molecular proportion led us to suspect that a similar combination occurred between aluminium chloride and guaiacol esters, and that this prevented the aluminium chloride from producing isomerisation. In later experiments, two molecular proportions of aluminium chloride were consequently added to guaiacol esters and 4-acyl-guaiacols were then produced together with a proportion of the corresponding acylpyrocatechols. The position taken up by the acyl group was proved by the facts (1) that guaiacyl acetate gave acetovanillone, (2) that guaiacyl butyrate gave a ketone which was reduced to a butylguaiacol identical with that obtained by Nomura and Hotta (*Sci. Rep. Tōhoku Imp. Univ.*, 1925, 14, 119) by the reduction of zingerone, and (3) that the propylguaiacol obtained in the same manner from guaiacyl propionate was identical with dihydroeugenol.

(3) Pope (Brit. Pat. 287,967) has described a method for the preparation of 4-*n*-alkylresorcinols by isomerisation of resorcinol monoacyl esters by heating with zinc chloride. We have found that, although this method gives good yields (80—90%) of resacetophenone<sup>1</sup> and 4-*n*-hexoylresorcinol when applied to resorcinol monoacetate and mono-*n*-hexoate, it gives only poor yields of acylphenols when applied to esters of phenol, *m*-cresol, and guaiacol.

(4) The condensation of guaiacol and acetic acid by means of phosphorus oxychloride gave isoacetovanillone (5-acetylguaiacol), which was obtained previously by Schneider and Kraft (*Ber.*, 1922, 55, 1892) by condensing guaiacol and acetic anhydride by means of sulphuric acid. Propionic and butyric acids were also condensed with guaiacol by means of phosphorus oxychloride, and gave compounds isomeric with 4-propionylguaiacol and 4-*n*-butyrylguaiacol, which are doubtless 5-*propionylguaiacol* and 5-*n-butyrylguaiacol*.

#### EXPERIMENTAL.

(1) *The Nencki Reaction.*—*o*- and *p*-Acetylphenols. Phenol (150 g.) was added to a hot solution of anhydrous zinc chloride (200 g.) in glacial acetic acid (100 c.c.) and the mixture was boiled for 1 hour. After the mass had cooled, water was added and the product was distilled with steam. The oil separated from the distillate was dissolved in excess of warm 5*N*-sodium hydroxide, and from this solution, on cooling, pale yellow crystals were deposited which after decomposition with dilute hydrochloric acid gave

*o*-acetylphenol (5 g.; yield, 2%\*) having b. p. 110°/15 mm. and m. p. 28° (Found: C, 70.5; H, 5.8. Calc.: C, 70.6; H, 5.9%). The oxime melted at 112°. Auwers (*Ber.*, 1925, 58, 36) gives b. p. 218° and m. p. of oxime 112°. The non-volatile oil remaining after the steam distillation was distilled under diminished pressure and gave *p*-acetylphenol (7 g.; yield, 3%) having b. p. 190°/15 mm. and m. p. 106—107°. Michael and Palmer (*loc. cit.*) give m. p. 108° and Perkin (*J.*, 1897, 71, 805) gives m. p. 107°.

The great difference in boiling point exemplified in the case of the *o*- and *p*-acetylphenols is found generally for *o*- and *p*-acylphenols and their methyl homologues. The *o*-hydroxyketones differ further from *p*-hydroxyketones in being volatile in steam and in giving red to violet colorations with ferric chloride. Moreover, the sodium salts of the *o*-acylphenols are readily obtained in yellow crystals freely soluble in water, and are easily precipitated by a small excess of alkali, whereas the sodium salts of the *p*-compounds are colourless and are easily soluble in water and in dilute sodium hydroxide solution.

As a general rule, the phenylhydrazones of the *o*-compounds are more readily made than the *p*-compounds, as is known to be the case with the oximes.

*p*-Propionylphenol was prepared by the method of Goldzweig and Kaiser (*loc. cit.*) in 10% yield.

*p*-*n*-Valerylphenol was obtained in 5% yield accompanied by the *o*-compound, of which the presence was indicated through the production of a violet colour on the addition of ferric chloride to an alcoholic solution of the steam-distillate of the reaction product. *p*-*n*-Valerylphenol has b. p. 210°/15 mm. and crystallises from benzene—light petroleum in cubes, m. p. 62—63° (Found: C, 74.0; H, 7.9.  $C_{11}H_{14}O_2$  requires C, 74.2; H, 7.8%).

*p*-*n*-Hexoylphenol (yield, 8%) forms colourless plates, m. p. 63—64°, from benzene (Found: C, 75.1; H, 8.4.  $C_{12}H_{16}O_2$  requires C, 75.0; H, 8.3%).

*p*-*n*-Heptoylphenol (yield, 9%; b. p. 220°/15 mm.) crystallises from benzene in well-formed prisms, m. p. 93—94° (Found: C, 75.9; H, 8.6.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%).

*p*-Heptoylphenyl benzoate crystallises from alcohol in needles, m. p. 92—93° (Found: C, 77.0; H, 7.1.  $C_{20}H_{22}O_3$  requires C, 77.4; H, 7.1%).

4-Propionyl-*m*-cresol was isolated from the product of the fusion of propionic acid and *m*-cresol with zinc chloride by distillation with steam and rectification of the oil obtained in a vacuum. The

\* Yields are given in % of the theoretical, and the substances are colourless except where it is otherwise stated.

fraction, b. p. 125—135°/15 mm., was crystallised from dilute alcohol, giving needles or plates, m. p. 45—46° (yield, 11%). It did not depress the melting point of 4-propionyl-*m*-cresol, prepared by the isomerisation of *m*-tolyl propionate, for which Auwers (*Annalen*, 1924, 439, 132) gives m. p. 45—46°.

4-*n*-Butyryl-*m*-cresol was similarly obtained from *m*-cresol and butyric acid (yield, 17%) and identified as the oxime, m. p. 74—75° (see page 288).

*Pæonol*. To zinc chloride (40 g.), dissolved in hot glacial acetic acid (40 c.c.), resorcinol monomethyl ether (25 g.) was added. The mixture was brought to the boiling point, allowed to cool in an oil-bath, and distilled with steam. The oil which distilled was separated by fractional distillation under diminished pressure into about 10 g. of unchanged resorcinol monomethyl ether and a fraction of higher boiling point from which 6 g. (29%) of *pæonol*, m. p. 50°, were obtained.

4-*Acetylpyrocatechol*. Pyrocatechol (25 g.), glacial acetic acid (50 g.), and zinc chloride (100 g.) were fused together in the usual manner. The mass was poured into water, and the solution extracted with ether. After distillation under diminished pressure, pyrocatechol and a fraction of b. p. about 180° (15 g.) were obtained. This was dissolved in hot benzene and allowed to cool; the crystals which separated were recrystallised and gave 8 g. (20%) of 4-acetylpyrocatechol, m. p. 116°. 4-*n*-Butyrylpyrocatechol and 4-*n*-hexoylpyrocatechol were obtained by exactly similar methods of procedure. Each was compared and found to be identical with the corresponding product obtained from the guaiacol ester by treatment with aluminium chloride.

*Acetovanillone*. To zinc chloride (100 g.) in hot glacial acetic acid (200 c.c.), guaiacol (100 g.) was added. The mixture was boiled gently under reflux for 3 hours, and acetic acid then distilled off under diminished pressure. After cooling, the residue was poured into water and extracted with ether. The extract was distilled under diminished pressure; a fraction, b. p. 170—190°, solidified and after recrystallisation from ether gave acetovanillone (5 g.; 4%), m. p. 113—114°.

4-*n*-Butyrylguaiacol and 4-*n*-hexoylguaiacol were prepared similarly and proved to be identical with the products, described later, obtained by the isomerisation of guaiacol esters with aluminium chloride; in each case considerable quantities of pyrocatechol and of the corresponding acylpyrocatechols were obtained as by-products.

(2) *The Fries Isomerisation*.—Phenyl butyrate, hexoate, and heptoate were converted into mixtures of *o*- and *p*-acylphenols by

heating with 1.1 mols. of aluminium chloride at 160—180° for 1—2 hours, and separated by distillation with steam or under diminished pressure.

*o-n-Butyrylphenol* (yield, 60%) had b. p. 124—126°/14 mm. and m. p. 8° (Found: C, 72.9; H, 7.3.  $C_{10}H_{12}O_2$  requires C, 73.2; H, 7.3%). Its *phenylhydrazone* is yellow and melts at 85—87° (Found: N, 11.0.  $C_{16}H_{18}ON_2$  requires N, 11.0%). *p-Butyrylphenol* (yield, 19%) has b. p. 200°/15 mm. and m. p. 91°. Perkin (J., 1889, 55, 546) gives m. p. 91°. *p-Butyrylphenyl benzoate* crystallises from alcohol in platelets, m. p. 106—107° (Found: C, 75.8; H, 6.0.  $C_{17}H_{16}O_3$  requires C, 76.1; H, 6.0%).

*o-n-Hexoylphenol* (yield, 50%) has b. p. 145—147°/15 mm. and crystallises from alcohol in prisms, m. p. 22° (Found: C, 74.8; H, 8.4.  $C_{12}H_{16}O_2$  requires C, 75.0; H, 8.3%). Its *phenylhydrazone* crystallises from alcohol in yellowish leaflets, m. p. 102—103° (Found: N, 9.6.  $C_{18}H_{22}ON_2$  requires N, 9.9%).

*o-n-Heptylphenol* (yield, 58%) has b. p. 172—174°/20 mm. and separates from alcohol in prisms, m. p. 24° (Found: C, 75.3; H, 8.7.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%). Its *phenylhydrazone* separates from alcohol in yellow plates, m. p. 91—92°.

The isomerisation of *o*-tolyl acetate has been described by Auwers (Ber., 1925, 58, 36) and by Rosenmund and Schnurr (Annalen, 1927, 460, 56).

*5-Acetyl-o-tolyl benzoate* separates from dilute spirit in fine silky needles, m. p. 79—80° (Found: C, 75.5; H, 5.3.  $C_{16}H_{14}O_3$  requires C, 75.6; H, 5.5%).

*o*-Tolyl butyrate, valerate, and hexoate were isomerised by heating the ester with 1.1 mols. of aluminium chloride at 160—180° for  $\frac{1}{2}$  hour, and the *o*- and *p*-ketones were separated by distillation under diminished pressure.

*3-n-Butyryl-o-cresol* (yield, 60% at 160—180°; 40% at 100°) has b. p. 143°/11 mm. and solidifies in a freezing mixture (Found: C, 73.9; H, 7.9.  $C_{11}H_{14}O_2$  requires C, 74.2; H, 7.8%). Its oxime forms needles, m. p. 87—88°, from alcohol, and its *phenylhydrazone* separates from alcohol in yellow needles, m. p. 157—158° (Found: N, 10.3.  $C_{17}H_{20}ON_2$  requires N, 10.4%).

*5-n-Butyryl-o-cresol* (yield, 30% at the ordinary temperature in 2 days; 55% at 100°; and 30% at 160—180°), b. p. 195—200°/15 mm., forms prisms, m. p. 132—133°, from benzene (Found: C, 74.0; H, 7.8.  $C_{11}H_{14}O_2$  requires C, 74.2; H, 7.8%). The *phenylhydrazone* separates in yellowish plates, m. p. 110°.

*3-n-Valeryl-o-cresol* (yield, 46%) has b. p. 143—145°/15 mm. and m. p. 18° (Found: C, 74.6; H, 8.5.  $C_{12}H_{16}O_2$  requires C, 75.0; H, 8.3%). The *phenylhydrazone* forms pale yellow leaflets, m. p.

116—118°, from alcohol (Found : N, 9.8.  $C_{18}H_{22}ON_2$  requires N, 9.9%).

5-n-Valeryl-o-cresol (yield at 160°, 30%), b. p. 205°/15 mm., forms rhombic prisms, m. p. 103—104°, from benzene (Found : C, 74.8; H, 8.5.  $C_{12}H_{16}O_2$  requires C, 75.0; H, 8.3%). 5-n-Valeryl-o-tolyl benzoate separates from alcohol in small plates, m. p. 72—73° (Found : C, 77.0; H, 7.1.  $C_{19}H_{20}O_3$  requires C, 77.0; H, 6.7%). 5-n-Valeryl-o-cresol phenylhydrazone forms very pale yellow needles, m. p. 120—121° (Found : N, 9.8.  $C_{18}H_{22}ON_2$  requires N, 9.9%).

3-n-Hexoyl-o-cresol (yield, 60%), b. p. 152—154°/15 mm., separates from cold alcohol in prisms, m. p. 23° (Found : C, 75.9; H, 9.0.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%). Its phenylhydrazone separates from alcohol in leaflets, m. p. 93—94° (Found : N, 9.3.  $C_{19}H_{24}ON_2$  requires N, 9.5%).

5-n-Hexoyl-o-cresol (yield at 160°, 25%), b. p. 200—205°/15 mm., separates from benzene in plates which fall to powder on drying at 50°; it then melts at 79—80° (Found : C, 75.7; H, 8.9.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%). The benzoate crystallises from alcohol in shining leaflets, m. p. 59—60° (Found : C, 77.2; H, 6.9.  $C_{20}H_{22}O_3$  requires C, 77.4; H, 7.1%).

The ketones obtained by isomerisation of *p*-tolyl esters with 1.1 mols. of aluminium chloride for 2 hours at 160° were purified by steam distillation, crystallisation of the sodium salts, and subsequent distillation under reduced pressure.

3-n-Butyryl-p-cresol oxime forms needles, m. p. 96—97°, from light petroleum (Found : N, 7.3.  $C_{11}H_{15}O_2N$  requires N, 7.3%). 3-n-Butyryl-p-cresol phenylhydrazone separates from alcohol in rhombic prisms, m. p. 141—142° (Found : N, 10.15.  $C_{17}H_{20}ON_2$  requires N, 10.4%).

3-n-Valeryl-p-cresol (yield, 65%), made but not characterised by Wittig (*Annalen*, 1925, 446, 155), has b. p. 144—145°/15 mm. and separates from light petroleum in fine needles, m. p. 32—33° (Found : C, 74.9; H, 8.5.  $C_{12}H_{16}O_2$  requires C, 75.0; H, 8.3%). Its phenylhydrazone separates from alcohol in yellowish plates, m. p. 113—115° (Found : N, 9.7.  $C_{18}H_{22}ON_2$  requires N, 9.9%).

3-n-Hexoyl-p-cresol (yield, 80%), b. p. 150—152°/15 mm., crystallises from light petroleum in fine needles, m. p. 19° (Found : C, 75.3; H, 8.9.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%). The phenylhydrazone separates from alcohol in platelets, m. p. 110—112° (Found : N, 9.2.  $C_{19}H_{24}ON_2$  requires N, 9.5%).

Although there is the possibility of the production of both 4- and 6-acyl-*m*-cresols in the isomerisation of *m*-tolyl esters, if the reaction is carried out at the ordinary temperature in nitrobenzene solution as described by Rosenmund the yield of the 6-compound

is negligible, being only 2% in the case of *m*-tolyl butyrate. The ketones of this class were purified by steam distillation, followed by distillation under reduced pressure.

4-*Propionyl-m-cresol oxime* separates from light petroleum in needles, m. p. 103–104° (Found: N, 7.7.  $C_{10}H_{13}O_2N$  requires N, 7.8%).

6-*n-Butyryl-m-cresol* separates from benzene in colourless plates, m. p. 97–98° (Found: C, 73.9; H, 7.8.  $C_{11}H_{14}O_2$  requires C, 74.2; H, 7.9%).

4-*n-Butyryl-m-cresol* (yield, 88%) has b. p. 142–144°/15 mm. and m. p. 17° (Found: C, 74.0; H, 7.6.  $C_{11}H_{14}O_2$  requires C, 74.2; H, 7.9%). Its *oxime* forms needles, m. p. 74–75°, from light petroleum (Found: N, 7.3.  $C_{11}H_{15}O_2N$  requires N, 7.3%). Its *phenylhydrazone* forms pale yellowish leaflets, m. p. 95–97°, from alcohol (Found: N, 10.2.  $C_{17}H_{20}ON_2$  requires N, 10.4%).

4-*n-Valeryl-m-cresol* (yield, 85%) has b. p. 152–154°/15 mm. and m. p. 16° (Found: C, 74.8; H, 8.2.  $C_{12}H_{16}O_2$  requires C, 75.0; H, 8.3%).

4-*n-Hexoyl-m-cresol* (yield, 93%), b. p. 162–164°/15 mm., separates from alcohol in prismatic needles, m. p. 23–24° (Found: C, 75.5; H, 8.8.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%). Its *phenylhydrazone* separates from alcohol in leaflets, m. p. 92–93° (Found: N, 9.3.  $C_{19}H_{24}ON_2$  requires N, 9.5%).

4-*n-Heptoyl-m-cresol* (yield, 84%) has b. p. 172–174°/15 mm. and m. p. 18° (Found: C, 76.0; H, 9.1.  $C_{14}H_{20}O_2$  requires C, 76.4; H, 9.1%).

The best conditions for the preparation of 4-acylguaiacols were found to be as follows: Aluminium chloride (270 g.; 2 mols.) was dissolved in nitrobenzene (600 c.c.) by heating at 100°, the solution cooled to 10°, and the ester (1 mol.) added quickly; the solution, which was at first clear, changed to a very viscous mass. On gentle warming, hydrogen chloride was evolved and the viscous mass became micro-crystalline. After remaining at about 80° for  $\frac{1}{2}$ –1 hour, the product was kept over-night; the crystals were then collected out of contact with moist air and washed successively with benzene, benzene-light petroleum, and light petroleum.

The aluminium chloride compound was thus obtained as a cream-coloured sandy powder. It was added gradually to an excess of dilute hydrochloric acid; the almost pure 4-acylguaiacol then separated as an oil, which quickly solidified and was obtained in a yield of upwards of 50% of the theoretical. The nitrobenzene filtrate from the aluminium compound was distilled with steam to remove nitrobenzene and the remaining oil was distilled under diminished pressure; a further quantity of the 4-acylguaiacol was

thus obtained, followed at a temperature some 30° higher by the corresponding acylpyrocatechol.

The 4-acylguaiacols and 4-acylpyrocatechols are easily crystallisable compounds, the acylguaiacols being more soluble in organic solvents but less soluble in water than the corresponding acylpyrocatechols. The solubility of 4-acetylpyrocatechol in water is such as to render water unsuitable for its recrystallisation, but this solvent may very conveniently be employed for recrystallising 4-propionyl- and 4-*n*-butyryl-pyrocatechols, both of which are, with difficulty, soluble in benzene. 4-*n*-Valerylpyrocatechol and 4-*n*-hexoylpyrocatechol are easily soluble in hot benzene.

4-Acylguaiacols and acylpyrocatechols give green and very deep bluish-green colorations, respectively, with alcoholic ferric chloride. Certain constants of these compounds, with analyses, are given below :—

	M. p.	B. p. (15 mm.).	Found.		Formula.	Required.	
			% C.	% H.		% C.	% H.
4-Propionylguaiacol .....	61—62°	180—185°	66.5	6.6	C <sub>10</sub> H <sub>12</sub> O <sub>3</sub>	66.7	6.7
4- <i>n</i> -Butyryl .....	54—55	185—195	67.9	7.2	C <sub>11</sub> H <sub>14</sub> O <sub>3</sub>	68.0	7.2
4- <i>n</i> -Valeryl „ .....	60—62	195—197	69.0	7.6	C <sub>12</sub> H <sub>16</sub> O <sub>3</sub>	69.2	7.7
4- <i>n</i> -Hexoyl „ .....	60—62	212—215	70.1	8.1	C <sub>13</sub> H <sub>18</sub> O <sub>3</sub>	70.3	8.1

4- <i>n</i> -Hexoyl „	93—94	240—250	69.1	7.6	C <sub>13</sub> H <sub>18</sub> O <sub>4</sub>	69.2	7.7

4-Propionylpyrocatechol and 4-*n*-butyrylpyrocatechol had b. p. 210—220° and 220—230°/15 mm. respectively. The m. p. of each was identical with that given by Rosenmund and Lohfert (*Ber.*, 1928, 61, 2601).

The following derivatives of the acylguaiacols have been prepared :—

4-Propionylguaiacyl benzoate, m. p. 108—110° (Found : C, 71.6; H, 5.8. C<sub>17</sub>H<sub>16</sub>O<sub>4</sub> requires C, 71.8; H, 5.6%). 4-Propionylguaiacol *p*-nitrophenylhydrazone, yellowish needles, m. p. 151—152°, from alcohol (Found : N, 13.3. C<sub>16</sub>H<sub>17</sub>O<sub>4</sub>N<sub>3</sub> requires N, 13.3%). 4-*n*-Butyrylguaiacyl benzoate, m. p. 75—77° (Found : C, 72.0; H, 6.0. C<sub>18</sub>H<sub>18</sub>O<sub>4</sub> requires C, 72.5; H, 6.0%). 4-*n*-Butyrylguaiacol phenylhydrazone, pale yellow needles, m. p. 91—92°, from dilute alcohol (Found : N, 9.6. C<sub>17</sub>H<sub>20</sub>O<sub>2</sub>N<sub>2</sub> requires N, 9.9%). 4-*n*-Valerylguaiacyl benzoate, m. p. 85—87° (Found : C, 73.0; H, 6.3. C<sub>19</sub>H<sub>20</sub>O<sub>4</sub> requires C, 73.1; H, 6.4%). 4-*n*-Hexoylguaiacyl benzoate, m. p. 54—55° (Found : C, 73.4; H, 6.8. C<sub>20</sub>H<sub>22</sub>O<sub>4</sub> requires C, 73.6; H, 6.7%).

(3) *Isomerisation of Esters with Zinc Chloride.*—(a) Phenyl acetate (100 g.) and powdered zinc chloride (15 g.) were heated at 125° for 3 hours. The product gave *o*-acetylphenol (4 g.; yield, 4%) and *p*-acetylphenol (8 g.; yield, 8%).

(b) *m*-Tolyl propionate (75 g.) and powdered zinc chloride (37.5 g.) were heated at 150—160° for 1 hour. The product was dissolved

in dilute hydrochloric acid and distilled with steam. Extraction of the distillate with ether and distillation of the extract under low pressure gave 15 g. of pure 4-propionyl-*m*-cresol (yield, 20%).

(c) To guaiacyl acetate (20 g.) at 200°, powdered zinc chloride (5 g.) was added. Vigorous ebullition took place, and after 1 minute the melt was poured into water and boiled with dilute hydrochloric acid. Ether then extracted an oil, which was distilled under reduced pressure. A fraction, b. p. 180—200°/15 mm., solidified on cooling, and after crystallisation from benzene gave acetovanillone (5 g.), m. p. 113—114° (yield, 25%).

(4) *Condensation of Guaiacol with Fatty Acids by Means of Phosphorus Oxychloride*.—Guaiacol (100 g.) and glacial acetic acid (200 g.) were mixed, and phosphorus oxychloride (200 g.) was added slowly. After being warmed gently on the steam-bath until the evolution of hydrogen chloride ceased (3 hours), the product was poured into water, and the guaiacol distilled with steam. The non-volatile oil was extracted with ether and distilled under diminished pressure. The fraction, b. p. 180—200°/15 mm., solidified, and after crystallisation from benzene gave isoacetovanillone (26 g.), m. p. 91—92° (yield, 20%) (Found: C, 65.4; H, 6.3. Calc.: C, 65.1; H, 6.1%). It crystallised from water in long needles (m. p. 59—60°) containing water of crystallisation (Schneider and Kraft, *loc. cit.*, gave m. p. 91°, and 66—69° for the hydrate). isoAcetovanillone phenylhydrazone melts at 102° (Found: N, 10.8.  $C_{15}H_{16}O_2N_2$  requires N, 10.9%), and isoacetovanillone benzoate at 141—142° (Found: C, 70.7; H, 5.3.  $C_{16}H_{14}O_4$  requires C, 71.1; H, 5.2%).

5-Propionylguaiacol was prepared similarly (yield, 25%). It melts at 93—94°, and is moderately easily soluble in hot water or benzene (Found: C, 66.4; H, 6.7.  $C_{10}H_{12}O_3$  requires C, 66.7; H, 6.77%). The benzoate melts at 96—98° (Found: C, 71.6; H, 5.8.  $C_{17}H_{16}O_4$  requires C, 71.8; H, 5.6%).

5-*n*-Butyrylguaiacol, prepared similarly, melts at 81—82° (Found: C, 67.9; H, 7.2.  $C_{11}H_{14}O_3$  requires C, 68.0; H, 7.2%).

#### *Reduction of Acylphenols to Alkylphenols.*

For the conversion of the carbonyl group into the methylene group in the series of hydroxyketones, the usual procedure was to boil the ketone (1 part) under reflux on the steam-bath for 12—20 hours with amalgamated zinc (3 parts) and dilute hydrochloric acid (1:1) (6 parts) to which alcohol (2 parts) had been added. (When *o*-hydroxyketones were being reduced, the end of the reaction was clearly indicated by the failure of the colour reaction with ferric chloride.) The alcohol was removed by distillation with steam and the lower phenols were separated by continued distillation with

steam, but the rate of distillation became too slow with the higher members of the series to permit of their being separated by this method. They were therefore extracted from the reaction mixture, distilled in a vacuum, and recrystallised wherever possible from light petroleum. The following table shows the new phenols which were prepared and certain constants and analytical data :—

Phenol.	B. p. (15 mm.).	M. p.	Found.		Formula.	Calc.	
			% C.	% H.		% C.	% H.
<i>p</i> - <i>n</i> -Hexylphenol .....	155°	29°	80.8	10.1	C <sub>12</sub> H <sub>18</sub> O	80.9	10.1

A number of the phenols prepared in the course of this work were known previously, but had not been obtained crystalline, namely, *p*-*n*-butylphenol, m. p. 12°; *p*-*n*-amylphenol, m. p. 18°; 4-*n*-propyl-*m*-cresol, m. p. 16°; and 4-*n*-propylguaiaacol, m. p. 16°. *p*-*n*-Propylphenol had m. p. 24°; Clemmensen (*Ber.*, 1914, 47, 51) gives m. p. 21—22°. Aqueous solutions of sodium *o*- and *p*-butylphenoxides are colourless, contrary to the statements of Read and Mullen (*J. Amer. Chem. Soc.*, 1928, 50, 1764). 4-*n*-Butylguaiaacol, prepared by the reduction of 4-*n*-butyrylguaiaacol, had b. p. 140—142°/15 mm. and its benzoate had m. p. 91.5°; Nomura and Hotta (*loc. cit.*) give b. p. of the reduction product of zingerone as 141—142°/13.5 mm. and m. p. of its benzoate as 92—93°.

The following benzoates of the above phenols are new :—

Benzoate.	M. p.	Found.		Formula.	Calc.	
		% C.	% H.		% C.	% H.
<i>p</i> - <i>n</i> -Propylphenyl .....	37—38°	79.6	6.8	C <sub>16</sub> H <sub>18</sub> O <sub>2</sub>	80.0	6.7
<i>p</i> - <i>n</i> -Butylphenyl .....	24—25	80.1	7.0	C <sub>17</sub> H <sub>18</sub> O <sub>2</sub>	80.3	7.1
<i>p</i> - <i>n</i> -Hexylphenyl .....	24	80.4	7.9	C <sub>19</sub> H <sub>22</sub> O <sub>2</sub>	80.8	7.8
<i>p</i> - <i>n</i> -Heptylphenyl .....	32—33	80.6	8.3	C <sub>20</sub> H <sub>24</sub> O <sub>2</sub>	81.0	8.1
4-Ethylguaiaacyl .....	58—59	74.7	6.3	C <sub>16</sub> H <sub>18</sub> O <sub>3</sub>	75.0	6.2
5-Ethylguaiaacyl .....	53	74.8	6.4	C <sub>16</sub> H <sub>18</sub> O <sub>3</sub>	75.0	6.2
4- <i>n</i> -Hexylguaiaacyl .....	82—83	76.8	7.9	C <sub>20</sub> H <sub>24</sub> O <sub>3</sub>	76.9	7.7

We desire to thank Mr. C. A. Hill of Boots Analytical Department for carrying out many of the analyses recorded in this paper.

# XLIV.—*Reduction Products of the Hydroxyanthraquinones. Part XI.*

By EDWIN JOHN CROSS and ARTHUR GEORGE PERKIN.

WHEN unsymmetrical hydroxyanthraquinones are reduced, in general only one of the two theoretically possible hydroxyanthranols is produced; *e.g.*, 1-hydroxyanthraquinone yields 1-hydroxyanthranol (or anthrone) (I), there being no evidence of the simultaneous formation of the 4-hydroxy-compound (II).

The anthrone formula, which is applicable to 1-hydroxyanthranol (Meyer and Sander, *Annalen*, 1920, **420**, 113) and possibly to other 1-hydroxyanthranols, is adopted in all cases throughout this paper for the sake of simplicity.

Although hitherto it has not been possible to speculate with any certainty as to the influence of the hydroxyl group or groups of hydroxyanthraquinones in definite positions on the production therefrom of this or that isomeric hydroxyanthranol, a determination of the exact structure of the latter has added considerably to our knowledge in this respect. For this purpose the conversion of hydroxyanthranol into hydroxybenzanthrone has been mainly studied, and the presence or absence of the  $\alpha$ -hydroxyl group in the latter ascertained by the employment of methyl iodide and alkali. Thus, when the hydroxybenzanthrone (III) derived from (I) is so treated, methylation does not occur, giving evidence that the former is, without doubt, the 4- or 5-hydroxy-compound (III), and the latter the 1-hydroxy-compound (Perkin and Spencer, *J.*, 1922, **121**, 474).

Although alizarin had hitherto been known to give but one anthranol (3:4-dihydroxyanthranol), Miller and Perkin (*J.*, 1925, **127**, 2684), employing stannous chloride and hydrochloric acid,

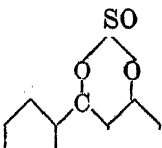

obtained from alizarin 2-methyl ether a mixture of 4-hydroxy-3-methoxy- and 1-hydroxy-2-methoxy-anthranol (IV). The constitution of the latter became evident from the fact that, by treatment with glycerol and sulphuric acid, *isobenzalizarin* (3:4- or 5:6-dihydroxybenzanthrone) (V) is obtained, a compound from which, by the reagents stated, only a monomethyl ether can be produced.

Adopting the same methods, it has been shown by Cross and Perkin (J., 1927, 1297) that the anthranols derived from anthrapurpurin, flavopurpurin, and anthragallol are respectively the 3:4:6-, 1:2:6-, and 1:2:3-trihydroxy-compounds, the last yielding 2:3:4-trihydroxybenzanthrone (VI).

The  $\alpha$ -hydroxyl group in hydroxybenzanthrones is not only resistant to methylation but is much less readily acetylated than the  $\alpha$ -hydroxyl of hydroxyanthraquinones: for instance, a fully acetylated derivative can be prepared from (V) only with difficulty, and from (VI), as yet, only a diacetyl compound has been obtained. Evidently, therefore, the chelate ring in  $\alpha$ -hydroxybenzanthrones possesses a much firmer character than that which is present in  $\alpha$ -hydroxyanthraquinones.

Green (J., 1927, 2341) suggests the employment of thionyl chloride as a reagent for the determination of the structure of hydroxy-anthranols, in that ortho- and peri-hydroxyls when present in a phenol yield thionyl derivatives, whereas such compounds are not given by meta- and para-dihydric phenols (J., 1924, 125, 1450; 1926, 1428, 2198; 1927, 500, 554). In order to illustrate the utility of this method, he examined only three anthranols, *viz.*, 1-hydroxy-anthranol (I), 4-chloro-1-hydroxyanthranol, and anthragallol-anthranol. Of these, the first two only yielded thionyl compounds,

evidently of the type , whereas the last did not so

react. From this scanty evidence, and notwithstanding the proof given by Cross and Perkin (*loc. cit.*) to the contrary, this author concludes that anthragallolanthranol is not the 1:2:3-trihydroxy-anthranol (1:2:3:9-tetrahydroxyanthracene) but the 2:3:4-

trihydroxyanthranol (1 : 2 : 3 : 10-tetrahydroxyanthracene). It appears at first sight somewhat strange that 1-hydroxyanthranol, which in reality is 1-hydroxyanthrone (Meyer and Sander, *loc. cit.*), reacts with thionyl chloride in the manner indicated, unless in these circumstances tautomerisation of the anthrone to the anthranol is presumed to occur.

It has been shown by Dimroth and Faust (*Ber.*, 1921, 54, 3020) that when  $\alpha$ -hydroxyanthraquinones are treated with boroacetic anhydride, boric esters are produced. 1-Hydroxyanthraquinone thus yields 1-hydroxyanthraquinone boroacetate (VII), and diboroacetates are given by 1 : 4- and 1 : 5-dihydroxyanthraquinones.

The compounds are decomposed by water, giving  $\alpha$ -hydroxyanthraquinone and boric and acetic acids. The application of this method to  $\alpha$ -hydroxyanthranols (anthrones) was tested first with 1-hydroxy-2-methoxyanthrone: a boroacetate, however, could not be prepared, for, although with the boiling reagent chemical alteration evidently occurred, in the cold a product of an indefinite character resulted. Anthragallolanthranol at first gave substances of an indefinite character, and it was only by the employment of special conditions that success was attained. Though different preparations of the orange crystalline product varied somewhat in composition, there could be no doubt that they essentially consisted of a *boroacetic ester* of 1 : 3-dihydroxy-2-acetoxyanthranol (VIII), and this result further confirms the statement of Cross and Perkin (*loc. cit.*) that the anthranol prepared by the reduction of anthragallol itself is the 1 : 2 : 3-trihydroxy-compound (IX).

The fact that, with stannous chloride and hydrochloric acid, 2-ethylcarbonatoalizarin gives 1-hydroxy-2-ethylcarbonatoanthranol, apparently as sole product (Perkin and Story, J., 1929, 1405), suggested as desirable a study of the influence, if any, of the acyloxy-group in acyloxyanthraquinones on the orientation of the hydroxy- or acyloxy-groups in the anthranols derived therefrom by reduction. The method here adopted, which consists in adding stannous chloride-hydrochloric acid to a hot solution of the acyl compound in acetic acid, has given results of interest. From triacetylanthragallol, thus treated, two anthranols are obtained: (a) the 1 : 2 : 3-trihydroxy-compound (IX), present in but small amount, and (b)

the main product, which consists, as shown below, of the hitherto unknown 2 : 3 : 4-trihydroxy-9-anthranol (X).

As the acetoxy-group is so readily hydrolysed in the circumstances, it is remarkable that such a process can be applied to acetyl compounds. That the elimination of the acetyl group here only occurs when reduction is complete and not, at least to any extent, prior to this process in most instances, is due to the extreme rapidity of the latter reaction, for this in general occupies but a few seconds, though in practice a somewhat longer digestion has usually been employed. If stannous chloride-hydrochloric acid is added to a warm solution of the acetoxyanthraquinone in acetic acid and the mixture is kept without further heating, complete reduction usually occurs over-night.

In order to ascertain the constitution of (X), it was heated with glycerol and sulphuric acid, and there was thus obtained, with considerable difficulty and in small amount, a trihydroxybenzanthrone, here termed *benzanthragallol*. This compound, which differs considerably in properties from the *isobenzanthragallol* (VI) derived from 1 : 2 : 3-trihydroxy-9-anthranol, readily gives a *trimethyl* ether when treated with methyl iodide and alkali, whereas the isomeride does not. *Benzanthragallol*, therefore, has the constitution (XI), and can thus have only originated from the 2 : 3 : 4-trihydroxy-9-anthranol (X).

A complete proof is thus afforded that, on reduction, anthragallol itself gives 1 : 2 : 3-trihydroxy-9-anthranol, and not, as suggested by Green, the 2 : 3 : 4-trihydroxy-9- (or 1 : 2 : 3-trihydroxy-10-) anthranol. It is moreover evident that thionyl chloride is hardly a trustworthy reagent for the detection of the 1-hydroxyl group in hydroxyanthranols.

The reduction of 2 : 3-diacetylanthragallol in a similar manner was now studied, the result being the production of 1 : 2 : 3-trihydroxy-9-anthranol (IX) identical with that given by anthragallol itself.

In order to illustrate more clearly the effect of the acetyl and other groups in this connexion, the results of this section of the investigation are embodied in the following table, and here, for purposes of comparison, the reduction products given by the free hydroxyanthraquinones are also included.

Anthraquinones.	Anthranols obtained by reduction.	
Anthragallol	1 : 2 : 3-Trihydroxy-9-anthranol	
Triacetylanthragallol	" "	2 : 3 : 4-Trihydroxy-9-anthranol
Diacetylanthragallol	" "	
Tribenzoylanthragallol		Dibenzoyl-2 : 3 : 4-tri-hydroxy-9-anthranol
Dibenzoylanthragallol	Dibenzoyl-1 : 2 : 3-tri-hydroxy-9-anthranol Monobenzoyl-1 : 2 : 3-tri-hydroxy-9-anthranol	
Triethylcarbonato-anthragallol	2 : 3-Diethylcarbonato-1-hydroxy-9-anthranol	Dicarbethoxy-2 : 3 : 4-tri-hydroxy-9-anthranol
Diethylcarbonato-anthragallol	" "	
	2-Ethylcarbonato-1 : 3-dihydroxy-9-anthranol

Acetylalizarin 2-methyl ether		" "
1-Acetoxyanthraquinone		4-Hydroxy-9-anthranol
1 : 8-Dihydroxy-anthraquinone	1 : 8-Dihydroxy-9-anthranol	
1 : 8-Diacetoxy-anthraquinone		4 : 5-Dihydroxy-9-anthranol (XII)
1 : 2 : 6-Trihydroxy-anthraquinone	1 : 2 : 6-Trihydroxy-9-anthranol	

Although acetoxyanthraquinones are reduced very rapidly (*loc. cit.*) by the method here employed, the reduction of ethylcarbonatoanthraquinones (or at least of triethylcarbonatoanthragallol) occurs more slowly, because, though, in the circumstances employed, the carbethoxy-group is less readily eliminated than the acetyl group, it is apparent that, in the instance above cited, some hydrolysis with removal of the ethylcarbonato-group has taken place, both before and after the reduction. Thus, under the conditions employed (see above), triethylcarbonatoanthragallol (A) yields in part diethylcarbonatoanthragallol (B). (A) on reduction

gives 2:3:4-*triethylcarbonatoanthrone*, passing by subsequent hydrolysis to the *diethyl* compound, whereas from (B) 1-*hydroxy-2:3-diethylcarbonatoanthrone* is obtained.

Among the points of interest indicated above are the preparation, not only of the two new hydroxyanthranols (II) and (X), but of 4-hydroxy-3-methoxy- and 1:2-dihydroxy-9-anthranols, compounds hitherto not readily obtained, in almost quantitative yield. That 1:2-dihydroxy-9-anthranol can also be prepared in this way directly from alizarin—though in conjunction with the 3:4-dihydroxy-compound—has also been ascertained for the first time, and this affords evidence that reduction of an  $\alpha$ -hydroxyanthraquinone in acid solution and in an alkaline medium does not of necessity proceed in an identical manner in both cases.

The results of this investigation indicate that when hydroxyanthraquinones containing an  $\alpha$ -hydroxy-group are reduced in an acid solution in the manner indicated, the  $\alpha$ -hydroxy-group as a rule is found to be in the 1-position adjacent to the carbonyl group, or to the hydroxyl in the 9-position of the resulting hydroxyanthrone or hydroxyanthranol. If, on the other hand, the  $\alpha$ -hydroxyl of the hydroxyanthraquinone is acylated before reduction, the reverse is the case, this hydroxyl then occupying the 4-position in the product. In other words, the carbonyl adjacent to the acyloxy-group in  $\alpha$ -acyloxyanthraquinones is preferably reduced: this is clearly shown by (I) and (II), which represent respectively the reduction products of 1-hydroxy- and 1-acetoxy-anthraquinone. If in these cases the reaction proceeds according to the usually accepted scheme (XIII), an explanation of the fact cited above, in the light of our present knowledge, is difficult, because it is in no way clear why, in the

change of (XIV) into (XV) ( $c \rightarrow d$ ) during the reduction of 1-hydroxyanthraquinone to 1-hydroxyanthrone (or anthranol), water should be split off only in the manner indicated, and not in both directions

with the simultaneous formation of 1- and 4-hydroxyanthranols. It seems reasonable to infer that the influence dominating the formation of 1-hydroxyanthranols from  $\alpha$ -hydroxyanthraquinones by acid reduction is the chelate linkage between the  $\alpha$ -hydroxyl and

the carbonyl group of the latter. This renders the latter immune from reduction, a fact which can also be expressed by saying that the chelate linkage remains intact in the series of changes involved. Such a suggestion can be indicated (XVI) by the stages (a) dihydroxy-pinacol, (b) hydroxyanthranol, (c) dianthrone, (d) anthrone, (e) anthranol. On the other hand, when the  $\alpha$ -hydroxy-group is

acylated the chelate linkage is destroyed, and the adjacent carbonyl group is no longer immune from reduction. Of interest in this respect is the statement of Meyer and Sander (*loc. cit.*) that 1-hydroxy-9-anthranol is produced when 1-hydroxyanthraquinone is reduced in acid solution, and that only by the use of alkaline media could the corresponding anthranol be obtained. If the scheme outlined above is to be considered, at least in the main, correct, proof of the formation of hydroxydianthrone (stage c) during the reduction process is necessary, and though there have been indications during more recent work, in special instances, of the presence of such compounds in the final products, further investigation is necessary to determine if their formation in this manner from  $\alpha$ -hydroxyanthraquinones is of general occurrence.

An exception to the rule that  $\alpha$ -hydroxyanthraquinones yield on reduction 1-hydroxyanthrones (or anthranols) is the 1:2:7-trihydroxy-compound (anthrapurpurin) (*loc. cit.*), which gives both with stannous chloride-hydrochloric acid and with aqueous ammonia and zinc dust, 3:4:6-trihydroxy-9-anthranol. In the case of anthrapurpurin, however, two factors can be considered to influence the reaction: (a) the 1-hydroxy-group and (b) the remote  $\beta$ -hydroxy-group in the 7-position. Whereas it is to be anticipated that the former (compare alizarin) will tend, though only in part (*loc. cit.*), to give an  $\alpha$ -hydroxyanthrone, the latter (compare 2-hydroxy- and 2-acetoxy-anthraquinone, which, as experiment has shown, both yield 3-hydroxyanthranol as sole product) will desire to take up the 6-position in the resulting hydroxyanthranol. The latter influence evidently predominates in the present instance: this point will be further discussed in a subsequent communication.

In the German patent 187495 (Friedländer's "Fortschritte," IX,

816) two methods are given for the preparation of hydroxybenzanthrones: (a) the action of glycerol and sulphuric acid on hydroxyanthranols and (b) the similar treatment of hydroxyanthraquinones in the presence of reducing agents. That in these circumstances the product of the reduction, according to the patent, of a hydroxyanthraquinone and the anthranol derived therefrom by alkaline reduction, do not necessarily give the same hydroxybenzanthrone is obvious from the results of the present investigation, and indeed the properties given in the patent of the hydroxybenzanthrone derived from alizarin differ markedly from those of the 7:8-dihydroxy-compound (Perkin, J., 1920, 117, 702) which is obtained in a similar manner from 3:4-dihydroxyanthranol (deoxylizarin). Evidently, therefore, the former product is either 3:4- or 5:6-dihydroxybenzanthrone. Turski and Grynwasser (*Rocz. Chem.*, 1929, 9, 78) purport to have decided this point by synthetical methods and describe these compounds as melting at 285° and 185° respectively. Their paper\* is remarkable in that it consists merely of a series of statements. It contains no account of the properties or the melting points of the new compounds which were prepared for the purpose of these syntheses, and but one analysis seems to have been performed, the figures of which are not stated. The results of these authors, at least in regard to one or other of the dihydroxybenzanthrones they describe, are not in harmony with those of Miller and Perkin (*loc. cit.*), who obtained *isobenzalizarin* (V) from 1-hydroxy-2-methoxyanthranol; for this, which melts at 265°, is either the 3:4- or the 5:6-dihydroxy-compound. A reinvestigation has confirmed the correctness of the melting points previously given both for this compound and for its acetyl derivative (243—245°). The action of glycerol and sulphuric acid on alizarin in the presence of aniline sulphate was now studied, with the result that the crude product obtained resembled that described in the patent, more especially in regard to its giving strongly fluorescent solutions both in sulphuric acid and in dilute alkali. This substance is, however, a mixture, for on treatment by the method described below, a more sparingly soluble fraction can be isolated in small amount, which is devoid of fluorescent property. This yielded an acetyl compound melting at 243—245°, and without doubt consisted of *isobenzalizarin*. There is no reason why alizarin, in the circumstances, should not yield isomeric hydroxybenzanthrones, and if this is so, it is possible that the compound, m. p. 185°, described by Turski and Grynwasser as 5:6-dihydroxybenzanthrone, which gives fluorescent solutions in the manner indicated, is present in

\* For a translation of this paper, which is written in Polish, we are indebted to the kindness of Mrs. J. W. McLeod of Leeds.

the more soluble fraction of the reaction product. Should such be the case, then isobenzalazarin is 3 : 4-dihydroxybenzanthrone, and the nature of the compound they describe as melting at 285°, and to which they ascribe the same constitution, is not clear.

#### EXPERIMENTAL.

*Reduction of Triacetylanthrakgallol.*—To a boiling solution of triacetylanthrakgallol (10 g.) in acetic acid (100 c.c.), stannous chloride (40 g.) dissolved in warm hydrochloric acid (100 c.c.)\* was added. The pale yellow liquid darkened, became lighter when boiled for a short time, and deposited crystalline 2 : 3 : 4-trihydroxy-9-anthranol (X). After cooling, this was collected, washed with a mixture of acetic and hydrochloric acids and with water, and dried (yield, 4.3 g.). Addition of water to the filtrate gave a precipitate (1.5 g.) of which the colour reactions and the m. p. of the monoacetyl derivative, m. p. 239—240° (decomp.) (Breare and Perkin, J., 1923, 123, 2607), showed that it was 1 : 2 : 3-trihydroxy-9-anthrone (or anthranol). The total yield of anthranols (5.8 g.) represents 91.6% of the theoretical amount.

2 : 3 : 4-Triacetoxy-9-anthranyl acetate was readily obtained by digesting the 2 : 3 : 4-trihydroxy-compound with boiling acetic anhydride and pyridine for a short time and adding alcohol to the product after cooling. The crystals obtained formed colourless prisms, m. p. 199—201°, after recrystallisation from alcohol-acetic acid (Found : C, 64.2; H, 4.45;  $C_2H_4O_2$ , 58.3.  $C_{22}H_{18}O_8$  requires C, 64.4; H, 4.4;  $C_2H_4O_2$ , 58.5%).

2 : 3 : 4-Trihydroxy-9-anthranol can be obtained only in a crude condition and of a deep green colour when the acetyl compound is hydrolysed with hydrochloric acid in the usual manner. If, however, a solution of the acetyl compound in boiling acetic acid is digested with half its volume of stannous chloride-hydrochloric acid until crystals commence to separate, the anthranol is obtained in needles which have, at most, a pale greenish tint. When heated, it gradually darkens, does not melt below 300°, and at this temperature is greenish-black (Found : C, 69.4; H, 4.2.  $C_{14}H_{10}O_4$  requires C, 69.4; H, 4.1%). The possibility, suggested by its high melting point, that this compound might be a dianthrone rather than an anthrone (anthranol) was disproved by a molecular-weight determination of the tetra-acetyl compound by the cryoscopic method with naphthalene as solvent (Found :  $M$ , 400.  $C_{22}H_{18}O_8$  requires  $M$ , 410. As the colourless solution, which has a faint blue fluorescence, gradually darkens, the initial readings only are trustworthy).

\* This concentration of stannous chloride in hydrochloric acid was employed throughout the investigation.

2:3:4-Trihydroxy-9-anthranol gives in 10% aqueous sodium hydroxide an orange solution which becomes yellow and finally brown in air: in the same circumstances, 1:2:3-trihydroxy-9-anthranol gives an orange liquid which eventually develops a deep violet tint. Again, the latter in alcoholic solution gives with benzoquinone violet crystals of anthragallol dianthronequinone (Breare and Perkin, *loc. cit.*), but the 2:3:4-trihydroxy-compound is devoid of this characteristic. When oxidised with chromic acid in acetic acid solution, 2:3:4-triacetoxy-9-anthranyl acetate yielded orange crystals, m. p. 218—220°; these probably consisted of 2:3-diacetylanthragallol, as triacetylanthragallol was obtained from them by acetylation. Attempts to prepare a dianthrone from 2:3:4-trihydroxy-9-anthrone have been unsuccessful.

*Benzanthragallol*.—A mixture of 2:3:4-trihydroxy-9-anthranol (1 g.), sulphuric acid (8 c.c.), water (6 c.c.), and glycerol (2 g.) was heated with stirring to 120—125° during 20 minutes, and kept there for the same period. The product was poured into water, the washed precipitate dried and digested with alcohol, the concentrated solution poured into ether, and the ethereal solution well washed. Evaporation gave a brown residue, from which, by acetylation with acetic anhydride and pyridine, minute yellow crystals (0.05—0.07 g.) were obtained. These were again acetylated, crystallised from acetic acid, and, being still impure, hydrolysed with hydrochloric acid in the usual manner. The product was dissolved in alcohol, and boiling water added to the filtered solution, which caused the separation of small orange-yellow prisms. These gradually darkened above 200° and became black at about 290° without any sign of fusion (Found: C, 73.0; H, 3.8.  $C_{17}H_{10}O_4$  requires C, 73.4; H, 3.6%). This substance, *benzanthragallol*, dissolves in sulphuric acid with a crimson, and in 1% caustic soda solution with a violet colour which quickly fades to a yellow tint in air. With 10% caustic soda solution, a deep blue colour is obtained which becomes green and then yellow in air. *Benzanthragallol* dyes mordanted woollen cloth in shades distinct from those given by anthragallol and by *isobenzanthragallol*, although they approximate in depth to those given by the former colouring matter. Orange, orange-brown, red-brown, and dark brown shades are given by tin, aluminium, chromium, and iron mordants respectively.

*Triacetylbenzanthragallol*, prepared in the usual manner, gives a fluorescent solution in acetic acid and crystallises therefrom in pale yellow needles, m. p. 221—223° (Found: C, 68.3; H, 4.1;  $C_{17}H_{10}O_4$ , 68.5.  $C_{23}H_{16}O_7$  requires C, 68.3; H, 4.0;  $C_{17}H_{10}O_4$ , 68.8%).

*Methylation*. To a boiling mixture of triacetylbenzanthragallol

(0.5 g.) in methyl alcohol (7.5 c.c.) and methyl iodide (3 c.c.), caustic potash (0.5 g.) \* in methyl alcohol was added during 12 hours. The product was concentrated, poured into ether, insoluble resinous matter removed, and the ethereal solution washed with dilute alkali and evaporated. The residue, crystallised first from benzene and then from alcohol, yielded lemon-yellow, hair-like needles (0.07 g.), m. p. 143—144° (Found : C, 74.6; H, 5.1; CH<sub>3</sub>, 13.9. C<sub>20</sub>H<sub>16</sub>O<sub>4</sub> requires C, 75.0; H, 5.0; CH<sub>3</sub>, 14.1%). *Benzanthragallol trimethyl ether* can also be prepared by methylating benzanthragallol with methyl sulphate in the usual manner. Its yellow ethereal and alcoholic solutions have a green fluorescence.

*Reduction of 2 : 3-Diacetylanthragallol.*—On treatment of this compound with stannous chloride—hydrochloric acid by a similar method to that employed with triacetylanthragallol, only 1 : 2 : 3-trihydroxy-9-anthrone (or anthranol) was produced.

*Tribenzoylanthragallol.*—Dibenzoylanthragallol (see below) (2 g.), dissolved in pyridine (6 c.c.), was treated with benzoyl chloride (1 c.c.); crystals (2.3 g.) separated, and after dilution with an equal volume of alcohol these were removed and recrystallised from benzene—alcohol, pale yellow prisms, m. p. 213—215°, being obtained (Found : C, 73.8; H, 3.35. C<sub>35</sub>H<sub>20</sub>O<sub>8</sub> requires C, 73.9; H, 3.5%).

*Reduction.* To *tribenzoylanthragallol* (1 g.) in boiling acetic acid (50 c.c.), a boiling solution of stannous chloride—hydrochloric acid (25 c.c.) was added; the green precipitate first formed became colourless and crystalline after a few minutes' boiling. When cool, the crystals (0.5 g.) were removed (filtrate A), washed with hydrochloric acid and water, and recrystallised from acetone, almost colourless prisms containing acetone of crystallisation being obtained. When freed from solvent of crystallisation, these melted at 212—214° (Found : C, 74.4; H, 4.1; C<sub>7</sub>H<sub>6</sub>O<sub>2</sub>, 55.6. C<sub>28</sub>H<sub>18</sub>O<sub>6</sub> requires C, 74.7; H, 4.0; C<sub>7</sub>H<sub>6</sub>O<sub>2</sub>, 54.2%). A further quantity of this substance was isolated from filtrate A by dilution with water; the precipitate was collected, washed with hydrochloric acid and water, dried, and dissolved in boiling alcohol, from which crystals (0.25 g.) separated on cooling.

In order to eliminate the benzoyl groups from this compound, *dibenzoyl-2 : 3 : 4-trihydroxy-9-anthrone* (or *anthranol*), it was suspended in methyl alcohol, caustic soda solution added in small amount, and the mixture boiled for a few seconds. Acidification now yielded a dark purple precipitate, which was extracted with sodium bicarbonate solution to remove benzoic acid, dried, and acetylated. The product, repeatedly crystallised from alcohol—

\* Commercial stick. Theory requires 0.415 g. KOH for hydrolysis of the acetoxy-groups and formation of the trimethyl ether.

acetic acid, was obtained as colourless prisms, identical (mixed melting point) with 2 : 3 : 4-triacetoxy-9-anthranyl acetate.

*Dibenzoylanthragallol*.—Benzoyl chloride (2.3 c.c.) was slowly added to anthragallol (2 g.) in pyridine (10 c.c.) and after a while the solution was diluted with alcohol (10 c.c.). Crystals (2.5 g.) separated, and on recrystallisation from benzene were obtained as yellow leaflets, m. p. 204—206°. As this melting point is very similar to that of tribenzoylanthragallol (m. p. 213—215°), a determination of the molecular weight was necessary (Found : C, 72.4; H, 3.6; *M*, 453.  $C_{28}H_{16}O_7$  requires C, 72.4; H, 3.45%; *M*, 464).

*Reduction*. To a boiling solution of *dibenzoylanthragallol* (1 g.) in acetic acid (60 c.c.), stannous chloride—hydrochloric acid (20 c.c.) was added slowly in order to avoid precipitation and the mixture was boiled for 5 minutes. On cooling, crystals (0.6 g.) were gradually deposited (filtrate A); these were washed with hydrochloric acid and then with water, and recrystallised from acetic acid, very pale yellow needles, m. p. 188—190°, being obtained (Found : C, 74.8; H, 4.0.  $C_{28}H_{18}O_8$  requires C, 74.7; H, 4.0%).

This substance, *dibenzoyl-1 : 2 : 3-trihydroxyanthrone* (or *anthranol*), suspended in boiling alcohol, was treated with a few drops of caustic soda solution (10%). The deep yellow liquid first formed quickly became brown and from this by acidification and dilution with water a dark violet precipitate separated. This was collected, extracted with sodium bicarbonate solution to remove benzoic acid, and acetylated with a mixture of equal parts of acetic anhydride and acetic acid. Crystals separated as the boiling proceeded, and these, which after recrystallisation from much acetic acid melted at 239—240° (decomp.), consisted without doubt (mixed melting point) of monoacetyl-1 : 2 : 3-trihydroxyanthrone (or anthranol).

From the filtrate (A), on dilution with water, a precipitate (0.2 g.) separated. This, repeatedly crystallised from alcohol—acetic acid, gave colourless plates, m. p. 213—216° (decomp.) (Found : C, 72.7; H, 4.2.  $C_{21}H_{14}O_5$  requires C, 72.8; H, 4.05%). As this compound on alkaline hydrolysis yielded an anthranol having the characteristic properties of the 1 : 2 : 3-trihydroxy-compound, it was evidently *monobenzoyl-1 : 2 : 3-trihydroxyanthrone* (or *anthranol*).

*Triethylcarbonatoanthragallol*.—Diethylcarbonatoanthragallol (Perkin and Storey, J., 1928, 242) (6 g.) was dissolved in a mixture of pyridine (3 c.c.) and benzene (60 c.c.) and, after partial cooling, ethyl chloroformate (12 c.c.) was added all at once to the stirred solution. Viscid matter was gradually deposited, and after addition of charcoal the mixture was boiled, and the liquid filtered and evaporated to dryness with stirring. The residue, after being

washed with alcohol, crystallised from alcohol-acetic acid in very pale yellow prisms (5.9 g.), m. p. 103—105° (Found: C, 58.4; H, 4.3.  $C_{23}H_{20}O_{11}$  requires C, 58.5; H, 4.2%).

If a suspension of *triethylcarbonatoanthragallol* in cold pyridine is kept over-night, it is converted without apparent solution into the diethylcarbonato-derivative. Tribenzoylanthragallol is, however, not thus affected. Diethylcarbonatoanthragallol is again produced when a cold acetic acid solution of the triethylcarbonato-compound is treated with stannous chloride-hydrochloric acid, and the mixture kept over-night. This accounts for the fact (see below) that, when triethylcarbonatoanthragallol is reduced in the manner indicated, the products are identical with those given by the diethylcarbonato-derivative.

*Reduction.* To a boiling solution of triethylcarbonatoanthragallol (4 g.) in acetic acid (40 c.c.), a boiling solution of stannous chloride-hydrochloric acid (40 c.c.) was added. The precipitate first formed rapidly redissolved and the deep orange solution gradually became pale yellow. After 2 days, the crystals (0.9 g.) (filtrate A) were removed and recrystallised from alcohol-acetic acid, pale yellow prisms, m. p. 131—132°, being obtained (Found: C, 62.4; H, 4.9.  $C_{20}H_{18}O_8$  requires C, 62.2; H, 4.7%).

The removal of the carbethoxy-groups from this compound, which evidently consisted of 1-hydroxy-2:3-diethylcarbonato-9-anthranol, and the acetylation of the product were carried out as with dibenzoyl-1:2:3-trihydroxyanthranol, monoacetyl-1:2:3-trihydroxy-9-anthranol being obtained.

Addition of water to filtrate (A), which had a strong odour of ethyl acetate, gave a resinous precipitate. This, after being washed, was dissolved in a little alcohol; the crystals (1 g.) obtained, on recrystallisation from alcohol, yielded colourless needles, m. p. 156—158° (Found: C, 62.1; H, 4.8.  $C_{20}H_{18}O_8$  requires C, 62.2; H, 4.7%). As this substance gave 2:3:4-triacetoxy-9-anthranyl acetate by alkaline hydrolysis and subsequent acetylation, it consisted of *dicarbethoxy-2:3:4-trihydroxy-9-anthranol* (or *anthrone*).

*Diethylcarbonatoanthragallol.*—The method employed for the preparation of this compound differed somewhat from that given by Perkin and Storey (*loc. cit.*). To anthragallol (5 g.) in hot pyridine (20 c.c.), ethyl chloroformate (6.5 c.c.) was slowly added, followed, after cooling, by alcohol; the crystals obtained melted at 174—175° after recrystallisation from acetic acid.

*Reduction.* A boiling solution of stannous chloride-hydrochloric acid (120 c.c.) was added to diethylcarbonatoanthragallol (6 g.) in boiling acetic acid (120 c.c.). Next day, the crystals (2.4 g.) which had separated were collected (filtrate A) and repeatedly crystallised

from alcohol-acetic acid. The product was identical with the diethylcarbonato-1 : 2 : 3-trihydroxy-9-anthrone (mixed melting point) prepared in part (see above) by the reduction of triethylcarbonatoanthragallol.

From the filtrate (A) by addition of water a precipitate was obtained which, when digested with alcohol, yielded crystals (1 g.); these, recrystallised from acetic acid, gave almost colourless prisms, m. p. 218—219° (decomp.) (Found: C, 64.9; H, 4.7.  $C_{17}H_{14}O_6$  requires C, 65.0; H, 4.5%). Alkaline hydrolysis gave 1 : 2 : 3-trihydroxy-9-anthrone (or anthranol)—evidence that the compound was its *monocarbethoxy*-derivative. From the alcoholic filtrate, only resinous matter could be isolated.

*Reduction of Monoacetylalizarin.*—To monoacetylalizarin (5 g.) in boiling acetic acid (50 c.c.), boiling stannous chloride-hydrochloric acid (50 c.c.) was added, and the digestion continued for a few minutes. The mixture slowly deposited pale orange plates of 1 : 2-dihydroxyanthrone (3 g.), which, after recrystallisation from alcohol, melted at 149—151° (Found: C, 74.7; H, 4.7. Calc. for  $C_{14}H_{10}O_3$ : C, 74.3; H, 4.4%). Acetylation in the usual manner gave 1 : 2-diacetoxy-9-anthranyl acetate, which crystallised from alcohol-acetic acid in colourless plates, m. p. 185—187° (Found: C, 68.1; H, 4.8.  $C_{20}H_{16}O_6$  requires C, 68.2; H, 4.5%).

The filtrate from the reduction mixture gave a further 0.4 g. of 1 : 2-dihydroxyanthrone on addition of water.

*Reduction of Diacetylalizarin.*—Stannous chloride-hydrochloric acid (50 c.c.) was added to diacetylalizarin (5 g.) in boiling acetic acid (50 c.c.), and the mixture boiled for a few minutes. The liquid, at first orange-red, soon became lighter in colour and, on keeping, deposited orange needles consisting apparently of the oxonium salt. These were removed (filtrate A) and decomposed by digestion with boiling water, yielding a pale yellow product (2.35 g.) which was shown to be deoxyalizarin by the melting point of its acetyl compound in admixture with acetyldeoxyalizarin.

The filtrate A, on dilution with water, gave a precipitate (0.35 g.) (filtrate B) of 1 : 2-dihydroxyanthrone, identified in the form of its acetyl derivative, m. p. 185—187°.

From the filtrate B, by saturation with sodium chloride, a further amount (0.65 g.) of deoxyalizarin was isolated.

*Reduction of Acetylalizarin 2-Methyl Ether.*—A solution of the ether (30 g.) in boiling acetic acid (300 c.c.) was slightly cooled, and stannous chloride-hydrochloric acid (120 c.c.) then added. An orange precipitate immediately separated which became crystalline and lighter in colour on keeping. After 60 hours, the crystals (22 g.) were collected: they consisted, without doubt, of 4-hydroxy-

3-methoxyanthranol (Miller and Perkin, *loc. cit.*). From the acid filtrate, a trifling amount of the same compound could be isolated.

*Reduction of Alizarin.*—To a boiling solution of alizarin (2 g.) in acetic acid (100 c.c.), hot stannous chloride–hydrochloric acid (100 c.c.) was added and the mixture was boiled for a few minutes and then diluted with an equal volume of boiling water. On cooling, crystals (0.8 g.) of 1:2-dihydroxyanthrone separated; after recrystallisation from alcohol, they melted at 149–151°. The filtrate was further diluted with water and saturated with sodium chloride, the precipitate collected and dissolved in a little alcohol, and the solution treated with boiling water. On cooling, crystals (0.5 g.) separated having all the properties of 3:4-dihydroxy-anthranol.

When alizarin is digested with stannous chloride–hydrochloric acid in the absence of acetic acid (compare Goodall and Perkin, J., 1924, 125, 473), a viscid mass is obtained, reduction, at least in part, proceeding beyond the anthranol stage. From the product, which is readily soluble in alcohol, only 3:4-dihydroxy-9-anthranol in trifling amount has hitherto been isolated.

*Reduction of 1-Acetoxyanthraquinone.*—To 1-acetoxyanthraquinone (2 g.) in hot acetic acid (15 c.c.), stannous chloride–hydrochloric acid (12 c.c.) was added, causing a deposit to separate (stage A). This, on further heating, yielded an orange-brown liquid, which rapidly became pale yellow and then deposited crystals. These were collected after 12 hours and recrystallised, first from acetic acid containing stannous chloride–hydrochloric acid, and then from toluene. The almost colourless, flat needles of 4-hydroxy-9-anthranol obtained melted at 240–242°. If the mixture at stage A is kept in the cold for 2 days, complete conversion into the anthranol also occurs without further heating (Found: C, 79.7; H, 4.9.  $C_{14}H_{10}O_2$  requires C, 80.0; H, 4.8%). From the reduction mother-liquors, a trace of the same compound only could be isolated, and there was no evidence of the formation of the isomeric 1-hydroxy-9-anthrone. *Acetyl-4-hydroxy-9-anthranol*, prepared in the usual manner, forms colourless prisms, m. p. 173–175°. The alcoholic solution has a faint blue fluorescence (Found: C, 73.4; H, 4.7.  $C_{18}H_{14}O_4$  requires C, 73.5; H, 4.8%).

*Reduction of Diacetylchrysazin.*—To diacetylchrysazin (4.5 g.) in boiling acetic acid (150 c.c.), stannous chloride–hydrochloric acid (100 c.c.) was added. The crystals which separated on cooling were collected (yield, 3.5 g.) and crystallised from alcohol or nitrobenzene, from which solvents 4:5-dihydroxy-9-anthranol separated in almost colourless leaflets or prismatic needles respectively. These darkened

at 250° and melted at about 293—295° (Found: C, 74.0; H, 4.6.  $C_{14}H_{10}O_3$  requires C, 74.3; H, 4.4%).

*Acetyl-4:5-dihydroxy-9-anthranol* crystallises from acetic anhydride in needles, m. p. 220—222°, which gradually develop a brownish-black tint on exposure to sunlight (Found: C, 67.7; H, 4.5.  $C_{20}H_{16}O_6$  requires C, 68.2; H, 4.5%). Sulphuric acid dissolves it to form a brown liquid which slowly becomes green and finally orange.

*Reduction of 2-Acetoxyanthraquinone.*—To 2-acetoxyanthraquinone (2 g.) in acetic acid (15 c.c.), stannous chloride–hydrochloric acid (15 c.c.) was added, and the solution boiled for 5 minutes. The crystals which separated on cooling melted at 198—200° and evidently consisted of 3-hydroxy-9-anthranol, for on acetylation the acetyl compound, m. p. 155—157°, was produced. A further amount of the same substance was contained in the reduction mother-liquor, from which also the acetyl compound was prepared.

*Formation of isoBenzalizarin from Alizarin.*—A mixture of alizarin (5 g.), sulphuric acid (62° Bé; 125 g.), glycerol (10 g.), and aniline sulphate (7.5 g.) was gradually heated to 150° and kept there for 1 hour. The liquid, when poured into water, gave a green precipitate; this was dried and dissolved in alcohol and the solution was concentrated and poured into much ether. From the residue obtained by evaporation of the ether, only unchanged alizarin could be isolated. Better results were obtained by first heating the solution of alizarin and aniline sulphate at 150° for an hour, then adding the glycerol and heating again for an hour. The product, isolated with ether as above stated, gave on acetylation a small quantity of an acetyl compound, m. p. 243—245°, identical with monoacetylisobenzalizarin (mixed melting point).

*2-Acetylanthragallol Boroacetate.*—1:2:3-Trihydroxy-9-anthrone (1 g.) in cold acetic anhydride (6 c.c.) was treated with boroacetic anhydride (0.15 g.) and a few drops of pyridine, and the mixture kept over-night. The anthranol, without apparent solution, was converted into a dull orange, crystalline powder; this was collected, washed with acetic anhydride and with anhydrous ether, and centrifuged until dry. It was slowly decomposed by cold and rapidly by hot water, yielding, in addition to boric and acetic acids, 2-acetylanthragallolanthranol (m. p. 239—240°, decomp.) [Found by Dimroth's method (*loc. cit.*): 2-acetylanthragallolanthranol, 68.6, 69.8; acetic acid, 27.1, 26.4; boric acid, 13.7, 14.3.  $C_{16}H_{11}O_5B(OAc)_2$  requires 2-acetylanthragallolanthranol, 68.9; acetic acid, 29.1; boric acid, 15.05%].

We are much indebted to the British Alizarine Co. Ltd. for gifts of commercial 1-hydroxyanthraquinone, chrysazin and alizarin,

and to the British Dyestuffs Corporation Ltd. for anthragallol and for the preparation in considerable amount of alizarin 2-methyl ether.

## XLV.—*The Development of Colour by Photochemical Change in Concentrated Solutions of Ammonium Thiocyanate.*

By B. S. SHARMA.

LIESEGANG (Eder's *Jahrb. Photographie*, 1894, 49) showed that the colour developed when concentrated aqueous solutions of ammonium thiocyanate are exposed to light is not due to traces of iron, and Holmes (J., 1926, 1690) attributed it to colloidal sulphur produced in the irreversible change  $\text{NH}_4\text{SCN} \rightarrow \text{NH}_4\text{CN} + \text{S}$ . Werner and Bailey (*ibid.*, p. 2970), however, dissented from this view and suggested that the cause might be found in some tautomeric form of thiocyanic acid or in the formation of a coloured complex between thiocyanic acid and the solvent. Bhatnagar and others (*J. Indian Chem. Soc.*, 1927, 4, 229) concluded that the colour was due to cyanogen sulphide and that the precipitate was a polymeride  $(\text{CNS})_x$ , suggesting the mechanism  $\text{NH}_4\text{CNS} + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4\text{OH} + \text{HCNS}$ ,  $2\text{HCNS} + \text{O} \rightarrow \text{H}_2\text{O} + 2\text{CNS}$ ,  $x(\text{CNS}) \rightarrow (\text{CNS})_x$ . Montignie (*Bull. Soc. chim.*, 1928, 43, 106) and Patten and Smith (*Trans. Roy. Soc. Canada*, 1928, 22, III, 221) considered ferric thiocyanate to be responsible for the colour. According to Montignie, the reaction  $2\text{FeSO}_4 + \text{O} + 6\text{HCNS} \rightleftharpoons \text{H}_2\text{O} + 2\text{H}_2\text{SO}_4 + 2\text{Fe}(\text{CNS})_3$  occurs.

The work now described (finished before the last two papers were available) was initiated in view of the conflicting nature of the foregoing conclusions.

### EXPERIMENTAL.

1. Samples of ammonium thiocyanate which did not give rise to the colour on insolation were produced (i) by the action of either ammonium carbonate or ammonium sulphate on barium thiocyanate, prepared by treating ammonium thiocyanate with baryta, and also (ii) by boiling a fairly dilute solution of the salt with animal charcoal, boiled with pure hydrochloric acid and dried before use. Moreover, these samples did not develop colour when treated with pure hydrochloric acid, hydrogen peroxide, or chlorine.

2. Iron was detected in the salt by arc and spark spectral lines.

3. Traces of iron (as ferrous or ferric salt or as metal) added to the pure samples produced a colour upon insolation.

4. Both the intensity of the colour developed and the time required for its disappearance in the dark were proportional to the amount of iron introduced.

5. The ethereal extract of the colour developed with ferrous salt and ammonium thiocyanate was intensified by dilution.

6. A solution in water-free pyridine exhibited a photochemical change similar to that in aqueous solution.

7. Even after repeated insolutions and storage in the dark, aqueous solutions yielded no precipitate.

8. Gelatin inhibited the development of the colour.

*Discussion.*—Expts. 1, 2, and 3 show that traces of iron present as impurity are responsible for the coloration. Expt. 4 rules out the possibility that the iron functions as a catalyst, and shows that it actually takes part in the formation of the coloured compound, light supplying the energy. The formation of ferric thiocyanate is doubtful, for it is decolorised neither by heating (Scott, "Standard Methods of Analysis," 4th edtn., 1927, 246) nor by keeping in the dark (Dhar, *J. Indian Chem. Soc.*, 1929, 6, 143); moreover, it is bleached by light, and is entirely extracted by ether, the extract leaving a coloured residue on evaporation, whereas the extract from the insolated solutions does not behave so. The photochemical colour, produced with traces of ferric iron insufficient to show coloration ordinarily, can hardly be due to ferric thiocyanate (compare *J. Soc. Chem. Ind.*, 1929, 48, 336t). Expt. 5 distinguishes the colour developed with ferrous iron from that of ferric thiocyanate. Expt. 6 shows that the colour is probably not dependent upon hydrolysis or upon oxygen-containing solvents. The photochemical change in Expt. 7 appears to be reversible. The ready disappearance of the colour in the dark, on heating, or on dilution, its non-appearance in the absence of oxygen and traces of iron, and its appearance at high concentrations show that the compound is a sort of loose additive complex of ferrous thiocyanate with oxygen, and that its formation is probably connected with the changes at high concentrations.

Further work on the subject is in progress.

The author's thanks are due to Dr. H. B. Dunncliff for his interest in the work, and to Pundit M. M. Malinya, the Vice-Chancellor of the Benares University, for affording laboratory facilities.

XLVI.—*Hydroxyamino-acids.*

By WILLIAM JOHN NOBBS BURCH.

DAKIN has shown (*J. Biol. Chem.*, 1921, 48, 273) that maleic acid on treatment with chlorine water gives chlorohydroxysuccinic acid, which is converted by the action of ammonia into hydroxyaspartic acid.

Acrylic, crotonic, and tiglic acids behave in the same way under such conditions, giving mixtures of the  $\alpha$ - and  $\beta$ -acids :

Glutaconic acid, however, behaves abnormally, giving *dihydroxyglutaramic acid*, possibly owing to the intermediate formation of a lactam,  $\text{CO}_2\text{H}\cdot\text{CH}_2\cdot\text{CH}\cdot\text{CH}(\text{OH})\cdot\text{CO}$ . The conversion of chloro-

hydroxyglutaric acid into hydroxyglutamic acid by Gabriel's phthalimide process has been unsuccessfully attempted.

## EXPERIMENTAL.

*Preparation of Glutaconic Acid.*—Ethyl sodio- $\alpha,\gamma$ -dicarbethoxyglutaconate (Ingold and Perren, *J.*, 1921, 119, 1591) was converted into glutaconic acid by a method communicated to the author by Dr. G. A. R. Kon. The tetracarboxylic ester was liberated from the sodium derivative by means of a mineral acid in the presence of ether and, without being dried, the ethereal solution was evaporated. The ester was then heated with alcohol ( $\frac{1}{2}$  vol.) and 10% hydrochloric acid (3 vols.) until all the oil disappeared and no oil separated on cooling (5 hours). The alcohol was distilled off, and glutaconic acid (m. p. 132°) crystallised on cooling; a little more was obtained by extracting the mother-liquor with ether, drying the extract with sodium sulphate, concentrating it and adding benzene.

*Barium  $\alpha$ -Chloro- $\beta$ -hydroxyglutarate.*—Glutaconic acid (10 g.) was treated with a large excess of hypochlorous acid (prepared by extracting bleaching powder with water and distilling the extract in a vacuum with the calculated quantity of 5% nitric acid), after 24 hours the mixture was exactly neutralised with baryta and the filtered solution was concentrated in a vacuum, finally over concentrated sulphuric acid; the yellow crystals obtained (16 g.; yield, 66%) were recrystallised from water (Found: Ba, 43.5; Cl, 11.0.  $\text{C}_5\text{H}_4\text{O}_5\text{ClBa}$  requires Ba, 43.2; Cl, 11.2%).

*Ammonium Dihydroxyglutaramate*.—Barium  $\alpha$ -chloro- $\beta$ -hydroxyglutaramate was converted into *ammonium dihydroxyglutaramate* by removing the barium as sulphate and adding methyl alcohol saturated with ammonia.

A better yield was obtained as follows: A mixture of 10 g. of glutamic acid with a large excess of hypochlorous acid was kept for 24 hours and then evaporated to small bulk in a vacuum at 50°. Methyl alcohol saturated with dry ammonia was added in excess, and the mixture left in a stoppered bottle. Rosettes of tiny platelets began to form after 24 hours and the reaction was complete in about a week. The crystals were recrystallised from aqueous alcohol (yield, 6 g. or 43% of the theoretical) [Found: total N (by Kjeldahl's method), 15.65; N (as  $\text{NH}_4$ ), 7.0; C, 34.3; H, 6.7.  $\text{C}_5\text{H}_{12}\text{O}_5\text{N}_2$  requires total N, 15.55; N (as  $\text{NH}_4$ ), 7.8; C, 34.1; H, 6.8%].

*Dihydroxyglutaramic Acid*,  $\text{CO}_2\text{H}\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CO}\cdot\text{NH}_2$ .—The ammonium salt was treated in aqueous solution with silver oxide, and the product with hydrogen sulphide. The crystalline material obtained did not give the ninhydrin reaction for  $\alpha$ -amino-acids, and in an estimation of amino-nitrogen by Van Slyke's method, no nitrogen was obtained after 24 hours by means of acetic acid; the theoretical amount was evolved, however, after 24 hours on treatment with sodium nitrite and concentrated hydrochloric acid (Plimmer, J., 1925, 127, 2651). On prolonged boiling with baryta, the whole of the nitrogen in the compound was obtained as ammonia. The *acid* reduced ammoniacal silver nitrate and gave a deep blue colour with copper sulphate solution and caustic soda [Found: total N (by Kjeldahl's method), 8.4; N (by Van Slyke's method as above), 8.5; C, 36.5; H, 5.6; *M* (by means of the silver salt), 163.  $\text{C}_5\text{H}_9\text{O}_5\text{N}$  requires N, 8.6; C, 36.8; H, 5.5%; *M*, 163].

*$\alpha$ -Amino- $\beta$ -hydroxybutyric Acid*.—A solution of 4.5 g. of crotonic acid in water was mixed with hypochlorous acid (25% excess) and, after 12 hours, evaporated under diminished pressure. A solution of the residual yellow syrup in methyl alcohol was cooled in ice, saturated with dry ammonia, and heated in an autoclave at 120° for 10 hours. On cooling, no crystals formed. The solution was treated with an excess of baryta, the ammonia removed by aeration and the barium with sulphuric acid, the filtrate boiled with lead oxide to remove chloride, and the lead removed with hydrogen sulphide. The filtrate was treated with silver oxide to ensure complete removal of sulphide and chlorine, filtered, and evaporated in the dark; *silver  $\alpha$ -amino- $\beta$ -hydroxybutyrate* crystallised in thin platelets, which rapidly darkened in light (Found: Ag, 47.2.  $\text{C}_4\text{H}_8\text{O}_3\text{NAg}$  requires Ag, 47.8%).

The acid was obtained by removing the silver with hydrogen

sulphide, and the hydrogen sulphide by aeration. On evaporation in a vacuum, a pale yellow syrup was obtained which slowly crystallised in a vacuum over concentrated sulphuric acid (yield, 2.7 g.; 45% of the theoretical) [Found: total N (Kjeldahl), 11.6; amino-N (Van Slyke), 11.3. Calc. for  $C_4H_9O_3N$ : N, 11.8%]. The acid is very deliquescent, gives a strong ninhydrin reaction, and forms a pale blue crystalline copper salt and well-defined crystalline salts with cinchonine and quinine (Found for the *cinchonine* salt: N, 10.0.  $C_4H_9O_3N \cdot C_{19}H_{22}ON_2$  requires N, 10.2%).

The positive ninhydrin reaction and the fact that the total amino-nitrogen is only obtained after 10 minutes' shaking with sodium nitrite and glacial acetic acid suggest that the product of the above reaction is a mixture of the  $\alpha$ - and  $\beta$ -amino-acids.

*$\alpha$ -Amino- $\beta$ -hydroxy- $\alpha$ -methylbutyric Acid,*

—Tiglic acid (5 g.) was treated in the same way as the crotonic acid in the previous experiment. The *silver* salt is a white powder (Found: Ag, 44.6.  $C_5H_{10}O_3NAg$  requires Ag, 45.0%). The *acid* was obtained as a yellow syrup which slowly crystallised [Found: N (Kjeldahl), 10.3; amino-N (Van Slyke), 10.1.  $C_5H_{11}O_3N$  requires N, 10.5%]. All the preceding statements regarding  $\alpha$ -amino- $\beta$ -hydroxybutyric acid apply also to this acid (Found for the *brucine* salt: N, 7.5.  $C_5H_{11}O_3N \cdot C_{23}H_{28}O_4N_2$  requires N, 8.0%).

*isoSerine*.—This was similarly prepared from acrylic acid (Melikow, *Ber.*, 1880, 13, 1265). It gave the ninhydrin reaction, and the total amino-nitrogen was evolved only after 10 minutes' shaking with glacial acetic acid and sodium nitrite: this suggests that this product also is a mixture of serine and isoserine (the  $\alpha$ - and  $\beta$ -amino-acids).

*Hydroxyaspartic Acid*.—Maleic acid was converted in the same way and also by Dakin's method (*loc. cit.*) into hydroxyaspartic acid. The compound obtained by either method gave the ninhydrin reaction, and the whole of the amino-nitrogen was evolved after 5 minutes' shaking with glacial acetic acid and sodium nitrite.

The author gratefully acknowledges a research grant from Imperial Chemical Industries, Ltd., to Professor R. H. A. Plimmer, which has defrayed the cost of this work.

XLVII.—*Lichen Acids. Part I. Derivatives of  $\beta$ -Orcinol.*By ALEXANDER ROBERTSON and RICHARD  
JOHN STEPHENSON.

ALTHOUGH  $\beta$ -orcinol, the homologue of orcinol, was isolated in 1848 by Stenhouse (*Annalen*, **68**, 104) as a product of the action of lime-water on impure usnic acid from *Usnea ceratina*, it was not until 1880 that Stenhouse and Groves (*J.*, **37**, 405) were able to show that the phenol was derived from barbatic acid, which they obtained from *U. barbata*. This acid has since been isolated from a number of lichens, in which it invariably occurs along with usnic acid (for references, see Perkin and Everest, "Natural Organic Colouring Matters," 1918, pp. 530—542). Hesse (*Ber.*, 1898, **31**, 664; *J. pr. Chem.*, 1898, **58**, 526; 1903, **68**, 14) found that barbatic acid on hydrolysis gave rhizonic acid in addition to  $\beta$ -orcinol; rhizonic acid he believed to be the monomethyl ether of  $\beta$ -orcinolcarboxylic acid, and the depside to be derived from  $\beta$ -orcinolcarboxylic acid and rhizonic acid. The  $\beta$ -orcinol nucleus has since been found to occur in a number of depsides—atranorin (Hesse, *Ber.*, 1897, **30**, 358; *J. pr. Chem.*, 1898, **57**, 280), dirhizonic acid (Hesse, *ibid.*, 1898, **58**, 531; 1906, **73**, 120), soloric acid (Zopf, *Annalen*, 1909, **364**, 307; Hesse, *J. pr. Chem.*, 1915, **92**, 425), and armoric acid (Hesse, *ibid.*, 1907, **76**, 7).

In a study of the constitution of these depsides by synthetical means, it was essential first to devise a method for the preparation of  $\beta$ -orcinol in quantity, Kostanecki's process (*Ber.*, 1886, **19**, 2323) having been found unsuitable. Reduction of 2:6-dinitro-*p*-xylene (prepared from *p*-xylidine by Sonn's method; *Ber.*, 1916, **49**, 621) by ammonia and hydrogen sulphide invariably gave poor yields of 6-nitro-*p*-2-xylidine, but reduction by sodium disulphide in aqueous-acetone solution proved effective. The nitroxylidine was converted into 6-nitro-*p*-2-xylenol (compare D.R.-PP. 95,359 and 97,012), the reduction of which to 6-amino-*p*-2-xylenol was conveniently effected in alcoholic solution by iron (compare West, *J.*, 1925, **127**, 494). Attempts to prepare  $\beta$ -orcinolcarboxylic acid by the method adopted by one of us (A. R.) and Robinson (*J.*, 1927, 2196) for the preparation of *p*-orsellinic acid failed (compare Kostanecki, *loc. cit.*).

$\beta$ -Orcylaldehyde (I) was prepared by Gattermann's method (compare St. Pfau, *Helv. Chim. Acta*, 1928, **11**, 864): the dicarbo-methoxy-derivative (II) on oxidation with potassium permanganate

in acetone solution and hydrolysis of the product, gave  $\beta$ -orcinol-carboxylic acid (III).

The synthetic acid is identical with a specimen obtained by hydrolysis of the methyl ester prepared from atranorin by St. Pfau's method (*Helv. Chim. Acta*, 1926, 9, 650): the instability of the acid and its salts in warm aqueous solution may account for the inability of previous workers to isolate it by hydrolysis of the ester or of barbitic acid. The silver salt rapidly decomposed on exposure to light and was unsuitable for the preparation of esters. These, however, were readily formed in warm alcoholic solutions of the acid. The methyl ester thus obtained was identical with a specimen from atranorin. This ester has also been isolated from oak moss oil by Rosenthal and Walbaum (*Ber.*, 1924, 57, 770). Its reaction with ferric chloride depends on the concentration of the alcoholic solution—a fact which may account for the divergent results recorded by previous authors.

Partial methylation of  $\beta$ -orcyraldehyde (I) by the methyl iodide-acetone method (Robertson and Robinson, J., 1928, 1455) proved convenient for the preparation of rhizonaldehyde (IV). Sonn (*Ber.*, 1916, 49, 2589), who prepared this aldehyde from  $\beta$ -orcinol mono-methyl ether by the Gattermann method, believed it to be represented by the constitution (X) (*isorhizonaldehyde*).

The orientation of the ether (IV) determined by St. Pfau (*Helv. Chim. Acta*, 1928, 11, 864) has been confirmed, the condensation of (IV) with  $\omega$ -methoxyacetoveratrone giving 3:7:3':4'-tetramethoxy-5:8-dimethylflavylium chloride. Oxidation of the acetyl derivative (V) gave acetyl rhizonic acid (VI), which on deacetylation yielded rhizonic acid (VII). This acid (VII) has the properties attributed to it by St. Pfau (compare Sonn, *loc. cit.*).

Attempts to methylate the carbomethoxy-derivative (VIII) with diazomethane in ethereal solution failed, and when a mixture of nitrobenzene and ether was used a resinous product was obtained.

Agitation of an acetone solution of (VIII) containing methyl iodide and active silver oxide gave only a trace of (IX), but this was obtained when a methyl iodide solution of (VIII) was refluxed in presence of silver oxide. On hydrolysis, it gave *isorhizonaldehyde* (X) identical with that prepared by St. Pfau from  $\beta$ -orcinol mono-

methyl ether. As might be expected, the aldehyde (X) did not condense with  $\omega$ -methoxyacetovertone to give a flavylum salt. The production of (X) from (VIII) determines the orientation of the latter substance.

Experiments on the synthesis of barbatic acid and its ethyl ester are in progress.

#### EXPERIMENTAL.

**6-Nitro-p-2-xylylidine.**—A solution of sodium disulphide, prepared by refluxing a mixture of sulphur (16.5 g.), hydrated sodium sulphide (120 g.), and water (400 c.c.), was added in four portions to 2 : 6-dinitro-p-xylene (100 g.), dissolved in acetone (600 c.c.). When the vigorous reaction had ceased, the mixture was refluxed for 3 hours and poured into water (2 l.). After 12 hours, the solid was extracted three times with warm 10% hydrochloric acid, and on addition of aqueous ammonia to the combined extracts (1.5 l.) the nitroamine (68 g.) was obtained as a yellow solid, which crystallised from ligroin in orange-yellow needles, m. p. 96°.

**6-Nitro-p-2-xylenol.**—A solution of the nitroamine (50 g.) in a mixture of concentrated sulphuric acid (100 c.c.) and water (200 c.c.) was poured on ice (300 g.) to ensure the separation of the sulphate in small crystals. Sodium nitrite (20.7 g.), dissolved in water (100 c.c.), was then introduced, and the mixture stirred for 1.5 hours. The filtered diazo-solution was gradually added to boiling 30% sulphuric acid (300 c.c.); on cooling, the nitroxylenol separated. Crystallisation from water and then from ligroin gave the product (37 g.) in orange-yellow plates, m. p. 91°. The crude nitroxylenol, which could not be employed for the next stage, can be purified by distillation under diminished pressure, b. p. 185–187°/20 mm.; the warm residue in the flask is, however, liable to explode.

**6-Amino-p-2-xylenol.**—A mixture of the nitroxylenol (50 g.), iron powder (50 g.), alcohol (300 c.c.), and concentrated hydrochloric acid (5 c.c.) was refluxed for 6 hours, a test then showing that the reduction was complete. The filtered solution was con-

centrated to 75 c.c., saturated with hydrogen chloride, and kept at 0° for some hours. The hydrochloride was collected and washed with 96% alcohol saturated with hydrogen chloride. The salt crystallised in colourless elongated prisms (38 g.). Saturated sodium bicarbonate solution liberated 6-amino-p-2-xylénol, which crystallised from water in fern-like clusters of colourless plates, m. p. 155° (Found: C, 70.1; H, 8.3.  $C_8H_{11}ON$  requires C, 70.0; H, 8.1%). The amine is readily soluble in alcohol and in acetone.

2 : 6-Dihydroxy-p-xylene ( $\beta$ -Orcinol).—The aminoxylénol hydrochloride (20 g.) was dissolved below 0° in a mixture of concentrated sulphuric acid (55 c.c.) and ice and water (800 c.c.). Sodium nitrite (8 g.), dissolved in water (100 c.c.), was then introduced, and the mixture stirred for 45 minutes. The diazonium salt solution was heated on the steam-bath until the evolution of nitrogen had almost ceased and was then boiled for 5 minutes. A little charcoal was added and the solution was filtered, cooled, and saturated with ammonium sulphate. Part of the  $\beta$ -orcinol crystallised; the remainder was isolated by three extractions with ether. The product (12 g.) crystallised from benzene in pink stellate aggregates of prisms, m. p. 163°; distillation gave a colourless specimen, b. p. 277—280°.

$\beta$ -Orcylaldehyde (I).—A mixture of  $\beta$ -orcinol (20 g.), anhydrous hydrogen cyanide (15 c.c.), and ether (300 c.c.) was saturated with hydrogen chloride. The aldimine hydrochloride, which separated in almost colourless prisms in 2 hours, was collected after 12 hours, washed with ether, and dissolved in cold water (400 c.c.). The solution was heated on the steam-bath for 2 hours; a part of the aldehyde crystallised and the remainder separated on cooling. Recrystallisation from 30% alcohol gave a hydrate (22 g.) in colourless needles, m. p. 168° (Found: C, 61.9; H, 6.5. Calc. for

C, 61.7; H, 6.3%. Found in a specimen dried at 105—110° for 6 hours: C, 65.1; H, 6.1. Calc. for  $C_9H_{10}O_3$ : C, 65.1; H, 6.0%) (St. Pfau, *loc. cit.*, gives m. p. 163—164°). The ferric chloride reaction in alcohol is reddish-violet and addition of the aldehyde to aqueous calcium hypochlorite gives an intense yellow coloration. Acetylation with acetic anhydride and potassium carbonate gave a product which could not be purified.

2 : 4-Dimethylcarbonato-3 : 6-dimethylbenzaldehyde (II).—8% Aqueous sodium hydroxide (62.5 c.c.) was gradually added with vigorous agitation to a solution of  $\beta$ -orcyaldehyde (8.8 g.) in a mixture of acetone (80 c.c.) and methyl chloroformate (14.5 g.). After  $\frac{1}{2}$  hour, saturated sodium bicarbonate solution (50 c.c.) was introduced and on dilution with water (300 c.c.) the dicarbomethoxy-

derivative separated as an oil which solidified on being scratched. The substance crystallised from ligroin in tufts of colourless slender needles (13 g.), m. p.  $91^{\circ}$  (Found: C, 55.4; H, 5.2.  $C_{13}H_{14}O_7$  requires C, 55.3; H, 5.0%). This carbonate is readily soluble in acetone and moderately readily soluble in cold alcohols. It does not give a ferric chloride reaction.

*2 : 4-Dihydroxy-3 : 6-dimethylbenzoic Acid* ( $\beta$ -Orcinolcarboxylic Acid) (III).—(A) Potassium permanganate (5 g.), dissolved in water (80 c.c.), was gradually added to a solution of 2 : 4-dimethylcarbonato-3 : 6-dimethylbenzaldehyde (3 g.) in acetone (50 c.c.) maintained at  $50$ – $55^{\circ}$ . After 15 minutes, the reaction mixture, cooled to  $0^{\circ}$ , was cleared with sulphur dioxide, and on slow evaporation of the acetone a colourless solid separated. A solution of the solid, collected after 3 days, in 4% aqueous sodium hydroxide (15 c.c.) was kept at room temperature for  $\frac{1}{2}$  hour, then cooled to  $0^{\circ}$ , and acidified with 10% hydrochloric acid (10 c.c.). The precipitate was dissolved in saturated aqueous sodium bicarbonate (75 c.c.), and the solution filtered from traces of  $\beta$ -orcylaldehyde. Acidification with 10% hydrochloric acid gave almost pure  $\beta$ -orcinolcarboxylic acid (1 g.). Warm water was added to a solution of the substance in warm acetone until a faint turbidity appeared; the cooled solution gave the acid in elongated silky needles, m. p.  $184^{\circ}$  (decomp. to  $\beta$ -orcinol and carbon dioxide) (Found: C, 59.3; H, 5.7.  $C_9H_{10}O_4$  requires C, 59.4; H, 5.5%). The acid is readily soluble in alcohol and in acetone and sparingly soluble in cold water. It decomposes in boiling water to  $\beta$ -orcinol and carbon dioxide. The ferric chloride reaction in alcoholic solution is intense bluish-violet. Addition of the acid to aqueous calcium hypochlorite solution gives a transient blood-red coloration.

A solution of the acid (0.8 g.) in absolute methyl alcohol (20 c.c.) was refluxed for 4 hours, and the methyl ester precipitated from the cooled solution by means of 1% aqueous sodium bicarbonate (50 c.c.). The ester crystallised from 50% methyl alcohol in colourless, elongated, slender prisms, m. p.  $143^{\circ}$  alone or mixed with a natural specimen prepared from atranorin (Found: C, 61.1; H, 6.1. Calc. for  $C_{10}H_{12}O_4$ : C, 61.2; H, 6.2%). Ferric chloride added to a dilute alcoholic solution gives a greenish-brown coloration, which becomes brownish-purple on addition of water. A concentrated alcoholic solution gives a brownish-purple colour, unchanged by dilution with alcohol or by addition of water. The calcium hypochlorite coloration is a transient orange.

The *ethyl* ester was isolated from a solution of the acid (0.8 g.) in absolute alcohol (20 c.c.) which had been maintained at  $75^{\circ}$  for 6 hours. Crystallisation from 50% alcohol gave colourless slender

needles, m. p. 129° (Found: C, 62.8; H, 6.9.  $C_{11}H_{14}O_4$  requires C, 62.8; H, 6.7%). The ferric chloride coloration is purple, and the calcium hypochlorite an intense orange which rapidly fades.

(B) A solution of methyl  $\beta$ -orcinoicarboxylate (from atranorin) 5 g.) in 10% aqueous potassium hydroxide solution was kept in a tightly stoppered vessel at room temperature for 50 hours. The reddish-brown solution, cooled to 0°, was acidified with 10% hydrochloric acid. After  $\frac{1}{2}$  hour, the cream-coloured precipitate was collected and extracted with cold saturated sodium bicarbonate solution (100 c.c.). Addition of 10% hydrochloric acid to the solution, filtered from traces of unchanged ester, gave the acid (III) (3 g.), which crystallised from acetone-water in elongated silky needles, m. p. 184° (decomp.) alone or mixed with a synthetic specimen (Found: C, 59.2; H, 5.7%). The colour reactions are identical with those given by the synthetic acid.

2-Acetoxy-4-methoxy-3:6-dimethylbenzaldehyde (*Acetyl rhizonaldehyde*) (V).—A mixture of  $\beta$ -orcylaldehyde (10 g.), methyl iodide (8.2 g.), potassium carbonate (10 g.), and acetone (75 c.c.) was refluxed for 1½ hours; a further quantity of iodide (4.1 g.) was added after 45 minutes. After removal of the potassium salts and acidification with acetic acid, the mixture deposited rhizonaldehyde (IV) (7 g.); a further quantity (3 g.) was obtained by evaporation of the acetone residue, and by dissolving the potassium salts in 50% acetic acid. The substance crystallised from 50% alcohol in colourless prisms, m. p. 136° (Found: C, 66.6; H, 6.7. Calc. for  $C_{10}H_{12}O_3$ : C, 66.6; H, 6.7%). The ferric chloride reaction is reddish-brown. This aldehyde does not give a coloration with calcium hypochlorite.

Rhizonaldehyde (10 g.), on treatment with acetic anhydride (75 c.c.) and sodium acetate (10 g.) during 3 hours on the steam-bath, gave the *acetyl* derivative (V) (11 g.), which crystallised from 40% alcohol in colourless needles, m. p. 71° (Found: C, 64.9; H, 6.6.  $C_{12}H_{14}O_4$  requires C, 64.9; H, 6.3%). The substance is easily soluble in alcohol and acetone and does not give a ferric chloride reaction.

4% Aqueous sodium hydroxide solution (8 c.c.) was added to a mixture of rhizonaldehyde (1 g.), methyl chloroformate (1 g.), and acetone (25 c.c.) cooled to 0° (agitation). The carbomethoxy-derivative separated on addition of dilute sodium bicarbonate solution (40 c.c.) and was collected after 3 hours. It crystallised from light petroleum in clusters of prisms, m. p. 90°, which gave a faint brown ferric chloride coloration.

3:7:3':4'-Tetramethoxy-5:8-dimethylflavylum Ferrichloride.—Dark red needles with a green reflex separated when hydrogen chloride was passed into a solution of rhizonaldehyde (0.75 g.) and

$\omega$ -methoxyacetoveratrone (0.5 g.) in ethyl acetate (40 c.c.). After 3 days, the chloride was collected and converted into the *ferrichloride*, which crystallised from a mixture of formic and acetic acids (equal vols.) in dark red needles, m. p. 240—245° after sintering at 236° (Found: C, 45.6; H, 4.4.  $C_{21}H_{23}O_5Cl_4Fe$  requires C, 45.4; H, 4.2%).

*2-Acetoxy-4-methoxy-3:6-dimethylbenzoic Acid (Acetyl rhizonic Acid) (VI).*—Potassium permanganate (5 g.), dissolved in water (80 c.c.), was gradually added to a solution of acetyl rhizonaldehyde (4 g.) in acetone (50 c.c.) maintained at 50°. The solution, cooled to 0°, was cleared with sulphur dioxide, and on slow evaporation of the acetone *acetyl rhizonic acid*, mixed with a trace of unchanged aldehyde, crystallised. The acid (purified by solution in aqueous sodium bicarbonate as described for  $\beta$ -orcinolcarboxylic acid) crystallised from acetone–water (equal vols.) in rectangular plates, m. p. 146° (decomp.) (Found: C, 60.7; H, 5.8.  $C_{12}H_{14}O_5$  requires C, 60.5; H, 5.9%). It is readily soluble in acetone and alcohol and sparingly soluble in warm water, from which it separates in small plates.

A solution of the acetyl derivative (2 g.) in 4% aqueous sodium hydroxide solution was kept at room temperature for 3 hours. Acidification of the solution with dilute hydrochloric acid then gave rhizonic acid (VII), which crystallised from acetone–water in hexagonal plates, m. p. 232° (Found in a specimen dried at 100°: C, 61.1; H, 6.4. Calc. for  $C_{10}H_{12}O_4$ : C, 61.2; H, 6.2%). Addition of ferric chloride to an alcoholic solution gives a brown coloration, which becomes intense blue-violet on addition of water. The calcium hypochlorite coloration is yellow.

*2-Hydroxy-4-methylcarbonato-3:6-dimethylbenzaldehyde (VIII).*—4% Aqueous sodium hydroxide solution (25 c.c.) was gradually added to a mixture of  $\beta$ -orcyraldehyde (4 g.), acetone (40 c.c.), and methyl chloroformate (2.4 g.) cooled to 0° (agitation). After  $\frac{1}{2}$  hour, aqueous sodium bicarbonate (200 c.c.) was introduced, and after 2 hours the *carbomethoxy*-derivative was isolated; it crystallised from 70% acetone in masses of colourless slender needles, m. p. 110° (Found: C, 58.7; H, 5.6.  $C_{11}H_{12}O_5$  requires C, 58.9; H, 5.4%). The substance is easily soluble in acetone and in alcohol and insoluble in water. It crystallises from light petroleum in tiny prisms. The ferric chloride coloration is red-brown.

*2-Methoxy-4-methylcarbonato-3:6-dimethylbenzaldehyde (IX).*—Active silver oxide was added to a solution of the foregoing carbomethoxy-derivative (5 g.) in methyl iodide (30 c.c.), and the mixture refluxed until a sample did not give a ferric chloride reaction. The silver oxide was removed by filtration and washed with acetone

(150 c.c.). Evaporation of the combined filtrates gave a semi-solid product, which was extracted with boiling ligroin. The extract, decanted from the insoluble residue and cooled, gave the *ether* (IX) in tufts of colourless elongated prisms (4 g.), m. p. 74—75° (Found : C, 60.6; H, 6.2.  $C_{12}H_{14}O_5$  requires C, 60.5; H, 5.9%). The substance is readily soluble in alcohol and acetone and sparingly soluble in light petroleum.

A solution of the foregoing ether (0.6 g.) in 4% methyl-alcoholic sodium hydroxide (5 c.c.) was kept at room temperature for  $\frac{1}{2}$  hour, then acidified with 50% acetic acid, and diluted with water (40 c.c.); *isorhizonaldehyde* (X), thus precipitated, crystallised from 25% methyl alcohol in slender needles, m. p. 151°. This aldehyde does not give a ferric chloride reaction.

The authors wish to express their thanks to the Chemical Society for a grant which has partly defrayed the cost of this investigation.

## NOTES.

*The Interaction of Sodamide and Alkyl Iodides with Acetophenone and its Homologues.* By ALFRED RUSSELL.

NORMAL reaction, producing more than 50% of the theoretical yield of  $\alpha$ -ethyl- $\alpha$ -*n*-propyl- $\alpha$ -*n*-butylacetophenone, occurs between ethyl iodide and sodio-*n*-propyl-*n*-butylacetophenone in a neutral solvent (compare Haller and Bauer, *Compt. rend.*, 1909, **148**, 70).

In ether, the reaction between sodioacetophenone and methyl iodide also is normal; but in benzene no propiophenone is formed, the sole product being a *polymeride*,  $(C_6H_5 \cdot CO \cdot C_2H_5)_3$ , a white amorphous solid, m. p. 96—98°, b. p. 300—320°/15 mm. [Found : C, 81.1; H, 7.3; *M*, mean of ten determinations, 405.  $(C_6H_5 \cdot CO \cdot C_2H_5)_3$  requires C, 80.6; H, 7.3%; *M*, 402]. The substance is unaffected by acids or alkalis, permanganate, dichromate, and fusion with caustic potash, chars when heated strongly in the air, and is readily soluble in the common organic solvents but insoluble in water, acids, or alkalis. It gives no methyl iodide in the Zeisel reaction and is therefore not a trimethoxytriphenylcyclohexane. It may have a structure,  $O \begin{array}{c} \text{C} \text{Et} \text{Ph} \cdot \text{O} \\ \diagup \quad \diagdown \\ \text{C} \text{Et} \text{Ph} \cdot \text{O} \end{array}$ , similar to that of the acetals, which it resembles in chemical stability.—THE SIR DONALD CURRIE LABORATORIES, THE QUEEN'S UNIVERSITY, BELFAST. [Received, October 25th, 1929.]

*The Structure of the Isomeric Methyl Ferrocyanides.*

By S. GLASSTONE.

ALTHOUGH the suggestion that potassium ferrocyanide exists in two isomeric forms (Briggs, J., 1911, **99**, 1019) has been shown to be erroneous (Bennett, J., 1917, **111**, 490; Kolthoff, *Chem. Weekblad*, 1919, **16**, 1406; Briggs, J., 1920, **117**, 1026), the isomerism of the tetramethyl ferrocyanides (Hartley, J., 1913, **103**, 1196) appears to be well established. Hitherto, however, there has been no satisfactory explanation of this isomerism, and the following view is therefore proposed. If the structure of the so-called methyl ferrocyanide is considered to be  $[\text{Fe}(\text{CH}_3\cdot\text{NC})_4(\text{CN})_2]$ , with the four neutral  $\text{CH}_3\cdot\text{NC}$  groups (compare Hartley, J., 1911, **99**, 1549) co-ordinated to the iron atom (see Pfeiffer, "Organische Molekülverbindungen," 1927, p. 193, for other instances), the two valency electrons of the latter are shared with the two cyanide radicals, and the substance will be a non-electrolyte. Further, since it is of the type  $\text{MX}_4\text{A}_2$ , it can exist in *cis*- and *trans*-modifications, thus :

The *cis*-form, having adjacent polar cyanide radicals, is presumably the more soluble and more reactive; hence it corresponds to Hartley's  $\alpha$ -form. The substance  $(\text{CH}_3)_6\text{Fe}(\text{NC})_6\text{I}_2$ , produced by the action of methyl iodide on the  $\alpha$ -form, is probably  $[\text{Fe}(\text{CH}_3\cdot\text{NC})_6]\text{I}_2$  [compare  $\text{Mg}(\text{CH}_3\cdot\text{CN})_6\text{I}_2$ , possibly  $\text{Mg}(\text{CH}_3\cdot\text{NC})_6\text{I}_2$ ; Menschutkin, *Z. anorg. Chem.*, 1909, **61**, 110] and should be an electrolyte. The chloride and sulphate prepared by Hartley (J., 1910, **97**, 1725) are probably analogous.—THE UNIVERSITY, SHEFFIELD. [Received, November 21st, 1929.]

# XLVIII.—*The Catalytic Hydrogenation of Different Types of Unsaturated Compounds. Part V. The Hydrogenation of Cyclic Ethylenic Derivatives and of their Mixtures.*

By SERGUEY V. LEBEDEV and MICHAÏL PLATONOV.

THE following communication is closely connected with Part I of our investigation (J., 1925, **127**, 417), in which it was shown that the rate and nature of hydrogenation of single ethylenic compounds

and of their mixtures are determined by the characteristics of the type to which they belong (i.e., by the degree of substitution at the double linkage in the molecule) rather than by individual characteristics. Thus, in every case, monosubstituted ethylenic derivatives are hydrogenated preferentially, and tetrasubstituted last of all, the di- and tri-substituted types being intermediate.

This property is most marked in the hydrogenation of mixtures of different ethylenic derivatives. Compounds of the same degree of substitution at the double bond are hydrogenated concurrently in a mixture and their curves show no break, but those of different types are hydrogenated consecutively in the above order, so that their curves display definite breaks corresponding roughly to the end of hydrogenation of one component and the beginning of that of another. This is probably due to the fact that the affinity of the catalyst for monosubstituted is much greater than for poly-substituted ethylenic compounds, those of the same degree of substitution being adsorbed with approximately equal readiness.

Discussion is simplified by the following classification of ethylenic compounds according to the degree of substitution at the double bond, *c* denoting a cyclic structure and *R* the remainder of the ring system.

The present communication deals primarily with ethylenic derivatives in a *cyclohexane* ring, other cyclic systems being reserved for a future paper. We have studied the hydrogenation of single representatives of this class, and of their mixtures with one another and with open-chain ethylenic derivatives (in all, about forty binary mixtures were examined) and the results conform to the general rules given above for open-chain compounds. In those cases in which the hydrogenation of a mixture of two compounds shows a break in the curve, we are justified in assuming that both components are often (or perhaps always) hydrogenated simultaneously in each section, and this conclusion is supported by an examination of the distribution of hydrogen between the components in different phases of the process.

We have found that in some binary mixtures *practically* pure components are hydrogenated on both sections, whereas in other cases there are mixtures capable of being analytically separated.

We have also found that the position of the break on the curves of practically all of the binary mixtures examined of an open-chain (see Part I) and a cyclic ethylenic derivative exactly corresponds with the

consecutive hydrogenation of the pure components in the mixture. As appreciable deviations from this rule are extremely rare, it is possible to calculate the composition of the mixture to within a few units % from the volume of hydrogen absorbed on the different portions of the curve.

Two such deviations are shown in Fig. 8 (curves 1 and 4), the breaks being considerably removed from the calculated positions in each case. The only other deviation is much more peculiar. It was noted in the pair carvone-camphene (Fig. 11, Curve 3); here we have a mixture of two types of substitution at the double bond, *viz.*, an *as.*-disubstituted ethylene (in both camphene and carvone) and a trisubstituted one (in carvone), yet we find on the hydrogenation curve three sharply separated sections instead of the two expected. This case requires further study.

#### EXPERIMENTAL.

The method of investigation was the same as described in Part I. 0.02—0.0025 G.-mol. of the substance was used, and, unless otherwise stated, the other conditions were: 0.2 g. of platinum-black, 15—25 c.c. of alcohol as solvent, and a bath temperature of 20°. The curves are plotted as before, the transverse dash in each case indicating the point at which the preferentially hydrogenated compound is calculated to be saturated. Since *rate* of absorption is plotted against time, the volume of hydrogen absorbed up to any given time is given by the *area* under the curve.

#### *Hydrogenation of Single Compounds* (Table I).

*Disubstituted Compounds* (Type IIc; Fig. 1).—The curves for cyclohexene (Curve 1) and 1-methyl- $\Delta^3$ -cyclohexene (Curve 2) are very much alike; the rate is nearly constant to the end, and the reaction ceases sharply with the absorption of 100% of the hydrogen calculated for saturation of the latter and of about 90% of that calculated for the former.\* The rate of hydrogenation of indene (Curve 3) is lower, and the curve droops slightly. A fourth compound of this type examined was maleic anhydride (obtained by the method of Tanatar, *J. Russ. Phys. Chem. Soc.*, 1890, 22, 213; m. p. 52—55.5°). Its hydrogenation gave an entirely unexpected result; for the absorption in ethereal solution was exceedingly low. Several experiments showed that the hydrogenation of cyclohexene is hindered by the presence of this anhydride; and hence we conclude that maleic anhydride is an anti-catalyst, although neither the acid itself nor its esters possess this quality. Citraconic acid

\* The cyclohexene contained about 10% of benzene or some other hydrocarbon very little susceptible to hydrogenation.

and its anhydride (Type IIIc) behave similarly. An investigation of this phenomenon in anhydrides and acids is being undertaken.

*Trisubstituted Compounds* (Type IIIc; Figs. 1 and 2).—Menthene and pinene are hydrogenated very slowly, their curves falling continuously. Both seem to contain a proportion of some compound (? dipentene) having a higher absorption rate, as shown by the initial rapid fall (Fig. 2, Curves 4 and 5).

FIGS. 1, 2, 3.

The curves of terpineol and carvotanacetone are very much alike (Fig. 1, Curves 5 and 4): the rate of absorption rises somewhat at first, and then falls continuously to the end. The latter compound was prepared by 50% hydrogenation of carvone in the absence of solvent (compare Armstrong, *Chem. and Ind.*, 1925, 44, 701), and since its oxime (m. p. 74–76°) and semicarbazone (m. p. 171–172.5°) showed it to be pure, we are convinced that in the hydrogenation of carvone the double bond in the side-chain (Type IIas) is reduced before that in the ring system (Type IIIc).

The absorption curves of carvone and *l*-limonene resemble one another (Fig. 2, Curves 1 and 2): in both cases hydrogenation of the bond in the side chain proceeds first and at an almost constant

rate. The end of the absorption of the first molecule of hydrogen is marked by a sharp break in the velocity of reaction (compare Vavon, *Compt. rend.*, 1911, 152, 1675), which falls to a minimum and then increases somewhat. The second portions of the curves are like those of carvotanacetone and terpineol, in that the rate rises slightly at first and then falls slowly till the end of the reaction. In the case of carvone, after the absorption of 2 mols. of hydrogen a very slow hydrogenation of the ketonic group sets in. A second experiment with *l*-limonene (Fig. 2; Curve 3) was carried out with platinum-black which had been used previously; the rate of hydrogenation of the cyclic bond (Type IIIc) was somewhat slower, but that of the side-chain bond (Type IIas) remained practically the same.

*Tetrasubstituted Compounds* (Type IVc; Fig. 3).—Only one compound of this type was available, *viz.*, 1 : 2-dimethyl- $\Delta^1$ -*cyclo*-hexene, prepared as follows: 2-methyl*cyclo*hexanol was oxidised to the ketone by Sabatier's method (*Compt. rend.*, 1905, 141, 20), and this was treated with magnesium methyl iodide, and the product decomposed by 30% sulphuric acid; the required hydrocarbon was thus obtained with b. p. 132.5—134.5°,  $d_4^{20}$ : 0.8378 (Sabatier gives b. p. 132°,  $d_4^{20}$ : 0.8411). Its hydrogenation gave a very interesting result. Using small amounts, we observed only two sections in its curve (Fig. 3, Curve 1), the first corresponding to 44% of the total volume of hydrogen absorbed, but with larger amounts (Curve 2) we found three distinct sections, the first part of the curve showing an additional break, which would have corresponded to only 10—11 c.c. in Curve 1 and would therefore escape notice. The absorptions in the three sections are 7, 37, and 56%

respectively of the total. The explanation of these breaks is as follows. The dehydration of 1:2-dimethylcyclohexanol by sulphuric acid can occur in three directions, resulting in the formation, in successively decreasing yield, of the following three hydrocarbons :

Now, from the types to which they belong, it is seen that their ease of hydrogenation should be in the reverse order, the compound of Type IIas being reduced preferentially. In order to assure ourselves that the second section of the Curve 2 corresponds to the hydrogenation of the second compound, we hydrogenated a mixture of our hydrocarbon with terpineol. The curve obtained is shown in Fig. 6 (Curve 2). Owing to the small amount of hydrocarbon taken, we can discern only two portions in it, but the first has increased in agreement with the amount of terpineol used, proving that the linkings hydrogenated in this section are both of Type IIIc.

It is clear that the hydrocarbon was too impure for use as a standard compound of Type IVc, so, since the impurities (Types IIas and IIIc) are hydrogenated preferentially, the mixture was allowed to absorb 45% of the maximum hydrogen, whereby we obtained a mixture of saturated hydrocarbons together with the (presumably) unchanged hydrocarbon of Type IVc, which we used in subsequent experiments as a comparative standard of 55% content.

The foregoing results for individual cyclic hydrocarbons are completely analogous to those for open-chain compounds (Part I), and indicate that the absorption rates of the Types IIc, IIIc, and IVc decrease in that order. Moreover, the curves of the last two types fall slowly, although that of Type IIIc shows a slight rise initially; on the other hand, the curves for compounds of Type IIc (except indene) tend to be horizontal, pointing to a constant absorption rate.

#### *Hydrogenation of Mixtures of Cyclic Ethylenic Derivatives (Table II).*

*Mixtures of Compounds of the Same Degree of Substitution.*—  
(a) Type IIc (Fig. 3). We examined two binary mixtures in this category, viz., cyclohexene + 1-methyl- $\Delta^3$ -cyclohexene (Curve 3) and cyclohexene + indene (Curve 4). In each case both components were hydrogenated concurrently, the curves showing no breaks. The curve of the first mixture is nearly horizontal, whereas that of the second slopes somewhat as in the case of indene alone. The second mixture is interesting in that it suggests that the effect of

platinum-black is similar whether a 5- or a 6-membered ring is involved.

(b) Type IIIc (Fig. 4). Three such mixtures were examined: carvotanacetone + terpineol (Curve 1), carvone + *l*-limonene (Curve 2), and *l*-limonene + terpineol (Curve 3). The general character of the absorption curve of the first mixture is similar to that of the individual curves of its components; it has no breaks, and apparently both components are hydrogenated concurrently. The mixture of carvone + *l*-limonene corresponds to two binary mixtures, Type IIas as well as Type IIIc being present in each compound. The curve resembles those of the two components separately, and calculation shows that the only break corresponds with complete hydrogenation of the two Type II bonds, followed by simultaneous reduction of the bonds in the ring of each compound. We have no doubt that reduction occurs in this order, for 50% hydrogenation of carvone and of *l*-limonene produces carvotanacetone and carvomenthene respectively (Vavon; Armstrong; *loc. cit.*).

The curve for *l*-limonene + terpineol is similar to the preceding case, the stages being the hydrogenation of the bond of Type II, the abrupt fall in the rate to the minimum, and hydrogenation of the cyclic bonds simultaneously. The curve shows also the beginning of a third section, corresponding, apparently, to the very slow hydrogenation of the alcoholic group of terpineol.

*Hydrogenation of Mixtures of Cyclic Ethylenic Derivatives of Different Degrees of Substitution* (Table III).—(a) Types IIc + IIIc (Fig. 5). We examined six binary mixtures of this type, *viz.*, (1) *cyclo*hexene + carvotanacetone (Curve 1); (2) *cyclo*hexene + terpineol (Curve 2); (3) indene + terpineol (Curve 3); (4) 1-methyl- $\Delta^3$ -*cyclo*hexene + terpineol (Curve 4); (5) *cyclo*hexene + carvone; and (6) *cyclo*hexene + *l*-limonene. The last two, being combinations

of Types IIas + IIc + IIIc, are discussed under the head of mixtures of Types IIas + IIc (see p. 331). The curves of the other four mixtures are all similar, showing, first, the constant or slightly falling hydrogenation of Type IIc, then the abrupt fall to the minimum,\* and finally the slow fall characteristic of the hydrogenation of the compound of Type IIIc. The different sections of these curves are very similar to the curves for the individual components of the mixtures; moreover, each component retains its own rate of

FIGS. 4, 5, 6.

hydrogenation fairly closely, except that in the mixture indene + terpineol, the latter reacts much more slowly than when alone. Further, the breaks on the curves of these mixtures are much more pronounced than in the case of the corresponding open-chain mixtures (compare Part I, *loc. cit.*).

(b) Types IIc + IVc (Fig. 6). We examined only one mixture of this type, *viz.*, cyclohexene + 1:2-dimethyl- $\Delta^1$ -cyclohexene (Curve 1).

\* The minimum rate is not noticeable in the mixture indene + terpineol, probably because of the decreased absorption rate of the latter.

As expected, *cyclohexene* is hydrogenated first, and then the rate falls extremely sharply to a very small fraction ( $\frac{1}{60} - \frac{1}{90}$ ) of its value to that characteristic of the reduction of the other compound.

(c) Types IIIc + IVc (Fig. 6). Two of these mixtures were studied: 1:2-dimethyl-Δ<sup>1</sup>-*cyclohexene* with terpineol (Curve 2) and with carvotanacetone (Curve 3). The break in the curve for the first mixture was not pronounced, but that for the second was very sharp. The hydrogenation rate of carvotanacetone was nearly double its usual value, and it will be seen later that the reduction of tetramethylethylene is similarly accelerated in the presence of 1:2-dimethyl-Δ<sup>1</sup>-*cyclohexene*.

The results obtained with these mixed cyclic ethylenic derivatives show that the two components are hydrogenated concurrently if they are of a similar degree of substitution, or consecutively and at different rates if of different degrees; the corresponding curves are accordingly continuous or discontinuous, respectively. The ease of hydrogenation decreases according to type in the order IIc, IIIc, IVc, in conformity with the results obtained for open-chain compounds (Part I) and for individual cyclic compounds.

#### *Hydrogenation of Mixtures of Cyclic with Open-chain Ethylenic Derivatives.*

The results obtained in this series of experiments show that here again the degree of substitution determines the character of the hydrogenation. They also show that platinum-black acts differently

upon similarly substituted derivatives of open-chain and of cyclic structure during the hydrogenation of their mixtures.

(1) *Compounds of the Same Degree of Substitution* (Table IV).—  
(a) Types IIc + II<sub>s</sub> (Fig. 7). In each of the three mixtures, *cyclohexene* + *anethole* (Curve 1), *1-methyl-Δ<sup>3</sup>-cyclohexene* + *anethole*

FIGS. 7, 8, 9.

(Curve 2), and *cyclohexene* + *cinnamyl alcohol* (Curve 3), the components are hydrogenated at the same rate, the curves having no sharp breaks. The curves of the first two mixtures are very much like that of *anethole*.

(b) Types IIc + II<sub>as</sub> (Fig. 7). We examined three mixtures, *viz.*, those of *cyclohexene* with *camphene* (Curve 4), with *carvone* (Curve

§ For this expt. 1 g. of platinum-black was used.

5), and with *l*-limonene (Curve 6). The hydrogenation rate of the first mixture is constant throughout the whole reaction. The other two mixtures are each a combination of the types IIc + IIas + IIIc; the disubstituted compounds are hydrogenated together, the absorption rate being nearly constant. The end of the hydrogenation of the system IIc + IIas coincides with a sharp fall in the absorption rate, which reaches a minimum and then increases a little.

(c) Types IIIc + III (Fig. 8). Four mixtures were examined: carvotanacetone + methylheptenone (Curve 1), mesityl oxide + terpineol (Curve 2), mesityl oxide + carvotanacetone (Curve 3), and terpineol + methylheptenone (Curve 4). The curves of the two mixtures containing mesityl oxide have prominent breaks, for this compound is hydrogenated first and at an almost constant rate. The mixture of terpineol + methylheptenone is of interest because the break in the curve does not coincide exactly with the end of the hydrogenation of either of the components. Each section seems to correspond with the hydrogenation of a mixture of the two components in different proportions, and the size of the sections suggests

that methylheptenone probably predominates in the first portion. This anomaly is still more prominent in the pair methylheptenone + carvotanacetone: the break is not sharp and is strikingly displaced to the left. The resemblance between curves 1 and 4, on the one hand, and between curves 2 and 3, on the other, is noteworthy. It is clear that sometimes the shape of the curves depends, not only upon the characteristics of the type, but also on those of the individual.

These examples show that in the hydrogenation of their mixtures, compounds of the types III and IIIc are not equivalent. Apparently platinum-black absorbs the open-chain type preferentially and consequently compounds of this type are usually hydrogenated first.

(d) Types IVc + IV (Fig. 9). The mixture, 1:2-dimethyl- $\Delta^1$ -cyclohexene + tetramethylethylene (Curves 1 and 2) was studied, 1 g. of platinum-black (instead of the usual 0.2 g.) being used at first because both these hydrocarbons are hydrogenated very slowly. Two experiments showed abnormal reactivity on the part of the tetramethylethylene (Curve 1). Using only 0.2 g. of platinum-black, we obtained Curve 2, where again the end of the hydrogenation of tetramethylethylene is sharply defined and the reaction rate is abnormal, being 9.5 c.c./ $\frac{1}{2}$  min.

(2) *Compounds of Different Degrees of Substitution* (Table V).—

(a) Types IIc + I (Fig. 9). In the binary mixture, saffrole + cyclohexene (Curve 3), the former was hydrogenated first, at an almost constant rate, and the sharp break on the curve coincides closely with the end of this process.

(b) Types IIc + III (Fig. 10). We examined four mixtures: cyclohexene + mesityl oxide, cyclohexene + methylheptenone (Curve 1), cyclohexene + trimethylethylene (Curve 2), and indene + methylheptenone. In all four, the cyclic compound was hydrogenated first; the breaks were somewhat like those in the mixtures of Types IIc + III and IIas + III (Part I, *loc. cit.*), and much less well-defined than those in the curves of mixtures of Types IIc + IIIc and IIas + IIIc. This difference can be explained by the fact (see above) that Type III is much more readily adsorbed by platinum-black, and therefore more readily hydrogenated, than IIIc; hence Type III is more nearly allied to Type IIc than to Type IIIc.

In the mixture, cyclohexene + mesityl oxide, we have a very complicated case, owing to the presence of the conjugated system in the latter; it seems that cyclohexene is hydrogenated first. This curve, as well as that of the mixture indene + methylheptenone, is not given here.

(c) Types IIc + IV (Fig. 10). We examined the binary mixture cyclohexene + tetramethylethylene (Curve 3); the former is hydrogenated first at a constant rate, and a sharp break divides this

process from the reduction of the other component, which, however, is markedly higher than normally.

Camphene		0.8859			

\* Based on a content of 90% (see p. 323).

(d) Types IIIc + I (Fig. 9). In the mixture safole + terpeneol (Curve 4), the former is hydrogenated first and at a constant rate,

slightly increasing towards the end. The curve then falls sharply to a minimum, and the reduction of terpineol sets in with a slight rise followed by a gradual fall.

(e) Types IIIc + IIas (Fig. 11). This category is illustrated by 7 curves: (1) carvone, (2) *l*-limonene, (3) carvone + *l*-limonene, (4) terpineol + *l*-limonene, (5) camphene + terpineol (Curve 1), (6) camphene + *l*-limonene (Curve 2), and (7) camphene + carvone (Curves 3 and 3a). The curves for the first four reductions have already been given (Fig. 2, Curves 1 and 2; Fig. 4, Curves 2 and 3), since the simpler systems also contained those of the type now concerned. The mixtures of camphene with *l*-limonene and with terpineol gave curves of the same type: the minimum is very pronounced, particularly in the second case.

The mixture carvone + camphene is noteworthy. Its curve has three sharply separated sections corresponding with the hydrogenation (i) of the side chain of carvone, (ii) of camphene, and (iii) of the double bond in the ring of carvone (Curve 3). This is the first case in which a break has been found in the hydrogenation of a mixture of two bonds both of the type IIas; and it is quite unexpected, for carvone behaved like camphene in all the hydrogenations of mixtures, and it would be anticipated that the bonds in the side chains of carvone and camphene would be equivalent in respect to platinum-black when hydrogenated in presence of one another. In this case, evidently, the course of hydrogenation is chiefly determined, not by the degree of substitution at the double bond in the compounds, but by their individual qualities and their mutual influence on adsorption at the surface of the catalyst. We therefore made the following experiment. Immediately after the mixture of carvone + camphene had been reduced, a certain amount of carvone was introduced into the hydrogenation vessel, and the course of its reduction followed (Curve 3a). Comparison of Curves 3 and 3a shows that the rate of reduction of the nuclear bond (Type IIIc) of carvone is decreased in the second case: the reduction of its side chain is abnormally rapid in both cases.

(f) Types IIIc + IV (Fig. 10). In the mixture terpineol + tetramethylethylene (Curve 4), the latter is attacked first; the break is clearly visible, and the curve has a minimum. The third section of the curve corresponds with the hydrogenation of the alcoholic group of terpineol.

A general survey of our experiments establishes that the degree of substitution at a double bond is the chief factor determining the order and character of the hydrogenation of mixtures of ethylenic derivatives (either cyclic or open-chain). Other factors, as, for instance, the individual characteristics of the molecules or the

mutual influence of molecules of two different species on their adsorption (and hydrogenation) at the surface of platinum-black, predominate only in exceptional cases. Such phenomena occur only when one of the components of a mixture contains conjugated double bonds, as in mesityl oxide or carvotanacetone. The hydrogenation of individual compounds containing this system is anomalous, and the presence of such a component in a mixture changes the whole character of the hydrogenation.

### *Conclusions.*

(1) Cyclic disubstituted ethylenic derivatives are hydrogenated more readily than trisubstituted ones, and these, in turn, more readily than tetrasubstituted.

(2) Mixtures of cyclic ethylenic derivatives of a similar degree of substitution are hydrogenated at a common rate, the curves showing the absorption of hydrogen being continuous.

(3) In mixtures of cyclic ethylenic derivatives of different degrees of substitution, the components are hydrogenated consecutively in the order given in (1). The curves for such mixtures always have breaks, corresponding closely to the end of the hydrogenation of the first component, and in many cases being associated with a minimum in the rate of reaction.

(4) In a mixture, the section of the curve corresponding to the hydrogenation of any one component bears a strong resemblance to the curve obtained when this component is hydrogenated alone.

(5) The individual hydrogenation rates of the compounds may be considerably modified in mixtures.

(6) The hydrogenation of mixtures of cyclic with open-chain ethylenic derivatives of the same degree of substitution proceeds on the following lines. (a) In mixtures of cyclic with open-chain (*s.*- or *as.*-) disubstituted compounds, the components are hydrogenated concurrently, the curves for such mixtures being continuous. (b) In mixtures of cyclic with open-chain trisubstituted compounds, the components are hydrogenated consecutively, the latter reacting preferentially in virtue of a somewhat greater capacity for adsorption by platinum-black; the hydrogenation curves of such mixtures show rather considerable breaks. (c) In mixtures of a cyclic and an open-chain tetra-substituted compound, the latter is hydrogenated considerably more rapidly than the former.

(7) Mixtures of cyclic or open-chain (*s.*- or *as.*-) disubstituted compounds with cyclic tri- or tetra-substituted compounds show much sharper breaks in their hydrogenation curves than when the more heavily substituted compounds are open-chain.

(8) Mixtures of cyclic with open-chain ethylenic derivatives of

different degrees of substitution are usually hydrogenated consecutively, the component with the lower degree of substitution at the double bond being hydrogenated first.

(9) In mixtures containing a component with a conjugated system, deviations from the above generalisations are observed.

(10) Anhydrides of maleic and citraconic acids, unlike the acids themselves, are toxic towards platinum-black.

(11) Examination of the hydrogenation curves of mixtures of cyclic ethylenic derivatives of known constitution (standard derivatives) with those of unknown constitution enables us to determine the type of substitution at the double linking in the latter, but it is essential that the standards be cyclic.

MILITARY MEDICAL ACADEMY,  
LENINGRAD.

[Received, January 1st, 1930.]

## XLIX.—On Active Nitrogen. Part VII. Further Studies upon the Decay of the Nitrogen After-glow.

BY ERIC JOHN BAXTER WILLEY.

IN previous papers (Part V; J., 1928, 1620; see also 1929, 228) it was shown that the ternary reaction  $2N + N_2 \longrightarrow 2N_2$  (+ glow) would provide, upon a simple kinetic basis, a quantitative explanation of (i) the long life of the nitrogen after-glow, (ii) the negative temperature coefficient of the decay, and (iii) the amount of the chemically active species present under given conditions. Experimental work showed, however, that the process was to be represented as  $2N + 2N_2 \longrightarrow 3N_2$ , rather than as the simpler ternary reaction given above. It has, moreover, been concluded that the luminosity and chemical activity are closely related, and not independent, as suggested formerly (Part IV; J., 1927, 2831), and that it is not improbable that the chemically active species, which persists after the glow has been destroyed either by heat or by an electric discharge (Part IV; *loc. cit.*), represents a molecule which has acquired part of the energy of association of atoms recombining in a three-body process.

Shortly after Part V appeared, Kneser showed (*Ann. Physik*, 1929, 87, 717) that the effects of pressure upon the decay of the after-glow are in agreement with the three-body theory; he also concluded, in agreement with Lord Rayleigh (*Proc. Roy. Soc.*, 1912, A, 86, 262), that the walls may exert a considerable influence upon the reaction, but that the process is usually homogeneous, and that the Kaplan-Cario theory of the nature of active nitrogen is not in

disagreement with these findings. Herzberg also has (*Z. Physik*, 1928, 46, 578) emphasised the probable part played by the walls in the after-glow phenomena. The present author has suggested that the discrepancy between the two investigations might be due to different experimental conditions, and that a surface reaction occurring simultaneously with that in the gas phase masked the true homogeneous decay which it was desired to measure.

An unsatisfactory feature of both investigations was the measurement of the glow intensities by direct visual methods, a personal factor thus being introduced. It appeared advisable, therefore, to study the matter more completely, with special reference to any possible wall reaction which might enter. Bonhoeffer and Kaminsky (*Z. physikal. Chem.*, 1927, 127, 385) have concluded that the spectrum of the after-glow is independent of the nature of the impurity which, as is well known, must be present to cause nitrogen to develop its glow when sparked, and the view has gained ground that these "photogens" (as they may be termed) "poison" the walls and prevent recombination of atoms thereupon, the case being analogous to that of atomic hydrogen, whose life in "wet" vessels is much longer than in "dry" ones. If this theory be correct, a quantitative relation will exist between the decay mechanism and the purity of the nitrogen employed for any one vessel; it was decided to examine this point experimentally and to measure the glow by means of a photo-cell, the personal factor thus being eliminated.

#### EXPERIMENTAL.

*Apparatus.*—This was similar to that employed in the author's earlier investigation, save (i) that additional drying tubes were provided, together with an extra large trap, cooled by liquid air, through which the nitrogen passed after leaving the purification system, and (ii) that inlets were provided both (A) above and (B) below the discharge for admission of other gases as desired. The discharge, some 30 cm. long, burned between water-cooled aluminium electrodes; a condenser of 0.0125 microfarad was shunted across the spark gap, and the r.m.s. current was about 30 milliamps. The observation tube and manometer were built into a sheet-iron box (5' × 3' × 3'), with black cloth curtains on the front, and all precautions were taken to keep the observation cabinet light-tight, and to prevent light from the spark entering the observation tube, which was 60 cm. long and 2.5 cm. wide.

*Nitrogen.*—Preliminary experiments showed that after phosphorus has been in use for a fortnight or so to remove oxygen from the nitrogen, it becomes very slow in action, and about 0.03% of the gas escapes absorption, unless contact is very prolonged. Copper

at 600° gave a gas which was found, by addition of other gases through inlet A (the photogen feed tap) and observation of their effects upon the glow, to contain *ca.* 0.3% of argon (which did not appear to have any influence) and less than 0.01% of other gases, and to give little or no glow. It was therefore employed as the standard "pure" gas, and the use of phosphorus was discontinued.

*Measurement of Glow Intensity.*—The photographic method, with ordinary plates, was valueless, since the  $\alpha$ -bands were not recorded by reason of their long wave-length, while the number of observations to be made rendered the adoption of panchromatic plates inadvisable.

Attempts were therefore made to measure the luminosity by photoelectric methods, the phosphorus method of purification being temporarily used to obtain a gas which gave a strong glow. The ordinary potassium photo-cell is practically insensitive to yellow light,\* and when such a cell was employed, the photo-currents were found to be of the order of  $10^{-11}$  amp., even with strong glows. Such currents can be measured (a) by observing by means of a quadrant electrometer the fall in potential across an alcohol-xylene resistance of *ca.*  $10^{11}$  ohms; (b) by means of a Paschen or Downing galvanometer directly in circuit; or (c) by applying the potential obtained by method (a) to a valve amplifier specially constructed to deal with such cases—devices such as that of Wynn-Williams are admissible only with larger currents. When any one of these methods was tried, great difficulties were encountered owing to the discharge which produced the active nitrogen setting up a diversity of electromagnetic disturbances which necessitated the most rigorous shielding; the movement of a photo-cell along a tube through which active nitrogen was being streamed required flexible leads, and the difficulties were thus at once increased.

The method adopted after numerous failures was rendered possible through the kindness of Mr. C. F. Trippe, and the British Thomson Houston Co., Ltd., who placed at the author's disposal two special caesium cells having an emission some 50 times that of the best cell of any other type which was tried. These were placed in parallel and fitted in series with (a) a Tinsley moving-coil galvanometer of sensitivity  $5 \times 10^{-10}$  amp., and practically constant zero, and (b) a high-tension accumulator giving 130 volts; practically no "dark" current was obtained, and calibration experiments using an ordinary optical bench method showed that the deflexion of the galvanometer was directly proportional to the brightness of the light incident upon the cells. For the actual experiments,

\* Ordinary caesium cells have a much greater emission for yellow light, but are very unsatisfactory for quantitative work.

these were fixed in a light wooden frame held in a retort stand provided with a pointer on the base, and fitted to slide between rails parallel to and underneath the horizontal observation tube; the rails carried a scale, and the zero point was chosen some 10 cm. along the tube and 5 cm. downstream from the side limb B (see above).

*Procedure.*—For measurements of the glow, the cells were first placed at the zero point and screened from the light by means of a black cloth. The galvanometer reading was taken, and the cloth withdrawn to cause the cells to become illuminated; the second reading was then made, the instrument being practically dead-beat and coming to rest in 30 secs. or so. This was then repeated with the cells at the 5, 10, 15, 20, 25, etc., points until the deflexion became less than 0.3 cm., after which further measurements were made at the 22.5, 17.5, 12.5, 7.5, and 2.5 cm. points, some 15–20 observations being made for each run according to the glow intensity. The data were then plotted as the reciprocal of the square root of glow intensity against distance along the observation tube; for a reaction which is bimolecular with respect to the glow-producing system, a linear relation should thus be obtained (see, *e.g.*, Willey, *loc. cit.*).

### Results.

*The Production of a Glow in Pure Nitrogen.*—It was found that with the hot-copper method of purifying nitrogen and with the trap well cooled by liquid air, the faint glow visible in the nitrogen at first quickly diminished until the gas was quite non-luminous as it passed along the observation tube. Moreover, entirely negative results were obtained in attempts to detect chemical activity in the nitrogen by means of nitric oxide admitted at B, the peroxide being tested for according to the method previously described (Part IV). It appears then that nitrogen which is so pure as to give no glow is not chemically active.

*Glow Phenomena.*—The after-glow could easily be developed either by reducing the temperature of the copper or by the addition of small amounts of other gases through the photogen feed tap. The results of systematic investigation of the effect of added impurity are now given;  $I$  is the intensity of the glow, and  $t$  the time, which is proportional to  $D$ , the distance along the observation tube.

(a) *Form of the  $1/\sqrt{I}-t$  graph.* ( $\alpha$ ) With fairly pure nitrogen the line is strongly curved (Fig. 1, A), becoming less so with continued increase of photogen (Fig. 1, B) until it passes through a linear form (Fig. 1, C), and then again becomes curved (Fig. 1, D). This shows that the apparent "order" of the decay reaction is dependent upon the purity of the nitrogen employed. The points

for Fig. 1, A give a fairly straight line when plotted as  $\log I$  against  $D$ , indicating a decay reaction of approximately the first order.

( $\beta$ ) During a series of experiments which had as their object the determination of the relation between glow intensity and concentration of chemically active species, the following measurements were taken : (i) Decay curve (Fig. 2, A) ; (ii) three estimations of the chemically active species ; (iii) 20 minutes after this, a further

decay curve (Fig. 2, B) ; and finally (iv) three more analyses. During runs (i) and (iii), the nitric oxide stream was replaced by an equal one of pure nitrogen to keep the pressure constant, and the flow of gases and the spark were maintained throughout. It will be seen that the graphs are linear after the first few cm. but vary widely in slope ; in spite of this the same amount of chemically active nitrogen was found in all six cases. Hence it follows that a stream of luminous nitrogen may decay at widely different rates although it contains the same amount of the chemically active form throughout.

( $\gamma$ ) In another experiment a decay curve (Fig. 3, A) was plotted for fairly pure nitrogen (*ca.* 0.03% of oxygen being used as photogen), and the photogen concentration then increased to *ca.* 0.07%, after which Fig. 3, B was obtained. The apparatus was allowed to function for 90 minutes, and a further decay curve (3, C) obtained ; the observation tube was then flamed gently, the gases and spark being shut off and a vacuum of 0.0001 mm. maintained. After cooling, the gases were readmitted, the spark was run for 90 minutes, and curve 3, D was obtained.

( $\delta$ ) The clearest explanation of the results described in sections ( $\alpha$ ), ( $\beta$ ), and ( $\gamma$ ) is that they are due to wall effects. With nitrogen of a high degree of purity the walls are so clean that recombination of the atoms, assured now, as before, to be the primary glow-producing elements, occurs with great ease; adopting the author's earlier view (Part V) as to the origin of the chemical activity, the failure to obtain this in the absence of photogens is also readily explained, and is discussed later in the light of the Kaplan-Cario theory. The findings given in ( $\alpha$ ) arise from the progressive poisoning of the walls by the

FIG. 3.

primary glow-producing system, the slope of the curve is not determined solely by total gas pressure, as it should be for a reaction

FIG. 2.

photogen until probably a point of minimum wall activity is reached when the reaction becomes homogeneous and bimolecular (with respect to the glow-producing elements) as in Fig. 1, C, while in 1, D too much photogen is present and is influencing the gas phase reaction either by direct participation in the glow emission process or else possibly by reaction with the chemically active species.

In Fig. 2, B we have shown the influence of an adsorbed nitric oxide film upon the decay rate of the glow: it is much reduced, as would be expected. Furthermore, while the linear nature of the graph shows that the reaction is binary with respect to the

$2N + N_2 \longrightarrow 2N_2$ , when the condition of the walls necessitates their being taken into account. A more important phenomenon is the constancy of the chemical activity, suggesting that if, as the Kaplan-Cario theory indicates, the active species is a participant in the glow emission reaction, it has as a complement a substance which is very susceptible to wall influence (see later).

The results given in Fig. 3 are in striking agreement with the wall-effect hypothesis. Fig. 3, A has as its fellow Fig. 1, A, while at the time when 3, B was obtained sufficient photogen had entered the observation tube to poison the walls only so far along the direction of flow as the point of inflexion, and the practical

FIG. 4.

1900 C.c. of nitrogen per hour at N.T.P.

A = Decay curve for 4.6 mm.

B = " " " " 6.8 "

coincidence of 3, C and 3, D shows that they represent the final state of the walls for nitrogen of this particular degree of purity. No marked effect of the photogens upon the electrical conditions has yet been observed, and the findings in Fig. 3 cannot be attributed to progressive changes in the bulk composition of the gas, since the very small volume between the photogen inlet and the observation tube, taken in conjunction with the high flow-speed of the gas at the pressure employed (4.6 mm.), rules it out of consideration.

(e) The evidence presented in sections ( $\alpha$ ), ( $\beta$ ), ( $\gamma$ ), and ( $\delta$ ), that the condition of the

walls determines very largely the mechanism of the decay of the nitrogen after-glow, may be tested in the following manner. The activity of the surface may be expected, *ex hypothesi*, to be proportional to the area exposed; the more the gas adsorbed upon it, the less will it influence the decay, provided that reaction does not occur between the adsorbed film and the glow-emitting system. The simplest way of decreasing the wall effect without introducing any such complication is clearly to employ nitrogen as a photogen, i.e., by raising the over-all pressure to increase the adsorption of molecular nitrogen; if the departure from linearity in the

$1/\sqrt{I}-t$  graph is due to wall effects, the curves should be straightened in progressive runs from low to high pressures. This effect may readily be observed and is shown in Fig. 4.

(b) *The triple-collision hypothesis.* Assuming the glow emission to result from a reaction  $2N + N_2 \rightarrow 2N_2$ , it follows that for a constant concentration of N the initial intensity will be increased and the life of the glow diminished by addition of  $N_2$ . Kneser (*loc. cit.*) confirmed this deduction, but Bonhoeffer and Kaminsky (*loc. cit.*) dissented from it. The probability of the after-glow resulting from a three-body reaction has already been discussed (Part V, J., 1928, 1620; 1929, 228) and the balance of evidence considered to be in its favour; it will now be shown (i) that a further method of calculation produces a result in excellent agreement with experiment, and (ii) that measurements made in the light of the findings discussed earlier in this paper prove that the decay in the gas phase is a ternary reaction.

(i) It is required to calculate the mean life of the atoms, assuming that they can combine only through the medium of a triple collision involving two atoms and one molecule. Let  $\lambda_1$  be the mean free path of the atoms among themselves, and  $\lambda_2$  that of the molecules; further, let  $\bar{u}$  be the r.m.s. velocity of the molecules, then  $\bar{u}\sqrt{2}$  is that of the atoms. Now consider a particular atom  $a_1$ ; it will collide  $\bar{u}\sqrt{2}/\lambda_1$  times per sec. with a similar atom. If a molecule B converts one such atomic impact (between  $a_1$  and  $a_2$ ) into a triple collision at a point L, it must have travelled from a point distant between  $(\lambda_2 - \frac{1}{2}\bar{u}\tau)$  and  $(\lambda_2 + \frac{1}{2}\bar{u}\tau)$  from L,  $\tau$  being the "duration" of the  $a_1$ - $a_2$  collision. Hence, at a time  $t = \lambda_2/\bar{u}$  before the impact, the necessary B molecule must lie in a spherical shell of centre L, of mean radius  $\lambda_2$ , and of thickness  $\bar{u}\tau$  (assumed small compared with  $\lambda_2$ ). The probable number of B molecules in this shell is

$$v_B \cdot 4\pi\lambda_2^2\bar{u}\tau. \quad (1)$$

where  $v_B$  is the concentration of B molecules per c.c. In order, however, that the  $a_1$ - $a_2$ -B impact shall occur, B must be definitely aligned with regard to the colliding atoms, and the collision can follow only if B starts on its journey towards them in a solid angle  $\pi\sigma^2/\lambda_2^2$ , where  $\sigma$  is the radius of the  $a_1$ - $a_2$  complex. The probability that it will travel in this direction is

$$(\pi\sigma^2/\lambda_2^2)(1/4\pi) = \sigma^2/4\lambda_2^2 \quad (2)$$

and the probable number of B molecules present and moving in the right direction is given by the product of (1) and (2), i.e.,

$$[B] = v_B \cdot \pi\bar{u}\tau\sigma^2 \quad (3)$$

The number of such collisions per sec. which the atom  $a_1$  could make (if it were not demobilised by the collision \*) is then given by the product of (3) and the number of atomic collisions, *i.e.*,

$$Z = \pi v_B \bar{u} \tau \sigma^2 \times \bar{u} \sqrt{2} / \lambda_1 = \pi \sqrt{2} \bar{u}^2 \tau \sigma^2 v_B / \lambda_1 \quad . \quad . \quad (4)$$

For nitrogen at 10 mm. pressure and containing 1% of the active form, we have  $\lambda_1 = 8.8 \times 10^{-1}$  cm.,  $v_B = 3.6 \times 10^{17}$ ,  $\bar{u} = 5.0 \times 10^4$  cm./sec., and  $\sigma = 1.9 \times 10^{-8}$  cm.; hence, taking  $\tau$  as  $10^{-14}$  sec., we have  $Z = 1.64 \times 10^{-2}$ , whence the mean free life of an atom, and thus the duration of the after-glow, will be  $1/1.64 \times 10^{-2} = 61$  secs. This is rather longer than that actually observed (7–10 secs.), but in view of the uncertainty as to the numerical values of both  $\tau$  and  $\sigma$  (since the  $a_1$ - $a_2$  complex will probably be an excited molecule, and hence of abnormal diameter), the agreement between calculation and experiment is very good.

A ternary reaction being assumed to give rise to the glow, the intensity,  $I$ , will at any instant be proportional to the rate at which the atoms are combining, *i.e.*, to the number of triple collisions per c.c. per sec.; hence

$$k_1 I = -\partial v_a / \partial t = k_2 v_a^2 v_B$$

Integration gives  $1/v_a = (t + C)k_2 v_B$ ,  $C$  being a constant, but since  $I = k_2 v_a^2 v_B / k_1$ , we have

$$1/\sqrt{I} = \sqrt{k_1 k_2} (t + C) \sqrt{v_B}$$

and hence the slope of the line giving the relation between  $1/\sqrt{I}$  and  $t$  should vary as  $\sqrt{v_B}$ , *i.e.*, as the square root of the total gas pressure,  $P$ .

(ii) Previous attempts (Part V, *loc. cit.*) to examine this point experimentally led to scattered results which showed that the slope varied as  $P$  and not as  $\sqrt{P}$ , but the dependence of the decay rate upon the purity of the gas, and hence upon wall conditions, according to the results described earlier in the present communication, gave the clue to the source of the disagreement between theory and observation, and clearly indicated that the desired correlation should be carried out either (a) by using a gas rich in photogens or (b) in a purer gas but at higher over-all pressures.

Glowing nitrogen containing 0.03% of oxygen was streamed through the observation tube and its decay rate was measured as usual. In order to avoid the introduction of any corrections for changed flow-speed a constant flow of 1600 c.c./hr. at atmospheric pressure was maintained, and the pressure in the apparatus was

\* This does not vitiate the argument, since we are concerned with a statistical discussion of the probable life of the atom.

varied by a choking tap in the exhaust line. Fig. 5 shows that the slope ( $S$ ) is a linear function of  $\sqrt{P}$  between 5.4 and 12.8 mm., and that the decay of the glow may therefore be expressed as a third-order process, in agreement with theory.

(c) *The action of oxygen upon the after-glow.* It has been found that when about 5% or more of oxygen is fed to the glow stream and the yellow luminosity is destroyed, the photo-cells behave as if strongly illuminated, although the gases have apparently become dark at the point of observation just below the oxygen inlet. This can only mean that the glow emission is proceeding in the non-visible portions of the spectrum, and as the cells have been found to be practically insensitive beyond the orange region but slightly more so in the green and blue, it follows that a very large radiation in the blue region and beyond must be proceeding in these circumstances. The author is indebted to Mr. G. C. Eltenton for the information that he too has observed this phenomenon (see also Rayleigh, J., 1918, 113, 200).

(d) *Constancy of decay order with time.* Since, except under conditions which can be attributed to wall influence (e.g., Fig. 3), no change in form of the decay curves is found with time, it follows that the mechanism of the process does not alter, at any rate at these pressures, and that between about 5900 and 4000 Å.U. (the sensitivity limits of the photo-cells) the emission takes place regularly among the various bands concerned. This is probably not in disagreement with König and Klinkmann (*Z. physikal. Chem.*, 1928, 137, 335), since the range of curve-lengths over which they worked is much greater than here: the present measurements apply practically only to the  $\alpha$ -bands.

(e) *Photogens and chemical activity in nitrogen.* It has been found that the addition of photo-gas to "pure" nitrogen causes a large increase in the concentration of the chemically active species, this being determined by the reaction with nitric oxide as described in Part IV. Attempts to establish the relationship between glow

FIG. 5.

intensity and concentration of active nitrogen have not yet led to results which can be treated quantitatively, but it appears, in agreement with Bonhoeffer and Kaminsky (*Z. Elektrochem.*, 1926, **32**, 536) and König and Klinkmann (*loc. cit.*), that there is no simple expression which connects them; the former generally tends to rise more rapidly, as is shown in a typical experiment in which the brightness of the glow changed from 0.3 to 3.45, as measured at the point where the analysis was made by the galvanometer deflexion, whilst the concentration increased from 0.44 to 1.40%. The intensity of the green flame produced during the reaction between glowing active nitrogen and nitric oxide appears to bear much the same relation towards the concentration of active species as does the nitrogen glow alone under the same conditions, the supply of nitric oxide being replaced by an equal one of nitrogen to hold the pressure constant. The experiments do, however, show that the same amount of chemically active nitrogen may be present in glows which decay at widely different rates, a point to be discussed later.

(f) *The nature of photogens.* In agreement with Rayleigh (*Proc. Roy. Soc.*, 1915, *A*, **91**, 303) and with Bonhoeffer and Kaminsky (*Z. Elektrochem.*, 1926, **32**, 536), it has been found that the optimum supplies of these gaseous impurities correspond to about 0.1% concentration in the nitrogen, and that water vapour is to be placed very high in the order of effectiveness (compare Herzberg, *loc. cit.*; Lewis, *J. Amer. Chem. Soc.*, 1929, **51**, 654, 665). It has not been found possible to trace any effects of the photogens which can be ascribed to their specific natures, and hence it appears that their action is general in character.

#### *Discussion.*

These experiments appear definitely to clarify the state of our knowledge of active nitrogen. The existence of wall effect now demonstrated is in complete harmony with the results of Lewis and of Herzberg (published during the course of the present research). Among the phenomena to be anticipated from these researches are the reversal of the pressure and temperature effects normally found for the after-glow, and actually observed by Lewis, and also the divergences in the order of the decay process as observed by Kneser and the present author, the cause of this clearly being slight differences in composition of the nitrogen employed and in the surface of the vessels.

More important, however, is the strong evidence for the triple-collision hypothesis and consequent deductions as to the origin of the chemical activity and the close connexion apparently existing between this and the luminosity. It has already been shown, both

in this and in earlier papers, that the ternary-reaction theory leads to the assumption that the glow-producing and chemically active species are present in comparable concentrations, and Kaplan and Cario (*Nature*, 1929, **121**, 906) and Compton and Boyce (*Physical Rev.*, 1929, **33**, 145) have recently shown that active nitrogen contains two species of metastable atoms (2.3 and 3.6 volts) and a metastable molecule (8.2 volts), evidence thus being forthcoming for a substance whose energy agrees well with the value 2.0—2.2 volts (equivalent to 46,000—50,000 cal./g.-mol.) advanced in earlier papers of this series (Parts I, II, and III; J., 1926, 1804; 1927, 669, 2188) for the energy of active nitrogen as it appears in its chemical reactions. Upon these spectroscopic findings, Kaplan and Cario base a theory of the origin of the after-glow. Its emission may result from one or more of three reactions, viz.: (i) recombination of one neutral and one 2.3-volt atom; (ii) recombination of two neutral atoms, followed by excitation of the metastable molecule thus produced by collision with a 2.3-volt atom; (iii) collisional excitation of an 8.2 volt metastable molecule by a 3.6-volt atom: since the latest work (e.g., Gaviola, *Nature*, 1928, **122**, 313) shows that the heat of dissociation of  $N_2 \longrightarrow 2N$  is ca. 9.5 volts, the 11—11.5 volts necessary for emission of the  $\alpha$ -bands by the molecule are provided.

Frl. Sponer (*Z. Physik*, 1925, **34**, 622) has concluded that the emission of the  $\alpha$ -bands (the visible after-glow) follows the recombination of atoms in triple collision with a molecule, the energy of association being transferred to the third body, which is thus excited and re-emits the energy as radiation; as, at the time of her publication, the heat of dissociation of  $N_2 \longrightarrow 2N$  was regarded as 11.4 volts, no collisional excitation was deemed necessary. It seems not unreasonable that the glow emission may be represented by a combination of the Kaplan-Cario and Sponer theories, and that the process is

where  $N'$  is the 2.3-volt metastable atom, assumed to be the chemically active form.\* The right-hand side of this reaction must be regarded as a mere outline, but the left carries with it certain implications which may be considered.

1. It accounts for the third-order decay of the after-glow, and hence for the negative temperature coefficient of this reaction.

2. It is in conformity with the calculations made by the present author as to the comparable concentration of glow-producing and of chemically active species.

\* The findings discussed in sections (a) and (b) (p. 340) suggest also that the walls may under appropriate conditions act as the third body in the reaction.

3. If the analogy with active hydrogen is valid, the existence of strong wall effects may be attributed to adsorption and heterogeneous recombination of nitrogen atoms. Moreover, if we are prepared to admit preferential adsorption of N rather than of N' unless the surfaces are exceedingly "clean," it follows that the glow intensity and decay rates of an active nitrogen stream may be almost infinitely variable without corresponding changes in chemical activity, in agreement with the findings discussed in Part IV of this series and in sections ( $\alpha$ ) and ( $\beta$ ) (p. 340). Since a metastable atom or molecule can undergo many collisions without suffering deactivation—of which a good proportion must be upon the walls—whereas the case of atomic hydrogen shows that for normal atoms the surface influence is very great indeed, this assumption does not appear unjustifiable.

4. It links up glow effects and chemical activity and provides for an entity of the energy content which earlier work has postulated, *viz.*, the metastable atom of about 2.3 volts energy (53,000 cal./g.-mol.) (see p. 347).

There are, however, other possibilities to be considered. The principal objection to this view is that it accounts for only about one-sixth of the total energy available, and does not provide any clue as to why the other excited and metastable species present are apparently chemically inert. On the other hand, it is significant that in the majority of gaseous reactions the energy exchanges involved are much less than the 200,000 cal./g.-mol. with which we are here concerned, and it is possible that too abundant a supply of energy may be unfavourable to chemical changes in general.

Moreover, the Kaplan-Cario theory does not provide for a three-body recombination process, as found definitely in these experiments and less definitely by Kneser. The existence of the strong wall effects noted in this work suggests that it is just possible, although improbable, that the adsorption of the nitrogen varies as the pressure, leaving less free surface for the wall action and, by thus favouring the homogeneous decay, leading to an erroneous inference as to the effect of pressure upon the glow transformation process.

#### *Summary.*

1. The decay of the nitrogen after-glow has been restudied with an improved technique, and found to be most probably partly homogeneous and partly heterogeneous, according to experimental conditions.

2. Unless the walls of the vessels concerned are "poisoned" by foreign gases, the recombination process is non-luminous and occurs as a surface reaction; as the concentration of the impurity rises,

the wall reaction diminishes and the homogeneous decay increases, but above a limit of *ca.* 0.1% the impurity reacts chemically with the active nitrogen and interferes with the normal decay.

3. The order of the decay process is determined by the state of the walls, which in turn depends upon the purity of the nitrogen employed; when the surface reaction is minimised, the effects of pressure and addition of other gases are in agreement with the three-body recombination theory.

4. The after-glow probably originates in a reaction

$N'$  being a 2.3-volt metastable atom which is the chemically active species whose energy has been measured earlier.

5. No changes are to be seen in the order of the decay as it proceeds; neither do the spectral characteristics of the glow between *ca.* 5900 and 4000 Å.U. appear to alter.

The author's thanks are due to Major F. A. Freeth, F.R.S., and to Professor F. G. Donnan, F.R.S., for providing facilities for the prosecution of these researches, which were carried out in 1928 and the early part of 1929. The co-operation of his assistant, Mr. W. A. Bayliss, has been invaluable.

## L.—*A New Interpretation of the Isomerism amongst Co-ordination Compounds of Platinum.*

By FREDERICK GEORGE ANGELL, HARRY DUGALD KEITH DREW,  
and WILLIAM WARDLAW.

THE apparently well-established *cis*- and *trans*-isomerism found among compounds of quadricovalent platinum provides the strongest remaining evidence for the view that the four groups surrounding a central atom may be situated in a plane instead of at the corners of a tetrahedron. We are engaged in a re-examination of the cases in which isomerism of this kind is alleged, and the present paper is concerned with the compounds which platinous chloride forms with diethyl sulphide, these substances being typical of a group in which the evidence for a planar configuration seems most complete. We have now concluded, however, that the isomerism in this instance is of a structural and not of a spatial nature, and hence that, so far as these particular substances are concerned, there is no reason to doubt that the space distribution of four groupings associated with platinum is tetrahedral.

Blomstrand (*J. pr. Chem.*, 1888, **38**, 352) found that diethyl sulphide united with platinous chloride, giving two distinct dichlorides to which he assigned the structures (I) and (II), regarding

$\alpha$ -Dichloride (B).  $\beta$ -Dichloride (B).  $\alpha$ -Dichloride (K).  $\beta$ -Dichloride (K).

both substances as containing bivalent platinum. Klason (*Ber.*, 1895, **28**, 1493) extended these observations, and gave the new formulæ (III) and (IV), where platinum is quadrivalent, or perhaps sexavalent in the  $\beta$ -compound. Neither author contemplated a planar configuration, or gave really satisfactory proof of the structures he alleged, although useful and mainly accurate data were accumulated. Werner ("Lehrbuch der Stereochemie," pp. 338 *et seq.*; see also *Z. anorg. Chem.*, 1893, **3**, 310), ignoring the relevant chemical evidence of his predecessors, attributed the isomerism to the presence of *cis*- and *trans*-planar types, (V) and (VI), in which

platinum exhibited 4-co-ordination. His view is universally accepted at the present time, although Reihlen has consistently adhered to an hypothesis of the tetrahedral distribution of valencies (*Annalen*, 1927, **447**, 211; **448**, 1312; *Z. anorg. Chem.*, 1926, **151**, 71).

The structures which we propose as a result of the present work are shown in (VII) and (VIII). In the  $\alpha$ -dichloride each sulphur atom is united to tetrahedral platinum by a co-ordinate link \*

\* After this paper had been read, Dr. N. V. Sidgwick pointed out to us that dissociation of the  $\alpha$ - and  $\beta$ -dihalides would give rise to the *same* ions in both cases, if the co-ordinate links between the sulphur atoms and the platinum atom in the  $\alpha$ -compound were equivalent to semipolar double bonds:

With this proviso, therefore, the  $\alpha$ - and  $\beta$ -forms are inter-related in a manner close and unprecedented. The un-ionised forms are nevertheless not identical, because the halogen atoms are situated in different positions in the molecule in the two cases; nor do the two substances represent the ionised and un-ionised forms of the same substance, because the chemical evidence shows, to take one point of several which could be cited, that the  $\beta$ -dichloride is ionised

constituted by the sharing with platinum of two electrons derived from each sulphur atom; whilst in the  $\beta$ -dichloride the linkings between the sulphur atoms and platinum are covalencies and the chlorine atoms are potentially ionised as in the sulphonium halides.

Blomstrand and Klason observed that, whilst both the  $\alpha$ - and the  $\beta$ -dichloride had the normal molecular weight, the yellow colour of the  $\alpha$ -compound was deeper than that of the  $\beta$ -, and in addition the former substance was the more soluble in organic solvents. The  $\beta$ -compound alone showed noticeable solubility in water, and, more significant, it reacted much more rapidly with alcoholic silver nitrate. The conductivity of both dichlorides in aqueous alcohol was very low; but that of the  $\beta$ -isomeride was distinctly the higher. The  $\alpha$ - was transformed to the  $\beta$ -dichloride by treatment with hot aqueous diethyl sulphide. The reverse change could be effected by conversion, through silver sulphate and potassium bromide, or through the latter alone, into the dibromide, which with silver chloride gave the  $\alpha$ -dichloride. The dibromide and di-iodide existed in one form only, and this form was stated by Blomstrand to be a  $\beta$ -form and by Klason an  $\alpha$ -form.

By slight modification of the original procedure, we have been able to prepare at will either the  $\alpha$ - or the  $\beta$ -dichloride from diethyl sulphide and potassium chloroplatinite, the latter being best prepared from chloroplatinic acid and potassium oxalate. The  $\alpha$ -dichloride is readily purified by taking advantage of its solubility in light petroleum, and the  $\beta$ -dichloride by making use of the fact that it separates from benzene as a sparingly soluble crystalline

to the extent of about 50% in aqueous solution and yet exists therein free from the  $\alpha$ -form, although we should expect rapid recombination of the ions to produce the insoluble  $\alpha$ -form, which would be precipitated.

In our opinion, the crux of the matter lies in the assumption that the co-ordinate linkings in the  $\alpha$ -compound are equivalent to semipolar double bonds. This assumption cannot be true, because it contradicts the experimental evidence. We are left with only two reasonable alternatives, *viz.*, (1) that the co-ordinate link is an ordinary double bond consisting of two covalencies, which means that the normal shells for the sulphur atoms are expanded in the  $\alpha$ -compounds, the sulphur atom being quadricovalent; or (2) that the co-ordinate links in the  $\alpha$ -compounds are formed by the sharing with platinum of two electrons from each sulphur atom, the sharing not being such as to provide a free unit charge on the platinum atom for each co-ordinate link. The extent to which such sharing takes place cannot at present be assessed in any particular case; and it will depend in the general case on the nature of the two atoms concerned (compare *J. Soc. Chem. Ind.*, 1928, 47, 949). At present we refrain from deciding between these two possibilities. It may be that both types of bonding will be found among co-ordinately linked atoms; but we are inclined to prefer the second possibility in the case of the substances under consideration.

compound with a molecule of the solvent. We have confirmed the molecular weights and analyses of the two substances, and also their physical properties as given by Klason. The most noticeable physical differences between the isomerides, apart from the colours, lie in their solubilities, those of the  $\alpha$ -dichloride suggesting a non-polar compound whereas those of the  $\beta$ -dichloride indicate a weakly polar substance. The  $\beta$ -dichloride was sufficiently soluble in water for its conductivity to be measured, and the values obtained showed that the salt is considerably ionised—about 50% at  $v = 1000$  if  $\mu_{\infty}$  be taken as 100.

We find that the chemical properties of the two dichlorides are so different as to render it highly improbable that they are merely spatial isomerides. The ready transformation, under certain conditions, of the  $\beta$ -compounds to the  $\alpha$ - seems to have been the main cause which in the past has prevented a recognition of their true relationship. We have, for example, been able to isolate a second dibromide and to show that this is a  $\beta$ -compound, which, when melted at  $95^{\circ}$ , passes almost completely into the  $\alpha$ -isomeride, m. p.  $129^{\circ}$ ; and we have obtained evidence that a  $\beta$ -di-iodide exists and is still more easily converted into the  $\alpha$ -di-iodide.

On being kept in the solid state, or in solution or suspension in alcohol or benzene, either dichloride tends to pass into an equilibrium mixture of both. The isomeric dibromides change in a similar manner but much more rapidly; but here the equilibrium mixture consists almost entirely of the  $\alpha$ -compound. The di-iodides tend even more strongly to attain the  $\alpha$ -state. In carrying out reactions, therefore, it has been found necessary to work with freshly prepared or freshly tested substances and to effect the rapid isolation and examination of the products. In some cases, as will be seen later, the influence of solvents becomes important, and the effect of temperature must also be taken into account.

The most striking chemical difference between the members of the two series of isomeric dihalides, however, is shown by their interaction with silver oxide in presence of water. The  $\beta$ -dichloride, for example, reacts in a few minutes with the production of silver chloride and a markedly basic substance, *platinumbisdiethylsulphonium hydroxide* (IX), which is readily soluble in water. This substance, which may be referred to as the  $\beta$ -base, can be obtained in transparent, yellowish, deliquescent crystals which rapidly absorb carbon dioxide when exposed to the air. After being dried over phosphoric oxide, the base gives correct analytical figures for a dihydroxide. Its aqueous solution is strongly alkaline to litmus, has a moderate conductivity, precipitates metallic hydroxides, and neutralises acids, both mineral and organic, with the production of

pure  $\beta$ -salts provided that the temperature is below the point of their transformation to the  $\alpha$ -compounds.

In this manner, besides the  $\beta$ -dichloride, the  $\beta$ -dibromide and the  $\beta$ -oxalate (X) were prepared, and were shown to belong to the  $\beta$ -series by quantitative reconversion into the  $\beta$ -dichloride, the former by means of silver oxide and hydrochloric acid, and the latter by means of the acid alone. The oxalate, a colourless substance readily soluble in water and in benzene, reacts at once with lime-water, giving a precipitate of calcium oxalate and a solution of the pure  $\beta$ -base, a reaction which suggests ionisation of the oxalate in aqueous solution. Determination of the conductivity confirmed this.

When an aqueous solution of the base was gradually neutralised with 0.5*N*-hydrochloric acid, the  $\beta$ -dichloride initially precipitated rapidly redissolved, but the precipitate became permanent before the half-neutralisation stage was reached. At this stage 0.12 g. of pure  $\beta$ -dichloride had been precipitated from a measured volume of solution which, as shown by another experiment, would have given on full neutralisation a precipitate of 0.54 g. of  $\beta$ -dichloride. Thus, at half-neutralisation the alkaline filtrate from  $\beta$ -dichloride still contains that substance, together with the free base and possibly a proportion of hydroxychloride. On evaporation at the ordinary temperature, this filtrate gave a yellow alkaline oil which partly solidified in a paste. This experiment shows that the  $\beta$ -base is not a complex substance like the base derived from the  $\beta$ -series of Vernon's dimethyltelluronium dihalides.

The  $\alpha$ -dichloride, on the other hand, is only very slowly changed by moist silver oxide under precisely similar conditions, the reaction being incomplete after 48 hours. The evolution of diethyl sulphide commences at once, and the formation of silver chloride is attended by the precipitation of platinum as oxide or hydroxide. The filtrate is quite neutral to litmus:  $\text{Pt}(\text{Et}_2\text{S})_2\text{Cl}_2 + \text{Ag}_2\text{O} = 2\text{Et}_2\text{S} + 2\text{AgCl} + \text{PtO}$ . The same distinction holds good for the isomeric dibromides and di-iodides.

These experimental results cannot be explained adequately on Werner's formulæ. The fundamental difference between the  $\alpha$ - and the  $\beta$ -dichloride in their behaviour with silver oxide demonstrates most clearly that the isomerism is structural. On the new formulæ which we propose, the experimental results find a natural interpretation. The  $\alpha$ -dichloride should give wholly silver chloride and the unstable co-ordination compound  $(\text{Et}_2\text{S})_2\text{Pt}(\text{OH})_2$ , which would be expected to decompose into diethyl sulphide and platinum

oxide or hydroxide. The  $\beta$ -dichloride, on the other hand, should furnish silver chloride and the stable base (IX). Both the  $\beta$ -dichloride and the base should be ionised in aqueous solution. Each of these deductions has received confirmation. The reason why the  $\beta$ -dichloride is less polar in character than a true alkylsulphonium halide may well be that the influence of the bivalent platinum atom, which has clearly a tendency to attract electrons, prevents, by restraining to some extent the valency electrons possessed by the sulphur atom, the full development of ionisation of chlorine in the  $\beta$ -dichloride, since this development can occur only if the sulphur atoms are able to yield to the chlorine atoms their fourth valency electrons. The chlorine atoms are therefore partly covalent in the  $\beta$ -dichloride; nevertheless, in aqueous solution it exhibits appreciable conductivity. The  $\alpha$ -dichloride is completely non-polar because the chlorine atoms are attached to platinum by covalencies.

The only other example of the production of a basic substance from a platinum compound of this type is described by Blomstrand (*loc. cit.*, p. 362), who noticed that the sulphate derived from a dichloride of the dimethyl sulphide series gave an alkaline filtrate when sulphuric acid was removed by the action of baryta. The liquid left, on spontaneous evaporation, a brownish semi-solid residue, but Blomstrand states that the substance could not be obtained in a condition suitable for analysis. Imagining that the hydroxyl groups were attached to platinum, he gave the formula  $\text{Me}_2\text{S} \gg \text{Pt} \begin{smallmatrix} \text{OH} \\ \text{OH} \end{smallmatrix}$ , although he considered that the sulphate belonged to the  $\alpha$ -series. Owing, probably, to the gummy nature of his product, Blomstrand failed to follow up his observation by investigating the action of acids upon this substance, contenting himself with the remark that the base absorbed carbon dioxide.

Blomstrand found that either the  $\alpha$ - or the  $\beta$ -dichloride, when treated with aqueous silver sulphate and filtered, gave a solution of a sulphate which yielded a dibromide (m. p.  $118^\circ$ ) on treatment with potassium bromide. Klason, who gives m. p.  $124^\circ$ , states that this is an  $\alpha$ -dibromide and that the same substance is produced by the interaction of alcoholic potassium bromide with either dichloride. We now find that the interaction of the  $\beta$ -dichloride with silver sulphate and potassium bromide in the cold gives the pure  $\beta$ -dibromide (m. p.  $95^\circ$ ), identical with that produced by the interaction of the  $\beta$ -dichloride and alcoholic potassium bromide, and also with that prepared by neutralising the  $\beta$ -base with hydrobromic acid. The  $\alpha$ -dichloride does not interact either with alcoholic potassium bromide or with aqueous silver sulphate at the ordinary temperature; if, however, the latter mixture is boiled, some diethyl sulphide is

evolved (probably from the unstable  $\alpha$ -sulphate), and the aqueous diethyl sulphide then converts the remaining  $\alpha$ -dichloride into the  $\beta$ -isomeride, which interacts with the production of  $\beta$ -sulphate. It is evident, therefore, that Blomstrand and Klason must have heated the reaction mixture containing  $\alpha$ -dichloride, thereby producing  $\beta$ -dichloride, and also that they must at some stage have heated to at least  $95^\circ$  the  $\beta$ -dibromide prepared from the  $\beta$ -dichloride, thereby converting it into the  $\alpha$ -dibromide. These puzzling differences of opinion are therefore to be referred to the occurrence of inter-transformation between members of the  $\alpha$ - and the  $\beta$ -series.

Further convincing evidence in favour of our structures for the  $\alpha$ - and  $\beta$ -compounds has been obtained by the following methods. When chlorine is added to either of the isomeric dichlorides, conversion into the tetrachloride occurs. Our formulæ indicate that the  $\alpha$ -dichloride should give rise to the octahedral form (XI), whereas the  $\beta$ -dichloride should yield the tetrahedral form (XII). We should expect these compounds to differ in properties as profoundly as do the isomeric dihalides. Moreover, (XII) should become transformed to (XI) by means similar to those which effect the change  $\beta$ -dihalide  $\rightarrow$   $\alpha$ -dihalide.

Blomstrand states that no isomerism exists amongst the tetrahalides. He prepared the same yellow tetrachloride (m. p.  $175^\circ$ ) by the addition of chlorine to either dichloride, and he obtained similar results with the tetrabromides, tetraiodides, and a series of tetrahalides containing mixed halogens. We find, however, that the  $\alpha$ -dichloride gives rise quantitatively to a yellow crystalline  $\alpha$ -tetrachloride (XI), m. p.  $198^\circ$ , whilst the  $\beta$ -dichloride gives, also quantitatively, a paler yellow crystalline  $\beta$ -tetrachloride (XII), which melts at  $133^\circ$  and immediately resolidifies, forming the  $\alpha$ -tetrachloride (XI). The  $\beta$ -tetrachloride is transformed to the  $\alpha$ -isomeride on being boiled for a few minutes in ethyl or methyl alcohol, although by very rapid crystallisation it may be obtained unchanged from solution in the former solvent. Like the  $\alpha$ -tetrachloride, however, it is unaltered by crystallisation from hot benzene, a non-ionising solvent. The transformation of the  $\beta$ - to the  $\alpha$ -tetrachloride is therefore an ionic reaction which can be brought about by raising the temperature or by the use of a polarising solvent; and this is precisely what could be predicted from inspection of the formulæ (XII) and (XI).

The  $\alpha$ - and  $\beta$ -tetrabromides were prepared in an analogous manner. They are similarly inter-related, but the transformation of the  $\beta$ - to the  $\alpha$ -form is even more readily effected than it is among the tetrachlorides.

When the  $\beta$ -tetrahalides are kept in the solid state their melting points tend to rise, whilst those of the  $\alpha$ -tetrahalides appear to fall slightly. It would seem, therefore, that close parallelism exists among the  $\alpha$ - and  $\beta$ -dihalides and the corresponding tetrahalides, dynamic equilibria being set up in both cases. The  $\alpha$ -tetrahalides may be regarded as bis-dipolar compounds in which each platinum atom bears a double negative charge, whilst the sulphur atoms are each positively charged, this picture giving complete analogy with the accepted formulation of chloroplatinic acid except that the positively charged atoms are in that case free instead of being bound to the platinum atom by covalencies. Alternatively, the  $\alpha$ -tetrahalides may be regarded as containing each two co-ordination linkings between platinum and the sulphur atoms, as in the  $\alpha$ -dihalides.

It may be urged that the planar formulæ of Werner also account satisfactorily for the existence of two tetrachlorides, which would necessarily have the formulæ (XIII) and (XIV). Although we

considered that these formulæ, which might well represent difficultly interchangeable forms, could not account for the experimental results as convincingly as did (XI) and (XII), yet further evidence seemed necessary to prove finally the inadequacy of Werner's supposition. This was obtained from the results of an investigation of the dichlorodibromides.

On the planar hypothesis, if no spontaneous rearrangements of valencies occur, by adding chlorine to the  $\alpha$ -dibromide a dichlorodibromide (XV) should be produced which should differ from that

(XVI) obtained on adding bromine to the  $\alpha$ -dichloride. On our hypothesis, however, the two substances should be identical; and we find that this is indeed the case, the sole product being (XX).

As products of the corresponding changes in the  $\beta$ -series, the planar hypothesis demands, respectively, the two substances (XVII)

and (XVIII), which should be identical, but different from either (XV) or (XVI). We find that neither of these demands is satisfied.\* Labile tetrahedral forms, (XIX) and (XXI), are in both cases initially produced, which may readily be caused to change into the octahedral form (XX), and this is identical with the dichlorodibromide from the two  $\alpha$ -dihalides. There is thus, finally, only one dichlorodibromide from the four sources, and the order in which the two different halogens are added is immaterial. The labile forms (XIX) and (XXI) are different, although closely similar, substances, whose properties show that they belong to the  $\beta$ -tetrahalide series; whilst (XX) is, of course, an  $\alpha$ -tetrahalide.

A curious distinction was noticed between the  $\alpha$ - and  $\beta$ -compounds of both the di- and the tetra-halide series: the  $\alpha$ -compounds are without exception "electrified" when rubbed upon glass with a bone spatula, the particles scattering strongly when detached from the glass in the attempt to collect them; but the pure  $\beta$ -compounds, dried under the same conditions, do not become "charged." A small proportion of  $\alpha$ -compound present as impurity in a  $\beta$ -compound may be detected in this manner. We are not aware that this

\* Even if we suppose that Werner's configurations should be reversed, the  $\alpha$ -compounds being *trans*- and the  $\beta$ -compounds *cis*-planar forms, anomaly still persists.

phenomenon has been noticed before in connexion with isomeric series. The triboelectric character of the  $\alpha$ -compounds is presumably to be ascribed to asymmetry of crystalline structure.

The conclusion emerges from our experiments that virtually quadrivalent platinum in this series is of tetrahedral space structure, and that, when this is converted into the octahedral form, the two entering groups take up exclusively *cis*-positions. In other words, the octahedron is a simple derivative of the tetrahedron, without rearrangement of groupings, the six valency electrons of platinum having directions which are approximately fixed in space. This conclusion is entirely in accord with the results of Pope and Neville (J., 1902, 81, 1552) in connexion with octahedral sulphur and selenium. They find, for example, that, when mercuric iodide is added to optically active phenylmethylselenitine iodide, complete racemisation is produced, showing that the groups HgI and I must take up *cis*-positions:

The present experiments show, further, that tetrahedral platinum must be regarded as derived from the planar bivalent form by the similar *cis*-addition of groups, whence it follows that the valencies of platinum in platinous chloride are inclined at an angle of some  $90^\circ$ . It is improbable, therefore, that in passing from bivalent to quadrivalent (or quadricovalent) and to octahedral platinum the entering groups take up at either stage other than neighbouring positions of the developed octahedron; and it becomes unnecessary to suppose that the directions in space of the six valencies around the platinum atom are ever modified:

There is thus a possibility that the skew tetrahedron representing, *e.g.*, an  $\alpha$ -dihalide may be sufficiently permanent to confer molecular asymmetry. This aspect is under examination.

If it be accepted that in the  $\beta$ -compounds of this series the halogens are united with sulphur and not with platinum, far-reaching questions are at once raised. The case of the platinamines is so similar to that at present being considered as to suggest that the

structure must be analogous in both, and it would therefore follow that in the true  $\beta$ -series of platinamines the halogen atoms are united with nitrogen and should be capable of replacement by hydroxyl to give strongly basic substances, e.g.,  $\text{Pt} \begin{smallmatrix} \text{NH}_3 \cdot \text{OH} \\ \text{NH}_3 \cdot \text{OH} \end{smallmatrix}$ .

Evidence that a base of this nature can indeed be produced was put forward by Odling many years ago (*Chem. News*, 1870, **21**, 289), but the significance of his experiments appears to have been overlooked. It seems clear that the structures of many other amines must be re-examined in the light of these results, and we are now engaged in work upon the foregoing platinamines and other substances. We intend also to examine the possibility of resolving into optically active components (i) the halides of the  $\beta$ -series of the form  $\text{Pt} \begin{smallmatrix} \text{SRR}'/\text{Hal} \\ \text{SRR}'/\text{Hal} \end{smallmatrix}$ , in which the sulphur atoms should be centres of asymmetry, and (ii) compounds of type (XX), in which the molecule should be asymmetric on our theory but not on that of Werner.

#### EXPERIMENTAL.

*Preparation of the Isomeric Dichlorides.*—Potassium chloroplatinite, dissolved in about 5 times its weight of water, was shaken with a slight excess above 2 mols. of diethyl sulphide. (a) If the  $\alpha$ -dichloride was required, the yellow precipitate, which consisted mainly of this isomeride, was removed after 2 hours, and the  $\alpha$ -dichloride was crystallised from light petroleum (b. p. 40–60°), in which the  $\beta$ -isomeride did not dissolve. The aqueous mother-liquor, after concentration at the ordinary temperature, deposited yellowish-white needles of the  $\beta$ -dichloride. As soon as the aqueous liquid commenced to deposit potassium chloride, it was extracted with chloroform, which removed the remaining isomeric dichlorides. In one instance, pure  $\alpha$ -dichloride was obtained on evaporation of the chloroform extract. (b) If the  $\beta$ -dichloride was required, the yellow precipitate (above) was kept with the mother-liquor in a closed flask for a day, whereupon most of it redissolved. The filtrate from undissolved material (a mixture of the two dichlorides), when evaporated at the ordinary temperature or when freed from ethyl sulphide by passage of air through the liquid, yielded the pure  $\beta$ -dichloride. The residual liquid was finally treated as in (a). The total yield of the two isomerides was almost quantitative.

The  $\alpha$ -dichloride (VII), m. p. 106–108°, is insoluble in water, but readily soluble in ether, chloroform, benzene, and other organic solvents. It separates from light petroleum in bright yellow platelets, and from benzene in large yellow prisms which are without solvent of crystallisation. It crystallises well from alcohol in

prismatic needles (Found: C, 21.55; H, 4.5; Pt, 43.7; *M*, cryoscopic in benzene, 434. Calc. for  $C_8H_{20}Cl_2S_2Pt$ : C, 21.5; H, 4.5; Pt, 43.7%; *M*, 446.5). It reacts rather slowly with silver nitrate in alcoholic solution; after 2 days, the filtrate from silver chloride gives with potassium chloride a mixture of the  $\alpha$ - and the  $\beta$ -dichloride.

The  $\beta$ -dichloride (VIII) melts at 106–107° and is almost white. It is appreciably soluble in water and readily soluble in chloroform. In benzene it first dissolves and then separates in large, light yellow prisms, which often show square faces, containing 1 mol. of benzene of crystallisation which is lost on exposure to the atmosphere or at 60° (Found:  $C_6H_6$ , 14.2. Calc.:  $C_6H_6$ , 14.9%). The  $\beta$ -dichloride is only sparingly soluble in ether or in light petroleum. When melted, it gives after solidification a mixture of the  $\alpha$ - and the  $\beta$ -dichloride (Found, for solvent-free  $\beta$ -dichloride: C, 21.65; H, 4.55; Pt, 43.75; *M*, cryoscopic in benzene, 438).

When the  $\alpha$ - and the  $\beta$ -dichloride are mixed, there is very marked depression of the melting point.

*Interconversion of the Isomeric Dichlorides.*—The  $\alpha$ -dichloride is partly converted into the  $\beta$ -isomeride on being heated either alone or in alcoholic solution, or much more completely by Blomstrand's method of treating it with further aqueous diethyl sulphide, preferably in the warm (Klason), which causes it to enter into colourless solution in proportions so high as to suggest the formation of a new soluble complex with diethyl sulphide stable only in presence of an excess of the sulphide. The  $\beta$ -dichloride is partly converted into the  $\alpha$ -isomeride on being melted or on being allowed to remain in solution in benzene for some weeks. When kept, each of the crystalline dichlorides slowly reverts to a mixture of both.

*Action of Moist Silver Oxide on the Isomeric Dichlorides.*—(1) The  $\alpha$ -dichloride, ground in a glass mortar with excess of silver oxide and a little water, was only very slowly changed, with production of free diethyl sulphide, silver chloride, and insoluble platinum oxide or hydroxide. After 48 hours, the filtrate showed no alkalinity to litmus and gave no precipitate with dilute hydrochloric acid except a negligible trace of silver chloride. The precipitate, dried at the ordinary temperature and extracted with benzene, gave some unchanged  $\alpha$ -dichloride. The insoluble residue was shown to contain both silver chloride and platinum oxide or hydroxide.

(2) The  $\beta$ -dichloride reacted rapidly when treated with silver oxide in the same manner, the change being complete in less than  $\frac{1}{2}$  hour. The clear, faintly yellow filtrate from silver oxide and chloride had no odour of diethyl sulphide. It was strongly alkaline to litmus, and when neutralised with dilute hydrochloric acid gave a crystalline precipitate of the pure  $\beta$ -dichloride. The aqueous solution of this

$\beta$ -base, when evaporated to dryness in a vacuum over phosphoric oxide at the ordinary temperature, gave pale yellow hygroscopic crystals of *platinumbisdiethylsulphonium hydroxide* (IX), which, like the aqueous solution, soon absorbed carbon dioxide if exposed to air (Found, in base exposed to air as little as possible : C, 23.85; H, 5.15; Pt, 47.3, 47.75.  $C_8H_{22}O_2S_2Pt$  requires C, 23.45; H, 5.4; Pt, 47.7%). The dried base was easily soluble again in water or in ethyl alcohol. Hydrogen sulphide produced a brown precipitate of a sulphide of platinum, diethyl sulphide being liberated.

By neutralising the aqueous solution of the  $\beta$ -base with aqueous acids, the following salts, shown to be of the  $\beta$ -series by the reactions briefly summarised below, were prepared.

The  $\beta$ -dibromide,  $Pt(SET_2Br)_2$ , separated from alcohol in pale yellow, domed prisms, m. p.  $93-95^\circ$ ; the melt resolidified and then remelted at  $128-129^\circ$ . The substance was identical with a specimen of  $\beta$ -dibromide prepared by a second method, *viz.*, the action of alcoholic potassium bromide in the cold upon the  $\beta$ -dichloride, also dissolved in alcohol; a mixed m. p. of the two specimens showed no depression. A third method, the action (which is rapid) of moist silver sulphate upon the  $\beta$ -dichloride in the cold, followed by filtration and addition of aqueous potassium bromide to the filtrate, gave identically the same substance. The  $\beta$ -dibromide is more soluble in benzene than the corresponding dichloride (Found : Pt, 36.8.  $C_8H_{20}Br_2S_2Pt$  requires Pt, 36.45%). It slowly reverts to the  $\alpha$ -isomeride when kept, and more rapidly when left in contact with alcohol. The structure was checked by the following reactions :

The  $\alpha$ -dibromide,  $PtBr_2(SET_2)_2$ , prepared by heating the  $\beta$ -dibromide at  $100^\circ$  for a few minutes, the transformation being nearly quantitative, crystallised from ethyl alcohol in large, golden-yellow, hexagonal spangles, m. p.  $129^\circ$  (Found : Pt, 36.25%). An alcoholic solution of potassium bromide was without action upon the  $\alpha$ -dichloride : even when the liquid was warmed for a few minutes, the dichloride was recovered unchanged.

The  $\beta$ -oxalate (X) formed colourless transparent crystals when its aqueous solution was allowed to evaporate. It was very soluble in water, the solution being neutral to litmus and giving with lime-water a deposit of calcium oxalate and a solution of the  $\beta$ -base, from which, after filtration, the addition of hydrochloric acid precipitated the pure  $\beta$ -dichloride. The latter is also precipitated by direct addition of hydrochloric acid to a solution of the  $\beta$ -oxalate. The  $\beta$ -oxalate melts near  $60^\circ$  if heated slowly, but the melt is not clear and partial resolidification occurs, the solid melting again near  $95^\circ$ .

Probably partial transformation to an  $\alpha$ -form takes place at the lower temperature. The substance is in part soluble in benzene, separating as an oil which solidifies on standing to a crystalline mass apparently identical with the initial  $\beta$ -oxalate. For analysis it was crystallised from water and dried over phosphoric oxide (Found : C, 25.7; H, 4.4; Pt, 42.25.  $C_{10}H_{20}O_4S_2Pt$  requires C, 25.9; H, 4.35; Pt, 42.1%).

A sulphate crystallising with  $7H_2O$  was prepared by Blomstrand (*loc. cit.*) from either dichloride by treating it with aqueous silver sulphate, and hence he prepared what we now know to be the  $\alpha$ -dibromide, by treatment with potassium bromide. Klason afterwards showed that Blomstrand's  $\alpha$ -dichloride contained 20% of  $\beta$ -dichloride, to which its behaviour (above) is now shown to be due.

Although Blomstrand correctly assigned his sulphate to the  $\beta$ -series, he did so because he prepared from it a dibromide which he thought, incorrectly, to be a  $\beta$ -compound. In reality, he must have obtained the  $\beta$ -dibromide which he unwittingly transformed to the  $\alpha$ -isomeride by heating the solution at some stage. We prepared the  $\beta$ -sulphate,  $Pt \begin{smallmatrix} SEt_2 \\ SEt_2 \end{smallmatrix} SO_4$ , from the  $\beta$ -dichloride with silver sulphate and found (p. 354) that its aqueous solution precipitated the pure  $\beta$ -dibromide on treatment in the cold with aqueous potassium bromide. The same result was obtained when the  $\beta$ -base was neutralised with sulphuric acid, and potassium bromide added to the solution. The sulphate is therefore certainly a  $\beta$ -sulphate. We found, also, that the  $\alpha$ -dichloride was unaffected in the cold by moist silver sulphate after 16 hours. If, however, the mixture was heated at  $100^\circ$  for some minutes, diethyl sulphide was evolved, and this in the presence of water changed some unaltered  $\alpha$ -dichloride to the  $\beta$ -isomeride, which, in turn, reacted with silver sulphate to produce a proportion of  $\beta$ -sulphate. The  $\alpha$ -sulphate, therefore, is probably unstable; and, in any case, it cannot be prepared in this manner.

The  $\beta$ -dichromate, prepared from the  $\beta$ -base with potassium dichromate and sulphuric acid, separated from benzene in dark red needles, m. p.  $140^\circ$ . It was decomposed by hot ethyl alcohol.

*Attempts to prepare the Isomeric Di-iodides.*—Blomstrand prepared a di-iodide (m. p.  $136^\circ$ ) from the sulphate with potassium iodide. He considered this to be a  $\beta$ -compound, but Klason assigned it to the  $\alpha$ -series. The following experiments indicate that the  $\alpha$ -di-iodide melts at  $142$ – $144^\circ$  and that the  $\beta$ -di-iodide changes into it without melting. Attempts to isolate a pure specimen of the  $\beta$ -di-iodide have been fruitless.

(1) Alcoholic potassium iodide reacted in the cold with an alcoholic solution of the  $\alpha$ -dichloride (contrast the behaviour of potassium bromide, p. 361). Orange-red crystals of a di-iodide were obtained, which, after extraction by cold benzene, reddened near  $115^\circ$  and melted at  $141$ – $143^\circ$ . By crystallisation from alcohol, square orange prisms in serrated clusters, m. p.  $142$ – $144^\circ$ , were obtained. This substance gave no  $\beta$ -base with moist silver oxide; the mixture slowly evolved diethyl sulphide. The substance was therefore the  $\alpha$ -di-iodide. When the above reaction mixture is heated, some diethyl sulphide is evolved.

(2) Alcoholic potassium iodide reacted at once in the cold with an alcoholic solution of the  $\beta$ -dichloride, giving a di-iodide (m. p.  $138$ – $140^\circ$ ), which was apparently identical with the former substance. Silver oxide, however, acted upon it to give a very small proportion of  $\beta$ -base.

(3) The action of hydriodic acid (colourless) on a solution of the  $\beta$ -base at the ordinary temperature gave a product (orange-yellow, m. p.  $138$ – $140^\circ$ ), which crystallised from alcohol in the same form, and did not depress the m. p. of the former product. It gave no  $\beta$ -base with moist silver oxide.

When the reaction was carried out at  $0^\circ$ , a product was obtained (m. p.  $138$ – $140^\circ$ ) which, after crystallisation from alcohol (Found: Pt, 31.2. Calc. for  $C_8H_{20}I_2S_2Pt$ : Pt, 31.0%), gave a considerable proportion of  $\beta$ -base, together with diethyl sulphide, when treated with moist silver oxide (16 hours). The original material was therefore probably a mixture of the  $\alpha$ - and the  $\beta$ -di-iodide.

In another similar experiment, in which the  $\beta$ -base was treated below  $0^\circ$  with aqueous potassium iodide and then with a slight excess of dilute sulphuric acid, a brownish-yellow di-iodide, m. p.  $132$ – $135^\circ$ , was obtained. From methyl alcohol, it separated in minute yellowish-brown crystals, m. p.  $141$ – $143^\circ$ , which partly melted if plunged into a bath at  $125^\circ$ . With moist silver oxide, it gave a small proportion of  $\beta$ -base.

(4) When the  $\beta$ -dichloride was decomposed with aqueous silver sulphate, and to the filtered solution of the  $\beta$ -sulphate an excess of aqueous potassium iodide was added below  $0^\circ$ , a yellow di-iodide was precipitated. After extraction with benzene, however, the orange product was indistinguishable from the  $\alpha$ -di-iodide.

It must be concluded from these experiments that the  $\beta$ -di-iodide is easily transformed to the  $\alpha$ -isomeride.

*Tetrahalides.*—The  $\alpha$ -tetrachloride (XI) was prepared in quantitative yield by passing a slight excess of chlorine at  $0^\circ$  or at the ordinary temperature into a chloroform or benzene solution of the  $\alpha$ -dichloride. The crude product had m. p. ca.  $196^\circ$  (decomp.); it

separated from ethyl alcohol in lemon-yellow needles or in massive rectangular tablets belonging to the cubic system. The pure substance melts and decomposes at  $198^{\circ}$ , with sintering from  $188^{\circ}$ . It is readily soluble in benzene, from which it crystallises unchanged in cubic tablets (Found: C, 18.85; H, 4.25; Pt, 37.5.  $C_8H_{20}Cl_4S_2Pt$  requires C, 18.55; H, 3.9; Pt, 37.7%).

The  $\beta$ -tetrachloride (XII) was similarly obtained from the  $\beta$ -dichloride. The crude product melted between  $120^{\circ}$  and  $130^{\circ}$  but contained some  $\alpha$ -tetrachloride. Crystallised from benzene, in which it is much less soluble than the  $\alpha$ -isomeride, it separates in jagged, light-yellow prisms or (more slowly) in compact prisms capped by pyramids, the crystals being cubic (Found: C, 18.75; H, 4.2; Pt, 37.6, 37.9%). The powdered crystals melt completely when plunged into a bath at  $135^{\circ}$ ; the yellow melt then resolidifies, the solid melting again near  $195^{\circ}$ . When boiled with methyl or ethyl alcohol for a short time, it is changed to the  $\alpha$ -tetrachloride, which separates in the pure state; but it may be crystallised from ethyl alcohol by momentary heating and cooling, whereupon it separates in small, greenish-yellow, glistening platelets, melting first at  $133^{\circ}$  and then near  $198^{\circ}$ . The mixed m. p. of the two specimens of  $\alpha$ -tetrachloride, prepared (i) directly and (ii) through the  $\beta$ -tetrachloride, was the same as that of either.

The  $\alpha$ -tetrabromide,  $PtBr_4(SET_2)_2$ , obtained quantitatively by the action of bromine on a chloroform solution of the  $\alpha$ -dibromide, crystallises from ethyl alcohol in lustrous scarlet needles, sintering from  $192^{\circ}$  and melting at  $198^{\circ}$  (decomp.) (Found: C, 14.0; H, 2.95; Pt, 28.0.  $C_8H_{20}Br_4S_2Pt$  requires C, 13.8; H, 2.9; Pt, 28.1%); it is much more readily soluble in benzene than the  $\beta$ -form.

The  $\beta$ -tetrabromide,  $PtBr_2(SET_2Br)_2$ , was obtained by adding at  $0^{\circ}$  a slight excess of bromine in pure chloroform or, better, in benzene, to a solution of the  $\beta$ -dibromide in the same solvent. The crude product melted completely and resolidified in a few seconds if plunged into a bath at  $135^{\circ}$ , but if plunged at  $115^{\circ}$  and then heated it was changed without melting to the  $\alpha$ -isomeride. It separated from warm benzene in light red, flat, prismatic needles (Found: C, 13.6; H, 2.95; Pt, 27.8, 28.05%), which melted if plunged at  $125^{\circ}$  and then resolidified to the  $\alpha$ -compound, melting again at about  $195^{\circ}$ . When crystallised once from ethyl alcohol, it was changed to the  $\alpha$ -form, the m. p. and mixed m. p. with that substance being identical. This  $\beta$ -compound is more easily changed to the  $\alpha$ -form than is the  $\beta$ -tetrachloride. It should not be heated longer than a few seconds to effect solution even with benzene.

*Dichlorodibromides.*—In the following reactions addition of halogen to the dihalides was carried out in solution in alcohol-free

chloroform, in pure benzene, or in a mixture of chloroform and ligroin. Experiments indicated that benzene was the best solvent and that undue excess of halogen was to be avoided. In all cases the solvent was at once evaporated at the ordinary temperature, the product was quickly dried, and its m. p. observed. The whole product was then crystallised from pure benzene with momentary heating, and the crops were examined as to colour, crystalline form, and m. p. In all cases identities were checked by these means and by mixed m. p.'s and analyses.

(1) *Action of chlorine on the  $\alpha$ -dibromide.* The crude  $\alpha$ -dichlorodibromide (XX) separated as a mass of crystals, m. p. 190—193° (decomp.; after sintering). Crystallised from benzene, in which it was readily soluble, it separated in massive orange-red rhombs showing square and hexagonal faces. The powdered substance, which was strongly triboelectric, showed no signs of melting when plunged into a bath at 140°. It softened somewhat above 185° and melted at 190—193° (decomp.). It separated readily from ethyl alcohol in prismatic crystals, m. p. 192—193° (decomp.); but examination of the mother-liquors showed that the substance is partly reduced by alcohol, the use of which is therefore to be avoided in this connexion (Found: Pt, 31.8, 32.1, 32.3.  $C_8H_{20}Cl_2Br_2S_2Pt$  requires Pt, 32.2%). Even from benzene the substance should not be recrystallised more than once.

(2) *Action of bromine on the  $\alpha$ -dichloride.* The crude product consisted of crystals of the same  $\alpha$ -dichlorodibromide, m. p. 189—192° (decomp.) after sintering. The crystals from alcohol or from benzene were those of (XX). Analyses were carried out after one crystallisation from benzene (Found: C, 16.1; H, 3.65; Pt, 32.15, 32.1%) and then after a recrystallisation from the same solvent (Found: Pt, 31.8. Calc.: C, 15.8; H, 3.3; Pt, 32.2%).

(3) *Action of chlorine on the  $\beta$ -dibromide.* The crude orange-yellow crystalline product, which was thrown out of solution when chlorination was carried out at 0° in benzene, consisted of the  $\beta$ -dichlorodibromide (XIX), melting completely when plunged into a bath at 105° and then resolidifying and again melting near 188°. When crystallised from ethyl alcohol, it was completely changed to the  $\alpha$ -isomeride (XX); but it could be crystallised by momentary warming with benzene, from which it separated in small, dark yellow, complex prisms or in rhomboidal platelets melting if plunged at 110°, or near 120° (incompletely) if heated in the ordinary way (Found, in different preparations: C, 15.5; H, 3.4; Pt, 31.8, 32.1%). A mixture with the isomeric  $\beta$ -dichlorodibromide (XXI, below), m. p. 125°, melted completely if plunged into a bath at 115°, but if heated in the ordinary way melted only at 190—192°. This

dichlorodibromide was much less permanent than (XXI), changing, even on a few minutes' boiling with benzene, into the  $\alpha$ -isomeride, which was shown to be identical with (XX).

(4) *Action of bromine on the  $\beta$ -dichloride.* The crude product consisted of a mass of salmon-yellow prisms of the  $\beta$ -dichlorodibromide (XXI), completely melting when plunged at  $128^\circ$ , resolidifying, and again melting near  $188^\circ$ . Crystallised from benzene, in which it was much less soluble than the  $\alpha$ -isomeride, it separated in complex prisms, m. p.  $125^\circ$  (with resolidification), of salmon-yellow shade, showing rhomboidal faces (Found: C, 15.8; H, 3.35; Pt, 32.25%). One crystallisation from ethyl alcohol or 10 minutes' heating in solution in benzene changed it completely to the  $\alpha$ -form, which was again proved to be identical with (XX). This  $\beta$ -dichlorodibromide, which is of darker shade than (XIX), can be kept in the solid state for several days without suffering more than slight change to the  $\alpha$ -form.

All four of the  $\beta$ -tetrahalides prepared were easily wetted and decomposed by concentrated nitric acid, in marked contrast to the  $\alpha$ -tetrahalides, which were remarkably stable to the warm reagent.

In solution, the  $\alpha$ -tetrahalides are probably in equilibrium with small proportions of the partly ionised  $\beta$ -tetrahalides, for the  $\alpha$ -dichlorodibromide tends to pass after many crystallisations from benzene into an  $\alpha$ -chlorotribromide, large ruby-red prisms from benzene, m. p.  $196^\circ$  (decomp.) (Found: C, 15.05; H, 3.2; Pt, 30.0, 29.9.  $C_8H_{20}ClBr_3S_2Pt$  requires C, 14.75; H, 3.1; Pt, 30.0%).

*Equimolecular mixture of the  $\alpha$ -tetrachloride and  $\alpha$ -tetrabromide.* The mixed substances, intimately ground together, had the same m. p. as the  $\alpha$ -dichlorodibromide (XX), and it was practically unaltered when the latter was added to the mixture. Crystallisation from alcohol (Found: Pt, 31.7%) or benzene gave products very similar to those obtained by crystallising (XX) from the same solvent. It will be seen that the  $\alpha$ -tetrachloride does not depress to a normal extent the m. p. of the  $\alpha$ -tetrabromide, and this phenomenon is to be expected (compare J., 1928, 512). It is uncertain, therefore, whether an equimolecular mixture of these substances would depress to any noticeable extent the m. p. of a true  $\alpha$ -dichlorodibromide (XX). There remains the possibility that (XX) is produced when the mixture crystallises, or that mixed crystals of the two tetrahalides, indistinguishable from (XX) by the means employed, are formed. Again, it is possible that at temperatures near  $180^\circ$  the  $\alpha$ -dichlorodibromide (XX) becomes changed into an equimolecular mixture of the two simple  $\alpha$ -tetrahalides. The matter will be further examined.

*Physico-chemical Measurements.*

*Molecular Weights.*—These determinations were made to show that the isomerism of the  $\alpha$ - and  $\beta$ -salts could not be explained by supposing that one was a polymeride of the other, this view of the relationship of certain 4-co-ordinated platinum compounds being maintained by Reihlen and Nestle (*Z. anorg. Chem.*, 1927, **159**, 343; *Annalen*, 1926, **447**, 21, 312, 448).

The benzene used was supplied by the British Drug Houses, Ltd., especially for molecular-weight determinations. Traces of moisture were removed by distillation over phosphoric oxide (compare Sidgwick, J., 1920, **117**, 1340). A determination with naphthalene in this solvent gave  $M$ , 128.2. The  $\alpha$ - and  $\beta$ -salts were analytically pure and their m. p.'s were unchanged by successive recrystallisations from light petroleum (b. p. 40–60°) in the case of the  $\alpha$ -, and from hot benzene in the case of the  $\beta$ -form, benzene of crystallisation being afterwards removed [Found: for  $\alpha$ -salt,  $M$ , 434; for  $\beta$ -salt,  $M$ , 438.  $\text{PtCl}_2(\text{SEt}_2)_2$  requires  $M$ , 446.5].

*Conductivity Measurements.*—These determinations, which required special care on account of the small solubility of the substances in water, could not be accurately made by the use of a Kohlrausch slide wire. To overcome these and other disadvantages, a substitution bridge, constructed by Messrs. Tinsley and Son to the specifications of Mr. H. M. Spittle of this Department, was employed.

The arrangement of the apparatus is outlined in Fig. 1.

A valve oscillator, V, producing a pure sine wave of 1000 cycles, formed the source of alternating current, all capacity effects being eliminated by the use of two fixed inductances and one variable inductance, I, the effective inductance of which balanced the capacity of the liquid in the conductivity cell, C. Two 2000-ohm non-inductive resistances,  $R_1$  and  $R_2$ , formed two arms of the bridge, the third,  $R_3$ , consisting of a variable non-inductive resistance of 0–11,000 ohms. The fourth contained another variable non-inductive resistance of 0–10,000 ohms,  $R_4$ , which could be coupled with the cell, and, where necessary,  $R_3$  and  $R_4$  were increased by the introduction of additional, standardised non-inductive resistances. Readings were made by altering  $R_3$ , so that a balance was obtained with  $R_4$  about 50 ohms, when in series with the cell. By eliminating the cell, the true value of  $R_3$  was determined, the difference between the two readings giving the actual resistance of the cell, although the total resistance of the bridge remained unaltered. In this way successive readings of a resistance of any magnitude never fluctuated by more than 0.1%.

*Conductivity water.* The water used possessed a conductivity of

$3.1 \times 10^{-6}$  mho at  $18^\circ$ , and this did not materially increase during the course of several weeks.

*Conductivity vessel.* The conductivity vessel was constructed to hold 5 c.c. of liquid and fitted with a ground-glass stopper. After being washed with conductivity water, the vessel was dried in a vacuum desiccator, which was then opened in a slow stream of carbon dioxide-free air. Dilutions ( $v$ ) are given in litres per g.-mol., and the temperature was  $18^\circ$  in each case.

*Results.* Solutions of the  $\beta$ -dichloride were prepared in two ways: (a) by warming to  $30^\circ$ , followed by cooling to  $18^\circ$  (the solution was not acid to litmus or Congo-red paper), and (b) by shaking the salt (2 mg.) with water (5 c.c.) in the cell over-night.

	$v$ .	$\mu$ .		$v$ .	$\mu$ .
$\beta$ -Dichloride (solution a)	658.2	43.4	$\beta$ -Oxalate	355.3	18.6
" ( " b)	1037	50.9	$\beta$ -Base	276.4	11.4
" ( " b)	1178	50.4		115.0	7.2

Werner and Herty's conductivity data (*Z. physikal. Chem.*, 1901, 38, 347) for the diammines of platinous chloride are of interest in connexion with our results for the dichloride. Their initial values for  $\mu$  for the *cis*-form were low ( $\mu$  2–4) provided that the solution was prepared at  $25^\circ$ , but if it was first heated to  $50^\circ$  and then cooled to  $25^\circ$  a value of *ca.* 40 was recorded. Owing to the minute solu-

bility of the *trans*-form in water at 25°, they could not obtain suitable solutions for conductivity measurements by operating at this temperature, but they found that if the salt was dissolved in water at 50° and the solution then cooled to 25°, a conductivity of about 40 was registered. Hence they inferred by analogy with the behaviour of the *cis*-form that, if direct solution could have been effected at 25°, the *trans*-form would have been a non-electrolyte. Their statement that the *cis*- and *trans*-diammines are non-electrolytes is based, therefore, on analogy rather than on direct experimental evidence.

The authors wish to express their thanks to the Department of Scientific and Industrial Research for a grant to one of them (F. G. A.), and to the Chemical Society for their grant in aid of this investigation.

LI.—*The Partial Esterification of Polyhydric Alcohols.*  
*Part X. The Discovery of the First True  $\beta$ -Glyceride,*  
*and the Untrustworthiness of the Supposed Structures*  
*of Certain Diglycerides.*

By ARTHUR FAIRBOURNE.

THE following method of synthesising  $\beta$ -derivatives of glycerol has formerly been regarded as trustworthy for  $\beta$ -esters (Grün, *Ber.*, 1910, 43, 1288), although untrustworthy for  $\beta$ -ethers (Gilchrist and Purves, *J.*, 1925, 127, 2735):

In Part V (*J.*, 1926, 3148), however, it was shown to produce  $\alpha$ - instead of  $\beta$ -esters, and the publication of this result was followed by claims of the discoveries of the first true  $\beta$ -ester of glycerol (Helferich and Sieber, *Z. physiol. Chem.*, 1927, 170, 31; 1928, 175, 311) and also of the first true  $\beta$ -ether (Hill, Whelen, and Hibbert, *J. Amer. Chem. Soc.*, 1928, 50, 2235; Hibbert, Whelen, and Carter, *ibid.*, 1929, 51, 302).

In Part IX (*J.*, 1929, 2232) it was shown, on the other hand, that the method was trustworthy for the preparation of the  $\beta$ -ethers, thus precisely reversing the relative values assigned to the reaction in

the literature; and it was incidentally realised that the credit of synthesising the first true  $\beta$ -ether of glycerol is apparently due to Gilchrist and Purves (*loc. cit.*), who, however, mistakenly recorded their experiment as a failure instead of as a success.

An almost parallel re-investigation of this synthesis has now been independently carried out by Hibbert and Whelen (*J. Amer. Chem. Soc.*, 1929, **51**, 1943), who, reasoning from the evidence considered in Part VII of this series, studied the same reactions and reached identical conclusions. These authors, however, effected their final hydrolysis by a modified process which involved a treatment with acid. Since alkaline conditions frequently favour migratory changes, it is very doubtful whether acidic conditions ought thus to be substituted for them, in seeking to prove that migrations could not have occurred in Gilchrist and Purves's work. On the other hand, the introduction of acid has greatly improved the yield obtainable from these reactions, which therefore now constitute a trustworthy process for preparing true  $\beta$ -ethers of glycerol without the formation of their  $\alpha$ -isomerides.

If the conclusion reached in Part V (*loc. cit.*) is correct, that all the preparations of supposed " $\beta$ "-monoglycerides known in 1926 were illusory, Helferich and Sieber would appear to be justified (*loc. cit.*) in claiming that they have now isolated the first true  $\beta$ -glyceride ever obtained.

It is clearly desirable, for this and other reasons, that all supposed esterifications in the  $\beta$ -position of glycerol should be subjected to careful scrutiny, and the present paper consists of an inquiry into some of these cases.

Esters of inorganic acids, such as the nitrates and phosphates, have not normally been contemplated in connexion with the general statements referring to " $\beta$ "-monoglycerides and " $\beta$ "-mono-esters made in this series of papers, but " $\beta$ "-monochlorohydrin has necessarily been taken into consideration, to some extent, as an intermediate product in one of the suggested syntheses investigated in Part V (*loc. cit.*). Prepared by the method of Hanriot (*Ann. Chim.*, 1879, **17**, 76), the particular specimen employed in that investigation was proved by its *p*-nitrobenzoate to consist almost entirely of the unwanted  $\alpha$ -isomeride. Henry (*Bull. Acad. roy. Belg.*, 1897, **33**, 110), however, apparently succeeded in differentiating between samples of these isomerides by reducing them to propylene glycol and trimethylene glycol, respectively. Read and Hurst (*J.*, 1922, **121**, 989) also describe a preparation of the " $\beta$ "-monochlorohydrin, but give no satisfactory proof of the structure of their product. Smith and Samuelsson (*Z. physikal. Chem.*, 1918, **92**, 717; 1920, **94**, 691, 723) have shown that the proportion of the

isomerides which are produced when glycerol and hydrogen chloride react upon one another varies with the conditions adopted.

No record has been found of any attempt to prepare a  $\beta$ -monoglyceride from a veritable specimen of  $\beta$ -monochlorohydrin by the method Grün suggested (*loc. cit.*), although Delaby and Dubois recently contemplated this synthesis (*Compt. rend.*, 1928, **187**, 949) in connexion with their belief that the  $\beta$ -mono-ester predominates when glycerol and formic acid react; nor is it thought likely that such an attempt will succeed, since a preferential production of  $\alpha$ -mono-esters is usual whenever intermediate  $\alpha\beta$ -rings can occur (compare Part V, *loc. cit.*; Part VII, J., 1929, 129; Part IX, *loc. cit.*).

Grün considered, however, that the trustworthiness of his alternative process for preparing  $\beta$ -monoglycerides, based on the reactions discussed at the beginning of this paper, had been experimentally confirmed (*loc. cit.*) by his resulting " $\beta$ "-monolaurin reacting with phenylcarbimide, and by his " $\alpha$ "-monolaurin not doing so.

This reaction has therefore been re-investigated: it is found that both the  $\alpha$ - and the " $\beta$ "-monolaurin prepared by his method can yield diphenylurethanes, which are identical, since no depression of melting point is caused when they are mixed.

Thieme also synthesised a " $\beta$ "-monolaurin by a modification of Grün's process (*J. pr. Chem.*, 1912, **85**, 284):

Comparison of his product with an authentic specimen of  $\alpha$ -monolaurin led him to believe that they were different substances; he consequently extended his researches to include the corresponding " $\alpha\beta$ "- and " $\alpha\gamma$ "-dilaurins, which, again, he found to be different from each other. Finally (*loc. cit.*) he investigated the disintegration of trilaurin by sulphuric acid, and estimated the proportions of the various partly esterified laurins produced in that reaction.

The whole of this work is shown in the following experimental portion to rest on a double fallacy, since the " $\beta$ "-monolaurin obtainable by his method is undoubtedly identical with  $\alpha$ -monolaurin, when pure, and the supposedly isomeric " $\alpha\beta$ "- and " $\alpha\gamma$ "-dilaurins are identical with each other also.

The controversy which arose between Grün and Thieme (*Ber.*, 1912, **45**, 3691; 1913, **46**, 1653, 2198) is thus largely explained: both authors correctly recognised the same material as the one

they had synthesised, and each insisted on the structure which his own preparation appeared to support.

To make the evidence of identity more definite, Thieme's intermediate  $\alpha\gamma$ -di-iodohydrin  $\beta$ -monolaurate has now been synthesised in another way, and obtained for the first time as a solid. This was hydrolysed, like the crude material, to  $\alpha$ -monolaurin, which was again identified by a mixed melting point.

Another supposed  $\beta$ -monoglyceride is " $\beta$ "-monomyristin, isolated by Grün, Schreyer, and Weyrauch (*Ber.*, 1912, 45, 3420). Their preparation has therefore been repeated, and the product compared with an authentic specimen of  $\alpha$ -monomyristin obtained by the method of Fischer, Bergmann, Bärwind, and Pfähler (*Ber.*, 1920, 53, 1589, 1606, 1621). Both are identical.

Further, the corresponding " $\alpha\beta$ "- and " $\alpha\gamma$ "-dimyristins described by Grün and Theimer (*Ber.*, 1907, 40, 1792) have now been prepared by the recommended processes, and the samples obtained are again identical with each other.

A precisely similar case to the laurins and the myristins is that of the margarins, all five of which have recently been described by Thomson (*Trans. Roy. Soc. Canada*, 1926, 20, III, 445):

- |      |                                   |                                   |
|------|-----------------------------------|-----------------------------------|
| I.   | $\alpha$ -Monomargarin            | } m. p. 76°, $n_D^{20}$ 1.441.    |
| II.  | " $\beta$ "-Monomargarin          |                                   |
| III. | " $\alpha\beta$ "-Dimargarin      | } m. p. 70—72°, $n_D^{20}$ 1.439. |
| IV.  | $\alpha\gamma$ -Dimargarin        |                                   |
| V.   | $\alpha\beta\gamma$ -Trimargarin. |                                   |

By analogy with the cases just cited, and also from a consideration of the methods of preparation adopted for these glycerides, it is very probable (see Part V) that (I) and (II) should be identical, and (see Parts VII and VIII) that (III) and (IV) should be identical with each other also.

The eight recorded determinations of physical constants summarised in the above table appear to establish these identities, and make it clear that only two out of the four possible partly esterified margarins have really been isolated. (Mixed melting points would, however, still be desirable in confirmation of these identities.)

Among other similar cases of supposed isomerism, believed to be due to esterification in the  $\beta$ -position, may be mentioned the " $\alpha\beta$ "- and " $\alpha\gamma$ "-dipalmitins and the " $\alpha\beta$ "- and " $\alpha\gamma$ "-distearins.

The " $\alpha\beta$ "- and " $\alpha\gamma$ "-structures are still separately assigned to these diglycerides in authoritative modern works of reference (*e.g.*, Ubbelohde's "*Handbuch der Öle und Fette*," 1929, vol. I, pp. 174—176), and the reactions concerned in their preparations are still often relied upon as satisfactory evidence of constitution (see

Thomson, 1928, *loc. cit.*; Delaby and Dubois, *Compt. rend.*, 1928, **187**, 767, who now record the syntheses of " $\alpha\beta$ "- and " $\alpha\gamma$ "-diformates in these ways; also the work of Grün and Limpächer described below; and the applications of these reactions to the preparations of "symmetrical" and "unsymmetrical" mixed triglycerides by Whitby, J., 1926, 1458, by Humnicki and Lunkiewicz, *Bull. Soc. chim.*, 1929, **45**, 422, and by Weizmann and Haskelberg, *Compt. rend.*, 1929, **189**, 104).

Their syntheses have therefore been re-investigated, and the expected identities experimentally proved.

Thus, in the typical case of the distearins, the " $\alpha\beta$ "-isomeride is described as having been synthesised both from  $\alpha\beta$ -dibromohydrin by Guth (*Z. Biol.*, 1903, **44**, 78) and by Renshaw (*J. Amer. Chem. Soc.*, 1914, **36**, 537), and also from the  $\alpha\beta$ -distearate of monochlorohydrin by Grün and Theimer (*Ber.*, 1907, **40**, 1792):

Repetition of these two processes has now produced specimens of the supposed " $\alpha\beta$ "-distearin, melting, alone or mixed, at 78—79°; but the  $\alpha\beta$ -structure cannot be regarded as confirmed by this agreement (compare Part VII), since the same distearin, again causing no change in mixed melting point, has also been obtained from  $\alpha\gamma$ -dichlorohydrin by a repetition of the synthesis of " $\alpha\gamma$ "-distearin described by Guth (*loc. cit.*).

Fischer (*Ber.*, 1920, **53**, 1621) employed the  $\alpha\beta$ -distearate of moniodohydrin, instead of that of monochlorohydrin, in a reaction which is very similar to one of the three just mentioned, but he diagnosed the unexpected " $\alpha\gamma$ "-structure of his product indirectly from the difference in physical properties of its acetate and of  $\alpha$ -acetoxy- $\beta\gamma$ -distearin synthesised in another way:

The identity of the samples of the " $\alpha\beta$ "- and " $\alpha\gamma$ "-distearins now obtained is thus fully in accord with Fischer's interpretation

of his experiment, and with his prophecy that the " $\alpha\beta$ " mixed diglycerides of Grün and Schreyer (*Ber.*, 1912, **45**, 3420) will probably be found to have the  $\alpha\gamma$ -structure; moreover, it explains Renshaw's confidence (*loc. cit.*) that Hundeshagen (*J. pr. Chem.*, 1883, **28**, 219) must have isolated at least a small quantity of the " $\alpha\beta$ "-isomeride from his direct esterification of glycerol with stearic acid; it explains the similar claim of Kreis and Hafner (*Ber.*, 1903, **36**, 1123); but it discredits, for example, the constitution of the glyceride phosphate recorded by Renshaw and Stephens (*J. Amer. Chem. Soc.*, 1914, **36**, 1770).

No suggestion is now made that both possible isomerides may not be present to some extent in the crude products obtained from any, or indeed from all, of these reactions; all that is claimed in this connexion is that various processes separately recommended for the preparations of the " $\alpha\beta$ "- and " $\alpha\gamma$ "-dilaureins, -dimyristsins, -dipalmitins, and -distearins have produced specimens which, when purified, are identical with their supposed isomerides in every case.

Two of the reactions now under consideration can also give rise to identical glycerol di-ethers (Part VIII, J., 1929, 1151; Gilchrist and Purves, J., 1925, **127**, 2735). Since, in this case, no subsequent wandering of acyl groups can occur, these identical products must result directly from the syntheses themselves, and the explanation would consequently seem limited to the assumption that an  $\alpha\beta$ -oxide is formed (Part IX, *loc. cit.*),

an assumption which is strengthened by the experimental proof that initial substitution of its  $\alpha\beta$ -oxide, epichlorohydrin, for the dichlorohydrin does not affect the identity of the product obtained (Part VIII).

The formation of these intermediate  $\alpha\beta$ -oxides can doubtless occur also during the similar preparations of the glycerol esters. In addition, however, interchanges of acid radicals, with one another and also with different radicals, take place so easily (see Part VII) that an explanation of these changes, not involving a large or difficult movement of heavy radicals such as the stearyl and palmityl groups, is much needed.

If the tendency towards the formation of ortho-esters is taken into consideration (see Parts VII and IX), these changes can readily be represented merely by a rearrangement of valencies in which little or no actual migration or relative movement of the atoms themselves has to be presumed.

If conditions can exist in which the Hantzsch type of carboxyl group (*Ber.*, 1917, 50, 1422; Part VII, *loc. cit.*) actually occurs, the above two formulæ may even become identical,

and, in any case, a tendency towards the transitory formation of such  $\alpha\beta$ -oxidic rings would seem very probable.

It is specially noteworthy, moreover, that these "migrations" appear to take place most readily *while other reactions are in progress*: the "migration" of an acyl radical occurring simultaneously with the elimination of a halogen atom from a glycerol molecule, even if the latter does not contain a hydroxyl group, is frequently experienced (Part VII), but could not previously be explained. Such reactions, however, for example, the formation of identical di-*p*-nitrobenzoates from  $\alpha\beta$ - and  $\alpha\gamma$ -dibromohydrin palmitates (Part VII),

and of identical diphthalimido-compounds from the  $\alpha$ - and  $\beta$ -acetates of halogenohydrins (Part VII),

can easily be represented in this way.

The formation of  $\alpha$ -diglycerides, by the esterification and subsequent elimination of the halogen atoms of  $\alpha$ -monochlorohydrin and  $\alpha$ -monoiodohydrin, discussed earlier in this paper, can similarly be explained,

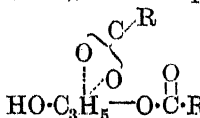

but in such cases, *where a free hydroxyl group is present or is produced*, a somewhat similar explanation has already been put forward tentatively by Fischer (*Ber.*, 1920, 53, 1621), the hydroxyl group being supposed by him to play an essential part in the mechanism of the change.

It is now clear, however, that these migrations occur whether a hydroxyl group is present or absent, and that a wider explanation is therefore required.

The only attempt to apply broadly the tendency towards the formation of ortho-esters to explain migratory changes in glycerides

appears to be that of Grün (*Ber.*, 1921, 54, 290), whose explanation,

however, involves the vague formula  for the

diglycerides themselves, instead of the simple mechanism now suggested.

In addition to complications arising (i) from the formation of intermediate glycidic rings, such as that in epichlorohydrin, mentioned earlier in this paper, and (ii) from the migratory effects just considered, there is also, in most syntheses, (iii) the possibility, due to the presence of metallic compounds, that hydrolyses and re-esterifications will take place rapidly (Fischer, Pfähler, and Brauns, *Ber.*, 1920, 53, 1634; Part III, J., 1925, 127, 2759). It is therefore thought that the  $\alpha\beta$ -formula should be accepted as representing the structure of any particular diglyceride only when optical rotation can be demonstrated, or when some other physical difference from the  $\alpha\gamma$ -isomeride, such as the depression of the latter's melting point, can be proved (compare Part VII).

Even in the event of an optical rotation being detected, caution should still be observed: Grün and Limpächer, for example (*Ber.*, 1926, 59, 1350), synthesised a lecithin from a supposed " $\alpha\beta$ "-distearin, m. p. 69°, the sulphuric ester of which had shown some evidence of containing an asymmetric material. The lecithin they obtained was afterwards found to be indistinguishable from that prepared from  $\alpha\gamma$ -distearin (*Ber.*, 1927, 60, 147). They further synthesised the corresponding kephalins (*ibid.*, p. 151), and were again unable to distinguish between their products.

A preparation of a sample of " $\alpha\beta$ "-distearin, with this melting point, and similarly made from its sulphuric ester, is described in detail by these authors in a later paper (*ibid.*, p. 264), but there is nothing in this description to prove that their product was a satisfactory specimen of the true  $\alpha\beta$ -isomeride as they supposed; it may have consisted, even substantially, of ordinary or  $\alpha\gamma$ -distearin, particularly as they mention that, during its final treatment, crystals were deposited which had the usual melting point of that compound.

The conclusions reached in Part V (*loc. cit.*), that every supposed isolation of a  $\beta$ -monoglyceride then recorded was probably illusory, and in Parts VII and IX (*loc. cit.*), that " $\alpha\beta$ - and  $\alpha\gamma$ -isomerism" in diglycerides is frequently accepted on insufficient evidence, are both thus fully confirmed, so far as the re-examination of " $\beta$ "-esters has yet been carried.

These conclusions, and the experimental evidence previously put

forward in their support, have recently been quoted in several connexions by Hibbert, Whelen, and Carter (*J. Amer. Chem. Soc.*, 1929, **51**, 304, 1602, 1606, 1944, 1945), who stress their importance in reaching an accurate view of the structures of glycerol compounds. It thus becomes increasingly clear that the relative values assigned to the various methods described in the literature for synthesising partly substituted glycerols require to be modified considerably, and a selection has consequently been made below, in accordance with the evidence obtained now and in the previous papers of this series, of what appear to be trustworthy processes for preparing  $\alpha$ -,  $\beta$ -,  $\alpha\beta$ -,  $\alpha\gamma$ -, and  $\alpha\beta\gamma$ -ethers and esters of definite structure:—

(i)  $\alpha$ -*Mono-ethers*, the structures of which were established by Irvine, Macdonald, and Soutar (*J.*, 1915, **107**, 337), are readily produced either by reacting upon monochlorohydrin with alkali and the requisite alcohol (Reboul, *Annalen Suppl.*, 1862, **1**, 238), or by the converse process (Parts I and III,\* *J.*, 1921, **119**, 1035; 1925, **127**, 2759; Cross and Jacobs, *J. Soc. Chem. Ind.*, 1926, **45**, 320r) of reacting upon sodium glyceroxide with the requisite halide.

The accidental production of higher ethers (Part III, *loc. cit.*) and of  $\beta$ -ethers (Part IX, *loc. cit.*) as by-products, however, is a complication arising from the use of sodium glyceroxide.

(ii)  $\beta$ -*Mono-ethers* may be prepared, as exemplified in the case of the  $\beta$ -methyl ether, by introducing an ethereal group either into  $\alpha\gamma$ -dichlorohydrin, or into certain other subsequently decomposable  $\alpha\gamma$ -compounds (Part IX, *loc. cit.*; Hibbert, Hill, Whelen, and Carter, *J. Amer. Chem. Soc.*, 1928, **50**, 2235; 1929, **51**, 302, 1943).

(iii)  $\alpha$ -*Monoglycerides* may conveniently be prepared from isopropylideneglycerol (Fischer, Bergmann, Bärwind, and Pfähler, *Ber.*, 1920, **53**, 1589, 1606, 1621), a synthesis which strongly indicates the  $\alpha$ -structure; confirmation being afforded by the rotatory evidence of Abderhalden and Eichwald (*Ber.*, 1915, **48**, 1847) and perhaps by the direct formation of these esters from allyl esters (Part IV, *J.*, 1926, 3146; Hibbert and Carter, *J. Amer. Chem. Soc.*, 1929, **51**, 1606).

They also result from the simple esterification of glycerol, or by the action of metallic salts on monochlorohydrin, but, in all such cases, are liable to be difficultly separable from higher glycerides occurring as by-products.

(iv)  $\beta$ -*Monoglycerides* were formerly believed to be obtainable by method (ii) above, but (see Part V, *loc. cit.*) the true  $\beta$ -isomerides have been produced by this method only when applied in a specially

\* These two papers, and also Parts II and VI (*J.*, 1921, **119**, 2076; 1926, 3240), were published under sectional titles only, and consequently were not numbered.

modified form, glycerol ditrityl ether being used as the initial  $\alpha\gamma$ -material (Helferich and Sieber, *loc. cit.*).

(v)  $\alpha\beta$ -*Diethers* of true structure have never been recorded (Part VIII, *loc. cit.*); successful methods for their preparation have been mentioned (Part IX, *loc. cit.*), and a further communication on this subject will be made later.

(vi)  $\alpha\gamma$ -*Diethers*. All syntheses yet recorded for glycerol diethers, whether " $\alpha\beta$ " or " $\alpha\gamma$ ," produce specimens which are identical after purification (Part VIII, *loc. cit.*) and can be proved to have the  $\alpha\gamma$ -structure by arguments not yet put forward.

(vii)  $\alpha\beta$ -*Diglycerides*. Of the various syntheses in the literature, only two would appear to be satisfactory: (a) indirect preparations from propylamines by Abderhalden and Eichwald and by Bergmann and co-workers (see Part VII, *loc. cit.*); (b) the method of Helferich and Sieber (*loc. cit.*) which employs glycerol  $\alpha$ -monotrityl ether.

(viii)  $\alpha\gamma$ -*Diglycerides*. With the exception of the methods of synthesis mentioned in (vii) above, all known preparations of diglycerides, whether by direct esterification or from chlorohydrins, etc., appear to produce the  $\alpha\gamma$ -isomerides preferentially, although many statements occur in the literature to the contrary. Probably a chemically pure  $\alpha\gamma$ -diglyceride is most conveniently prepared by Fischer's method (*Ber.*, 1920, **53**, 1621) from the  $\beta\gamma$ -di-ester of  $\alpha$ -iodohydrin.

(ix)  $\alpha\beta\gamma$ -*Tri-ethers and -esters*, containing different radicals, but of known constitution, are obtainable by mild methods (Fischer, *loc. cit.*) from the various types of partly substituted glycerols summarised above.

No investigation has yet been made to determine whether the alternative method of Whitby (*J.*, 1926, 1458) for synthesising "symmetrical" glycerides, also used by Thomson (*loc. cit.*), is affected by migratory changes such as have now been proved to occur in the very similar reactions considered in this paper and in Part VII (*loc. cit.*); for the same reasons the structures of the "symmetrical" and "unsymmetrical" triglycerides of Humnicki and Lunkiewicz (*Bull. Soc. chim.*, 1929, **45**, 422) and of Weizmann and Haskolberg (*Compt. rend.*, 1929, **189**, 104) must also be regarded as unproven.

#### EXPERIMENTAL.

$\alpha\gamma$ -*Di-iodohydrin  $\beta$ -Laurate*,  $C_{11}H_{23}\cdot CO\cdot O\cdot CH(CH_2I)_2$ .—(a) A crude material, believed to contain this substance, and obtained as an intermediate in the synthesis of " $\beta$ "-monolaurin, has been described by Thieme (*loc. cit.*); this complicated preparation has now been repeated, and the expected liquid obtained, but on hydrolysis, as stated below, it yielded  $\alpha$ -monolaurin instead of the  $\beta$ -isomeride.

(b) The pure *compound* has now been obtained as a colourless solid, m. p.  $34^{\circ}$  after recrystallisation from alcohol, by the direct esterification of  $\alpha\gamma$ -di-iodohydrin by the method described in Part V (*loc. cit.*) for the corresponding ester of  $\alpha\gamma$ -dichlorohydrin and for the *p*-nitrobenzoate of the latter (Found: C, 36.3; H, 5.6; I, 51.3.  $C_{15}H_{28}O_2I_2$  requires C, 36.4; H, 5.7; I, 51.4%).

$\alpha$ - and " $\beta$ "-*Monolaurin*,  $C_{11}H_{23}\cdot CO\cdot O\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot OH$ .—

(a) The supposed " $\beta$ "-monolaurin of Thieme was obtained from the crude  $\alpha\gamma$ -di-iodohydrin  $\beta$ -laurate as described by him. It unquestionably had the  $\alpha$ - and not the  $\beta$ -structure, however, since it melted at  $61$ – $62^{\circ}$ , alone or mixed with an authentic specimen of  $\alpha$ -monolaurin prepared by Fischer's method (*Ber.*, 1920, 53, 1600).

(b) The pure  $\alpha\gamma$ -di-iodohydrin  $\beta$ -laurate described above was also hydrolysed in an identical manner to  $\alpha$ -monolaurin, m. p., alone or mixed,  $61$ – $62^{\circ}$ .

$\alpha$ -*Monolaurin*  $\beta\gamma$ -*Diphenylurethane*,

$C_{11}H_{23}\cdot CO\cdot O\cdot CH_2\cdot CH(O\cdot CO\cdot NHPh)\cdot CH_2\cdot O\cdot CO\cdot NHPh$ .

—(a)  $\alpha$ -Monolaurin was warmed with excess of phenylcarbimide and kept for several days. The *diphenylurethane*, recrystallised from ligroin, melted at  $90^{\circ}$  (Found: C, 68.0; H, 7.9; N, 5.7.  $C_{29}H_{40}O_6N_2$  requires C, 67.9; H, 7.8; N, 5.5%).

(b) A sample prepared in an identical manner from the " $\beta$ "-monolaurin of Grün and Skopnik (*Ber.*, 1909, 42, 3750; see Part V, *loc. cit.*) melted, alone or mixed with (a), at  $90^{\circ}$ . The two samples therefore behave in the same way with phenylcarbimide, thus disposing of one of the arguments of Grün in support of the supposed " $\beta$ " structure of his preparation.

" $\alpha\beta$ "- and " $\alpha\gamma$ "-*Dilaurins*,  $(C_{11}H_{23}\cdot CO\cdot O)_2C_3H_5\cdot OH$ .—(a) A specimen of " $\alpha\beta$ "-dilaurin, prepared from  $\alpha$ -monochlorohydrin by Thieme's method (*loc. cit.*), melted at  $56^{\circ}$ .

(b) A specimen of " $\alpha\gamma$ "-dilaurin, prepared from  $\alpha\gamma$ -dichlorohydrin by Grün's method (*Ber.*, 1912, 45, 3691), melted, alone or mixed with (a), at  $56$ – $57^{\circ}$ , their identity thus being proved.

$\alpha$ - and " $\beta$ "-*Monomyristin*,  $C_{13}H_{27}\cdot CO\cdot O\cdot C_3H_5(OH)_2$ .—(a) The supposed " $\beta$ "-monomyristin of Grün, Schreyer, and Weyrauch (*Ber.*, 1912, 45, 3420) was prepared as described by them; it melted at  $68^{\circ}$ .

(b) An authentic specimen of  $\alpha$ -monomyristin was prepared from myristyl chloride and isopropylideneglycerol by means of the general method for preparing  $\alpha$ -mono-esters described by Fischer, Bergmann, Bärwind, and Pfähler (*Ber.*, 1920, 53, 1589, 1606, 1621). 10 G. of myristyl chloride were cautiously added with shaking to a mixture of 5.2 g. of isopropylideneglycerol and 5.8 g. of quinoline; after 2 days, the whole was treated with ether and the extract was

washed with *N*/2-sulphuric acid, potassium bicarbonate solution, then with water, and dried with anhydrous sodium sulphate. The product was shaken with hydrochloric acid (*d* 1.19); after crystallising several times from ether, it melted at 68°, alone or mixed with (a) (Found: C, 67.8; H, 11.1.  $C_{17}H_{34}O_4$  requires C, 67.6; H, 11.2%).

The supposed " $\beta$ "-monomyristin is therefore  $\alpha$ -monomyristin.

" $\alpha\beta$ "- and " $\alpha\gamma$ "-Dimyristin,  $(C_{13}H_{27}\cdot CO\cdot O)_2C_3H_5\cdot OH$ .—(a) The supposed " $\alpha\beta$ "-dimyristin prepared by the method of Grün and Theimer (*Ber.*, 1907, 40, 1792) melted at 64–65°.

(b) A specimen of " $\alpha\gamma$ "-dimyristin, prepared as described by the same authors (*loc. cit.*), also melted at 64–65°, alone or mixed with (a). Their two processes therefore gave rise to the same compound.

" $\alpha\beta$ "- and " $\alpha\gamma$ "-Dipalmitin,  $(C_{15}H_{31}\cdot CO\cdot O)_2C_3H_5\cdot OH$ .—(a) " $\alpha\beta$ "-Dipalmitin prepared from  $\alpha\beta$ -dibromohydrin by the method of Guth (*Z. Biol.*, 1903, 44, 78) melted at 69°.

(b) " $\alpha\gamma$ "-Dipalmitin prepared from  $\alpha\gamma$ -dichlorohydrin by a method also recommended by him (*loc. cit.*) melted at 69°, alone or mixed with (a). When pure, therefore, these specimens of Guth's " $\alpha\beta$ "- and " $\alpha\gamma$ "-dipalmitins are identical.

$\alpha\gamma$ -Dichlorohydrin  $\beta$ -Stearate,  $C_{17}H_{35}\cdot CO\cdot O\cdot CH(CH_2Cl)_2$ .—In an attempt to apply Grün's method for the synthesis of " $\beta$ "-mono-glycerides to the preparation of " $\beta$ "-monostearin, in a similar manner to that used in the previous investigations of the supposed " $\beta$ "-monolaurin, " $\beta$ "-monomyristin, and " $\beta$ "-monopalmitin,  $\alpha\gamma$ -dichlorohydrin was esterified by stearyl chloride in quinoline; the resulting  $\alpha\gamma$ -dichlorohydrin  $\beta$ -stearate, after crystallising from alcohol, melted at 39° (Found: C, 63.6; H, 10.0; Cl, 17.8. Calc. for  $C_{21}H_{40}O_2Cl_2$ : C, 63.8; H, 10.1; Cl, 18.0%).

Whitby (*J.*, 1926, 1458) obtained a compound of this melting point by treating epichlorohydrin with stearyl chloride, a result that must be regarded as an example of an acyl group spontaneously entering the  $\beta$ -position in the glycerol molecule. Humnicki also (*Bull. Soc. chim.*, 1929, 45, 279) prepared probably the same compound by direct esterification of dichlorohydrin with free stearic acid.

Attempts to hydrolyse this product to the  $\alpha$ - or " $\beta$ "-mono-glyceride, either by the method described in Part V (*loc. cit.*), or after preliminary treatment with potassium iodide such as was used in Thieme's process mentioned above, have been unsuccessful. It was recorded in Part V that, although the corresponding laurate and palmitate of  $\alpha\gamma$ -dichlorohydrin were successfully hydrolysed, the *p*-nitrobenzoate, the 3:5-dinitrobenzoate, and also the corresponding *p*-nitrobenzoate of  $\alpha\gamma$ -dibromohydrin could not be hydrolysed in that way. Grün was of opinion (*Ber.*, 1910, 43, 1288) that it is the esters of simple acids, such as acetic and benzoic

acids, which give only poor yields but it would appear that other radicals can produce the same effect. The stability of the halogen atoms is perhaps significant in connexion with the formation of  $\alpha\beta$ -oxidic rings (Part VII, *loc. cit.*) which account for some of the migratory changes that frequently occur. In this connexion there may also be mentioned the very stable  $\beta$ -methyl and  $\beta$ -trityl ethers of dichlorohydrin (Parts IX and VII), the distearate of monochlorohydrin (Grün and Theimer, *Ber.*, 1907, **40**, 1792), and the chloride of isopropylideneglycerol (Fischer and Pfähler, *Ber.*, 1920, **53**, 1606).

This ester also resisted an attempt to displace its chlorine atoms by means of potassium phthalimide in the manner described in Part VII.

" $\alpha\beta$ -" and " $\alpha\gamma$ "-Distearins,  $(C_{17}H_{35}\cdot CO\cdot O)_2C_3H_5\cdot OH$ .—(a) " $\alpha\beta$ "-Distearin has been prepared from  $\alpha\beta$ -dibromohydrin by the method of Guth (*loc. cit.*) and Renshaw (*J. Amer. Chem. Soc.*, 1914, **36**, 537), and obtained with the m. p. 78—79°.

(b) Another specimen of " $\alpha\beta$ "-distearin has been prepared from  $\alpha$ -chlorohydrin  $\beta\gamma$ -distearate by repeating the synthesis of Grün and Theimer (*loc. cit.*); it melted at 78—79°, alone or mixed with (a).

(c) " $\alpha\gamma$ "-Distearin was prepared from  $\alpha\gamma$ -dichlorohydrin by the method of Guth (*loc. cit.*; compare Bömer and Limpricht, *Z. Unters. Nahr. Genussmittel*, 1913, **25**, 354). This again melted at 78—79°, alone or mixed with either (a) or (b).

Throughout the work described in this paper, many recrystallisations from alternating solvents were frequently necessary in preparing specimens of supposed isomerides for mixed melting point determinations.

The author desires to express his indebtedness to the Chemical Society for a grant which has partly met the expenses incurred in this work.

KING'S COLLEGE, LONDON.

[Received, November 1st, 1929.]

### LII.—*Strychnine and Brucine. Part IX. Preparation of Some Isomerides of Dinitrostrychol and Trinitrostrychol.*

By JULIUS NICHOLSON ASHLEY, (the late) WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON.

IN 1898, Tafel (*Annalen*, **301**, 336) showed that, when strychnine was heated first with dilute and then with concentrated nitric acid, the base was nitrated and subsequently degraded, with the formation

of oxalic and picric acids, together with a compound,  $C_{10}H_5O_8N_3$ , considered to be  $C_9NH_2(OH)_2(NO_2)_2 \cdot CO_2H$  and termed dinitrostrycholcarboxylic acid.

The carboxyl group could be eliminated, or displaced by nitroxyl, dinitrostrychol,  $C_9NH_3(OH)_2(NO_2)_2$ , and trinitrostrychol,  $C_9NH_2(OH)_2(NO_2)_3$ , respectively being produced.

From the properties of these substances and of dinitrostrychol monomethyl ether, Tafel concluded that the hypothetical strychol is either a dihydroxyquinoline or a dihydroxyisoquinoline; he further considered that one of the hydroxyl groups is in proximity to a nitro-group and is responsible for the formation of the yellow neutral alkali-metal salts of dinitrostrychol and that the other hydroxyl exhibits a carbostyryl-like character and functions in the formation of the red alkaline-reacting salts. Finally, Tafel stated (*loc. cit.*, p. 300) that attempts to transform dinitrostrychol derivatives to known substances had been unsuccessful, and that synthetic experiments also had been fruitless; the details of the latter have not been published.

The work recorded in the present communication was completed in 1926, before there was any suggestion (Fawcett, Perkin, and Robinson, Part VII, J., 1928, 3082) that dinitrostrychol might be an isoquinoline derivative,\* and, at that time, we followed Tafel in regarding strychnine as a derivative of quinoline. It appeared highly improbable that the benzene ring of dinitrostrycholcarboxylic acid is not the original benzene ring of strychnine; brucine gives quite different products and nitric acid would not be expected to dehydrogenate the reduced rings of the alkaloid. The same argument applies to the picric acid which is formed alongside the dinitrostrycholcarboxylic acid. But the first action of nitric acid on strychnine is to nitrate it to dinitrostrychnine hydrate, which must then break down into picric acid and the strychol derivative. It follows from these considerations that the nitro-groups in dinitrostrychnine hydrate and dinitrostrycholcarboxylic acid are in the *m*-relation to each other.

On the assumption that dinitrostrychol is a dinitrodihydroxyquinoline, we can proceed a step further and restrict attention to the 6 : 8-dinitrodihydroxyquinolines, since the quinoline nitrogen atom would certainly be replaced by hydroxyl in the course of the reactions leading to the formation of picric acid from dinitrostrychnine hydrate. The same orientation follows from a consideration of analogies in connexion with the original nitration of strychnine; the

\* We have now a definite proof that the substance is a quinoline derivative. A communication on this subject will shortly be submitted to the Society.—R. R.

nitro-groups would, doubtless, enter the *op*-positions with respect to the nitrogen atom attached to the nucleus.

The positions 6 and 8 are therefore not possible situations for the hydroxyl groups of dinitrostrychol, and strychol might be 2:3-, 2:4-, 2:5-, 2:7-, 3:4-, 3:5-, 3:7-, 4:5-, 4:7-, or 5:7-dihydroxyquinoline.

Very little was known of the nitro-derivatives of such dihydroxyquinolines, and in order to study their properties we have synthesised some typical members of this group, selecting those representatives which had the best claim to be considered in connexion with the strychol problem.

The outcome has been to exclude the 2:4-, 2:5-, and 2:7-formulæ with certainty, and the 4:7-formula on somewhat less definite grounds. Of the remaining possibilities, all but the 2:3-, 3:4-, and 4:5-formulæ are highly improbable.

The first stage in the nitration of 2:4-dihydroxyquinoline was studied by Gabriel (*Ber.*, 1918, 51, 1500), who obtained 3-nitro-2:4-dihydroxyquinoline (I), and this substance has been found to yield 3:6(or 8)-dinitro-2:4-dihydroxyquinoline (II, 3:6) on further nitration in sulphuric acid solution. The introduction of a third nitro-group presented great difficulties, which were only surmounted after many unsuccessful experiments. The acetyl derivative of (II) was treated under special conditions with a mixture of 10% oleum and potassium nitrate, and the product was 3:6:8-trinitro-2:4-dihydroxyquinoline (III), an isomeride of trinitrostrychol.

The constitution of the substance is proved by its conversion into picric acid by means of boiling nitric acid, and this reaction constitutes one of the distinctions from trinitrostrychol, which cannot be similarly degraded. Attempts to effect the ring closure of *ethyl* 3:5-dinitro-2-acetamidobenzoate, which would have afforded 6:8-dinitro-2:4-dihydroxyquinoline, were not successful.

6:8-Dinitro-2:5-dihydroxyquinoline (IV) and 6:8-dinitro-2:7-dihydroxyquinoline (V) were obtained from the corresponding amino-carbostyrls by diazotisation, decomposition, and nitration without isolation of intermediate stages.

Neither of these substances was identical with dinitrostrychol; they did not yield trinitro-compounds but suffered degradation on boiling with nitric acid and gave rise to styronic acid.

Compound (IV) was much more stable than (V), and the yield of the trinitroresorcinol was poor; the reaction is of interest in that it confirms the view that the quinoline nitrogen atom is replaced by hydroxyl in all such nitration-oxidation processes.

A synthesis of 4-hydroxy-7-methoxyquinoline-2-carboxylic acid (VI) has been effected, and the results obtained on nitrating this substance were not in agreement with the view that strychnol is 4:7-dihydroxyquinoline.

Further, in some preliminary experiments on the synthesis of 4:5-dihydroxyquinoline derivatives, the Tiemann-Reimer reaction was applied to *m*-nitrophenol, and 6-nitrosalicylaldehyde (VII) obtained in 3% yield. The orientation of this substance follows from the facts that it is not a *p*-hydroxybenzaldehyde, being volatile in steam, and that its methyl ether yields an indigotin derivative on treatment with acetone and sodium hydroxide.

#### EXPERIMENTAL.

*Dinitrostrycholcarboxylic Acid and Dinitrostrychol*.—The method of Tafel (*loc. cit.*) was modified in that the mixture of strychnine and 20% nitric acid was heated on the steam-bath for 120 hours; losses by evaporation were compensated by the addition of 20% nitric acid. Strychnine nitrate (115 g.), nitric acid (900 g., *d* 1.42), and water (3600 c.c.) gave ultimately 10.3 g. of pure dinitrostrycholcarboxylic acid.

A large number of analyses of dinitrostrycholcarboxylic acid, of dinitrostrychol and its methyl ether have been carried out, and Tafel's view of the composition of these substances is unquestionably correct.

Dinitrostrychol crystallises best from acetic acid, in very pale yellow needles, *m. p.* 282° (Tafel, *loc. cit.*, crystallised the substance from alcohol or nitric acid, and gives the *m. p.* 284°).

When dinitrostrychol is reduced in alcoholic solution with zinc dust and hydrochloric acid, the resulting colourless solution exhibits a strong bluish-violet fluorescence; it becomes discoloured rapidly, and, on dilution with water and the addition of ferric chloride, develops a deep red coloration, changing to reddish-brown.

Attempts to reduce only one nitro-group of dinitrostrychol were unsuccessful.

Complete degradation, without formation of picric or styphnic acid, resulted when dinitrostrychol (0.5 g.) was heated in a sealed tube at 200° with nitric acid (4 c.c., *d* 1.5) for 4½ hours. With the same quantities, heated at 120–125° for 2 hours, the product was pure trinitrostrychol.

Dinitrostrychol monomethyl ether (Tafel, *loc. cit.*, p. 345) was obtained by heating the dry monopotassium salt of dinitrostrychol (2 g.) with methyl iodide (5 c.c.) in a sealed tube at 155° for 2½ hours, or by refluxing a mixture of the monopotassium salt (4 g.), purified methyl sulphate (5 c.c.), and xylene (150 c.c.) for 1½ hours (yield, 70–75%; m. p. 194–195°).

The conditions for the hydrolysis of the methyl ether by aqueous sodium hydroxide have been studied, and the following experiments are typical. (1) The finely powdered methyl ether (0.2 g.) was triturated with cold aqueous sodium hydroxide (10 c.c. of 1%); very little material passed into solution. On heating at 40° for 2 minutes, an orange-red solution was obtained, and this was filtered and acidified, yielding dinitrostrychol free from its methyl ether. (2) The finely powdered methyl ether (0.2 g.), when triturated with cold aqueous sodium hydroxide (10 c.c. of 8%), was converted into a deep red, insoluble sodium salt. This was collected and treated with dilute sulphuric acid, yielding the original methyl ether, m. p. 192°. It is evident that the monomethyl ether possesses very weak acidic character, and is hydrolysed by aqueous alkalis with special facility.

Tafel (*loc. cit.*) made the very interesting observation that dinitrostrychol behaves as a dibasic acid towards baryta, since, although the potassium salt, stable in the presence of water, has the composition  $C_9H_4O_6N_2K$ , the barium salt under similar conditions appears to be  $C_9H_3O_6N_2Ba$ . This suggested to us that the hydroxyl groups are probably in the ortho- or peri-positions with respect to each other, and we attempted to confirm this view by the preparation of an ethylene ether or an oxalyl derivative of dinitrostrychol. The disodium salt (5 g.) was refluxed for 50 hours with ethylene dibromide (4 c.c.) and absolute alcohol (100 c.c.). Apart from unchanged dinitrostrychol, a relatively very small amount of a sparingly soluble substance, crystallising from alcohol in pale brown needles, m. p. 186–187° (Found: N, 15.0, 14.8%), was isolated. This substance exhibited the behaviour of dinitrostrychol monomethyl ether towards 1% sodium hydroxide solution and was probably the corresponding monoethyl ether (N, 15.1%).

The dipotassium salt of dinitrostrychol (2.9 g.) was mixed with oxalyl chloride (2 c.c.) (Staudinger, *Ber.*, 1908, 41, 3563) and pure toluene (10 c.c.); the initial reaction was controlled by cooling in

water and, after 12 hours, the mixture was heated on the steam-bath for 2 hours. The filtered liquid was evaporated under diminished pressure; the pale yellow residue, after being lixiviated with water, crystallised from toluene in very pale yellow, irregular prisms, m. p. 161° (Found: N, 19.5, 19.5%). Unfortunately, the yield was poor, so that a full examination was not possible, but it is clear that the action of the oxalyl chloride must have removed either carbon or oxygen or both from the dinitrostrychol molecule (dinitrostrychol,  $C_9H_5O_6N_3$ , requires N, 16.8%).

The substance was insoluble in cold aqueous sodium carbonate, but, on boiling, it dissolved to an orange solution; it was immediately soluble in cold dilute aqueous sodium hydroxide to an orange-red solution. On boiling with nitric acid ( $d$  1.42, boiled), oxidation occurred and the evaporated liquid gave, with a little water, long, pale yellow rods, m. p. 278–279° (decomp.) (Found: N, 15.3%, a provisional figure in the absence of a duplicate). This substance was readily soluble in cold dilute sodium carbonate to a deep orange solution.

It is very difficult to explain these remarkable results, and the subject merits further investigation.

Trinitrostrychol was found to be more readily obtainable by the nitration of dinitrostrychol than from dinitrostrycholcarboxylic acid (Tafel). It sufficed to heat a mixture of dinitrostrychol (0.5 g.) and nitric acid (5 c.c.,  $d$  1.5) on the steam-bath for 1 hour. On the addition of water (15 c.c.), the trinitrostrychol separated in pale yellow, microscopic needles, m. p. 218°. No trace of picric or styphnic acid was produced. The pale yellow solution in dilute aqueous sodium hydroxide rapidly darkened on heating and became deep brown. This characteristic behaviour is exhibited by traces of trinitrostrychol, and advantage has been taken of this fact in showing that certain synthetic products do not contain the substance.

*2:4-Dihydroxyquinoline and Derivatives.*—According to Camps (*Arch. Pharm.*, 1899, 237, 688), the action of sodium on methyl acetylanthranilate (Mehner, *J. pr. Chem.*, 1901, 64, 83) gives a 60% yield of crude 2:4-dihydroxyquinoline, but we find that the yield of pure substance barely exceeds 40%. Other methods, however, including those of Erdmann (*Ber.*, 1899, 32, 3570) and of D.R.-P. 11767, were still less satisfactory. Camps's method was slightly modified. Dry powdered methyl acetylanthranilate (50 g.) was added to granulated sodium (6 g.) suspended in toluene (200 c.c.). Reaction occurred and the yellow liquid boiled spontaneously. The mixture was finally refluxed (oil-bath) until it became viscous. After cooling, the solid was collected, freed as far as possible from toluene, and dissolved in water (800 c.c.) at 70–80°. The solution

was just acidified to litmus, and the precipitated dihydroxyquinoline collected (Found : N, 8.7. Calc. : N, 8.7%).

Further addition of acid to the filtrate precipitated acetylanthranilic acid in a crystalline condition.

4(or 2)-*Hydroxy-2(or 4)-acetoxyquinoline* was obtained when 2 : 4-dihydroxyquinoline (1 g.) was heated with acetic anhydride (20 c.c.) and three drops of pyridine on the steam-bath for  $\frac{3}{4}$  hour. The derivative crystallised from alcohol in needles, m. p. 214—215° (Found : C, 65.1; H, 4.5; N, 6.6.  $C_{11}H_9O_3N$  requires C, 65.0; H, 4.5; N, 6.9%), readily soluble in acetic acid and acetone, moderately readily soluble in methyl alcohol, chloroform, ethyl acetate, and benzene, sparingly soluble in ether and light petroleum.

4(or 2)-*Hydroxy-2(or 4)-p-nitrobenzyloxyquinoline* possesses similar solubility properties and was prepared by refluxing a mixture of 2 : 4-dihydroxyquinoline (4 g.), alcohol (250 c.c.), *p*-nitrobenzyl bromide (6 g.), and potassium hydroxide (2 g.) for 2 hours. Yellow crystals separated from the filtered solution, and this substance crystallised from alcohol in pale yellow plates, m. p. 247° (decomp.) (Found : C, 64.8; H, 4.3; N, 9.7.  $C_{16}H_{12}O_4N_2$  requires C, 64.9; H, 4.1; N, 9.5%).

3-Nitro-2 : 4-dihydroxyquinoline (I) was prepared by Gabriel's method (*Ber.*, 1918, 51, 1500) in 85% yield, and also by nitration in sulphuric acid solution in somewhat inferior yield. A clear proof of the constitution of this derivative does not appear to have been recorded, but we have now observed that a small amount of aniline is formed on distillation with soda-lime.

The *monoacetyl* derivative was obtained under the conditions described above for the acetylation of 2 : 4-dihydroxyquinoline. It formed yellow needles, m. p. 194° (decomp.), from alcohol (Found : C, 53.6; H, 3.6; N, 11.1.  $C_{11}H_8O_5N_2$  requires C, 53.2; H, 3.3; N, 11.3%).

Attempts to obtain a methyl ether of 2 : 4-dihydroxyquinoline were unsuccessful, but the action of diazomethane was not tried.

3 : 6-Dinitro-2 : 4-dihydroxyquinoline (II).—Powdered potassium nitrate (16 g.) was added during 1 hour to a solution of 2 : 4-dihydroxyquinoline (10 g.) in sulphuric acid (100 c.c.) with stirring and cooling to below 5°. Nitric acid (20 c.c.) was then introduced in four portions, and the stirring continued at room temperature for 2½ hours. The brown liquid was added to crushed ice, and the yellow solid isolated and dissolved in hot aqueous sodium carbonate. On cooling, the *sodium* salt separated in glistening, slender, yellow needles (Found : Na, 8.2.  $C_9H_4O_6N_3Na$  requires Na, 8.4%). The regenerated nitrophenol was almost colourless and crystallised from acetic acid in long needles, m. p. 200° (decomp.) (yield, 60%)

(Found: C, 43.5; H, 2.2; N, 16.8.  $C_9H_5O_6N_3$  requires C, 43.1; H, 2.0; N, 16.7%).

3 : 6-Dinitro-2 : 4-dihydroxyquinoline is moderately readily soluble in the simple alcohols, acetone and hot water, but is very sparingly soluble in ether, light petroleum, benzene, ethyl acetate, and chloroform. It does not dissolve readily in cold aqueous sodium carbonate, but with sodium hydroxide an orange-red disodium salt is produced. The stability of this substance towards alkali is remarkable; 1 gram was heated with 15 c.c. of 10% sodium hydroxide solution in a sealed tube at 145° for 10 hours without suffering any decomposition.

A completely reduced acid solution became deep blue, quickly changing to reddish-brown, on the addition of ferric chloride.

The *monoacetyl* derivative was obtained by heating a mixture of the dinitrodihydroxyquinoline (1 g.) and acetic anhydride (20 c.c.), with stirring, just to the boiling point. The yellow solution deposited almost colourless plates, m. p. 190° (decomp.) after recrystallisation from acetic acid (Found: C, 45.3; H, 2.6; N, 14.2.  $C_{11}H_7O_7N_3$  requires C, 44.9; H, 2.4; N, 14.3%).

3 : 6 : 8-Trinitro-2 : 4-dihydroxyquinoline (III).—Finely powdered potassium nitrate (11 g.) was gradually added with shaking to a solution of 3 : 6-dinitrohydroxyacetoxyquinoline (5 g.) in 10% oleum (50 c.c.), and the yellow liquid stirred at 85° for 3 hours and then at 90—95° for 4 hours, the temperature having been raised very gradually. The product was slowly added to water (200 c.c.) with stirring. The pale brown solid obtained crystallised from acetic acid in pale yellow leaflets, m. p. 192—193° (decomp.) (yield, 65%) (Found: C, 36.9; H, 1.6; N, 18.4.  $C_9H_4O_8N_4$  requires C, 36.6; H, 1.4; N, 18.9%).

This *trinitrodihydroxyquinoline* is fairly readily soluble in water, alcohol and ethyl acetate and readily soluble in acetone; it is sparingly soluble in most other organic solvents.

The solution in aqueous sodium carbonate is golden-yellow. In aqueous sodium hydroxide the compound gives a deep yellow solution, from which a sparingly soluble sodium salt separates almost immediately; there is no change on boiling: this behaviour is in marked contrast with that of trinitrostrychnol.

The *monoacetyl* derivative was prepared by heating the trinitrodihydroxyquinoline with acetic anhydride for 5 minutes; it crystallised in colourless elongated plates, m. p. 158° (decomp.) (Found: C, 38.8; H, 1.9.  $C_{11}H_6O_9N_4$  requires C, 39.1; H, 1.8%).

The oxidation and nitration of the trinitrodihydroxyquinoline (1 g.) afforded a proof of its constitution and was effected by heating the substance with a mixture of acetic acid (10 c.c.) and nitric acid (10 c.c., *d* 1.5) for  $\frac{1}{2}$  hour on the steam-bath and, after addition of

water (10 c.c.), refluxing the solution for  $\frac{1}{2}$  hour and concentrating it to a syrup. The picric acid formed was isolated as its sodium salt and characterised by its m. p., undepressed by admixture with an authentic specimen, and by other properties.

**2-Chloro-3:5-dinitrobenzoyl Chloride.**—2-Chloro-3:5-dinitrobenzoic acid (Purgotti and Contardi, *Gazzetta*, 1902, **32**, i, 526) was treated with phosphorus pentachloride; the *chloride* (mentioned by Barnett, *Ber.*, 1925, **58**, 1610, without properties or analysis) crystallised from ether-benzene in white needles, m. p.  $62^{\circ}$  (Found: Cl, 26.7.  $C_7H_2O_5N_2Cl_2$  requires Cl, 26.8%). Attempts to condense the chloride with ethyl sodioacetoacetate and to hydrolyse the product were fruitless.

**3:5-Dinitro-2-methoxybenzoyl Chloride.**—The acid was obtained in 85% yield by following Ullmann's directions (*Annalen*, 1909, **366**, 85), and in 95% yield by nitrating *o*-methoxybenzoic acid (20 g.) with a mixture of sulphuric acid (100 c.c.) and nitric acid (30 c.c., *d* 1.5) for  $\frac{1}{2}$  hour at room temperature.

The *chloride* crystallised in plates when the crude product was washed with light petroleum; it had m. p.  $37-38^{\circ}$  (Found: Cl, 13.8.  $C_8H_5O_6N_2Cl$  requires Cl, 13.6%). Condensations with the sodium derivatives of ethyl acetoacetate and ethyl malonate led to no satisfactory outcome.

**Methyl 3:5-Dinitro-2-acetamidobenzoate.**—Salkowski (*Annalen*, 1874, **173**, 46) obtained methyl 3:5-dinitroanthranilate by the action of ammonia on methyl dinitroethoxybenzoate, and recorded the m. p.  $166^{\circ}$ . Esterification of 3:5-dinitroanthranilic acid (Purgotti and Contardi, *loc. cit.*) by means of 5% methyl-alcoholic sulphuric acid gave the same derivative, m. p.  $165-166^{\circ}$ , in 71% yield (Found: C, 39.6; H, 3.1. Calc. for  $C_8H_7O_6N_3$ : C, 39.8; H, 2.9%). The corresponding ethyl ester had m. p.  $136^{\circ}$ .

Acetylation of the methyl ester (2.5 g.) was carried out by means of acetic anhydride (25 c.c.) and a drop of sulphuric acid. The *acetyl* derivative crystallised from the solution after a few minutes and separated from benzene in long colourless rods, m. p.  $172-173^{\circ}$  (Found: C, 42.3; H, 3.4.  $C_{10}H_9O_7N_3$  requires C, 42.4; H, 3.2%). The related *ethyl* ester could be obtained by the use of acetic anhydride without a catalyst; it crystallised from benzene in clusters of needles, m. p.  $174^{\circ}$  (Found: C, 44.9; H, 3.7; N, 14.2.  $C_{11}H_{11}O_7N_3$  requires C, 44.5; H, 3.7; N, 14.1%). Ring closure of these esters was attempted under a variety of conditions, but it could not be effected and thus a long series of attempts to prepare 6:8-dinitro-2:4-dihydroxyquinoline failed.

**6:8-Dinitro-2:5-dihydroxyquinoline (IV).**—5-Aminocarbostyryl has been prepared by Claus and Setzer (*J. pr. Chem.*, 1896, **53**, 392),

but the method was modified in some details. 5-Nitrocarbostyryl (10 g.) was mixed with hydrated stannous chloride (36 g.) and concentrated hydrochloric acid (70 g.). After boiling for a few minutes, the solution was concentrated, then diluted, and tin eliminated as sulphide. The filtrate was again concentrated until crystals separated from the hot liquid. After cooling and keeping, the hydrochloride was isolated (6.5 g.); it crystallised in long colourless rods and gave a deep brownish-red coloration with ferric chloride in aqueous solution.

Sodium nitrite (4 g.), dissolved in water (10 c.c.), was gradually added to a stirred solution and suspension of 5-aminocarbostyryl hydrochloride (9 g.) in water (100 c.c.) and nitric acid (20 c.c.,  $d$  1.42) cooled to  $0^{\circ}$ . The mixture was kept at  $0^{\circ}$  for 1 hour and then heated on the steam-bath for 2 hours; nitrogen was evolved at about  $70^{\circ}$ . An almost black, resinous substance which separated was collected and dissolved in acetic acid; the solution deposited crystals and, after several recrystallisations, 6 : 8-dinitro-2 : 5-dihydroxyquinoline was obtained in pale yellowish-brown prisms, m. p.  $260^{\circ}$  (decomp.). A small additional amount was obtained from the reaction mother-liquor and had m. p.  $261^{\circ}$  (decomp.) (Found : C, 43.2; H, 2.3.  $C_9H_5O_6N_3$  requires C, 43.0; H, 2.0%). The substance is moderately readily soluble in alcohol, acetone, ethyl acetate, and water and sparingly soluble in chloroform, benzene, ether, and light petroleum. The aqueous solution is golden-yellow, and the solution in cold aqueous sodium carbonate is yellow. With aqueous sodium hydroxide, a deep red salt is produced; this dissolves to an orange-red solution on heating.

When the substance was refluxed with fifteen times its weight of nitric acid ( $d$  1.5) for 3 hours, a small amount of styphnic acid, m. p.  $175^{\circ}$ , was produced.

The reduced acid solution is not fluorescent and develops a bright red colour on the addition of ferric chloride.

The derivative obtained on acetylation with boiling acetic anhydride for 10 minutes crystallised from alcohol in clusters of very pale yellow needles, m. p.  $178^{\circ}$ .

6 : 8-Dinitro-2 : 7-dihydroxyquinoline (V).—Decker (*J. pr. Chem.*, 1901, 64, 99) recorded meagre details of his preparation of 7-nitrocarbostyryl and did not state the yield. Following his method as closely as possible, we found this to be 23% : under the following conditions, the yield is about 60%.

A solution of 7-nitroquinoline (22 g.) in water (1600 c.c.), boric acid (160 g.), and sulphuric acid (5 c.c.) was added to water (4400 c.c.) and heated on the steam-bath until a clear solution resulted. Fresh bleaching powder (200 g.) was digested with water (900 c.c.)

for 24 hours, and the filtered solution added to the nitroquinoline solution. After 24 hours, the precipitate was collected and boiled for 5 minutes with a solution of sodium hydroxide (14 g.) in water (1100 c.c.). Acidification of the alkaline filtrate afforded a voluminous precipitate of the carbostyryl. The reduction was carried out like that of the isomeride (above), and the diazotisation, decomposition and simultaneous nitration were also similar to those already described. Here, however, the black resin yielded nothing, and the filtrate from it, after being heated for a further period, was cooled and kept. The yellow solid that separated was collected, washed, and dried; it then crystallised from benzene in glistening yellow plates that gradually darkened on heating and had m. p. 207—208° (decomp.), exploding a few degrees higher. The results of analyses indicated a composition midway between that of a mono- and of a di-nitro-derivative. Accordingly, the product (1 g.) was dissolved in sulphuric acid (5 c.c.), and potassium nitrate (2 g.) added slowly with stirring. The mixture was poured into water (25 c.c.), and the precipitate crystallised several times from aqueous acetic acid, giving glistening, pale orange parallelepipeds, which darkened on heating but did not melt below 310°. At higher temperatures, explosion occurred, and for this reason no analysis by combustion could be performed. By using a very large excess of copper oxide, a Pregl-Dumas estimation of nitrogen could be carried out (Found : N, 16.6.  $C_9H_5O_6N_3$  requires N, 16.7%).

The substance is soluble in hot water to a yellow solution, and in this respect and in other solubility properties and colour reactions with alkalis it resembles the dinitro-2:5-dihydroxyquinoline described above.

The decomposition to styphnic acid was more facile than with the isomeride and could be effected by boiling the substance (0.5 g.) under reflux with nitric acid (5 c.c., *d* 1.5), acetic acid (5 c.c.), and water (5 c.c.) for  $\frac{1}{2}$  hour. The liquid was evaporated to dryness, and the residue extracted with ether; the resulting styphnic acid had m. p. 174—175°. This treatment does not change dinitro-2:5-dihydroxyquinoline to any appreciable extent.

*3-Nitroanisic Acid and Derivatives.*—The conditions for the nitration of *p*-tolyl carbonate (D.R.-P. 206,638) were modified.

A mixture of nitric acid (102 g., *d* 1.5) and sulphuric acid (265 g.) was gradually added to a stirred solution of *p*-tolyl carbonate (181 g.) in sulphuric acid (1200 c.c.) kept below 20°. After 5 hours, the product was isolated and hydrolysed; the yield of the nitro-cresol was 75%.

3-Nitroanisic acid has been obtained by Simonsen and Rau (J., 1917, 111, 235) by a series of reactions from 2-nitroanisic acid.

It can also be prepared by oxidation of 2-nitro-*p*-tolyl methyl ether in 35% yield. 2-Nitro-*p*-tolyl methyl ether (100 g.) was refluxed with a solution of potassium permanganate (120 g.) in water (2500 g.), further quantities of permanganate (180 g.) being introduced in the course of 5 hours and the boiling continued for 2 hours more. The acid, isolated in the known manner, crystallised from acetic acid in white hexagonal prisms, m. p. 195—196° (Found: C, 48.6; H, 3.9. Calc. for  $C_8H_7O_5N$ : C, 48.7; H, 3.6%).

Hydrogen chloride was the catalyst used in the preparation of the *ethyl ester*, which crystallised from alcohol in colourless plates, m. p. 71—72° (Found: C, 53.2; H, 5.0.  $C_{10}H_{11}O_5N$  requires C, 53.3; H, 4.9%).

The *chloride* was obtained by boiling the acid (50 g.) for 3 hours with pure thionyl chloride (140 c.c.). The yield was 53 g. and the derivative crystallised from light petroleum in small white tablets, m. p. 56° (Found: C, 44.3; H, 2.9.  $C_8H_6O_4NCl$  requires C, 44.5; H, 2.8%).

*2-Nitro-4-methoxybenzoylpyruvic Acid,*

—2-Nitroanisoyl chloride was brought into reaction with an equimolecular quantity of ethyl sodioacetoacetate in dry ethereal solution and suspension; the mixture was refluxed for 1 hour. The oily product gave a *potassium* salt which crystallised from alcohol in bright yellow leaflets (Found: K, 11.0.  $C_{14}H_{14}O_7NK$  requires K, 11.2%). The regenerated ester (25 g.) was refluxed for 8 hours with a mixture of sulphuric acid (50 g.) and water (100 c.c.), and about 6 g. of 2-nitro-4-methoxyacetophenone were isolated from the mixture as a yellowish-brown oil. This ketone (5 g.) and then ethyl oxalate (7 g.) were added with shaking and cooling to a solution of sodium (3 g.) in alcohol (100 c.c.). After 24 hours, water (500 c.c.) was introduced, and the filtered liquid acidified with hydrochloric acid. On keeping, a pale brown, flocculent substance was deposited which crystallised from benzene—light petroleum in almost colourless, feathery needles, m. p. 161° (yield, 65%) (Found: C, 49.4; H, 3.6.  $C_{11}H_9O_7N$  requires C, 49.4; H, 3.4%).

The *acid* is readily soluble in most organic solvents with the exception of light petroleum. It gives a bright yellow solution in aqueous sodium hydroxide and a deep reddish-brown ferric chloride reaction in alcoholic solution. Reduction with alkaline hydro-sulphite, followed by oxidation, gave a bluish-green precipitate of dimethoxyindigotin.

*4-Hydroxy-7-methoxyquinoline-2-carboxylic Acid* (7-Methoxykynurenic Acid) (VI).—A hot solution of crystallised ferrous sulphate (40 g.) in water (80 c.c.) was slowly added to one of 2-nitro-4-meth-

oxybenzoylpyruvic acid (10 g.) in water (100 c.c.) and aqueous ammonia (60 c.c.,  $d$  0.880). The liquid was heated for  $\frac{1}{2}$  hour on the steam-bath and filtered hot, and the precipitate washed with boiling dilute aqueous sodium carbonate. The combined filtrates were acidified, and the whole process was repeated on the isolated solid. The crude acid was boiled with acetic acid (50 c.c.), and the residue crystallised from a much larger volume of the same solvent, affording microscopic needles (2 g.), m. p.  $278^{\circ}$  (decomp.) (Found: C, 60.0; H, 3.8.  $C_{11}H_9O_4N$  requires C, 60.3; H, 4.1%). The acid is extremely sparingly soluble in the usual organic solvents. Its solution in sulphuric acid is yellow, and in alkaline solution it couples with benzenediazonium chloride to a red azo-compound.

*3(or 8)-Nitro-7-methoxykynurenic Acid.*—A solution of 7-methoxykynurenic acid (0.5 g.) in nitric acid (5 c.c.,  $d$  1.5) was stirred for 15 minutes, heated at  $30^{\circ}$  for 10 minutes, cooled, and poured into water. The derivative crystallised from acetic acid in clusters of almost colourless needles, m. p.  $250^{\circ}$  (decomp.) (Found: N, 10.5; MeO, 11.3.  $C_{11}H_8O_6N_2$  requires N, 10.6; 1MeO, 11.7%). The acid is soluble in alcohol, moderately readily soluble in acetone, chloroform and ether, and very sparingly soluble in other organic solvents of low b. p. It gives bright yellow alkaline solutions.

*3 : 6 : 8-Trinitro-7-methoxykynurenic Acid.*—A solution of 7-methoxykynurenic acid (0.5 g.) in nitric acid (5 c.c.,  $d$  1.5) was refluxed for 1 hour and then evaporated to dryness on the steam-bath; the residue crystallised from acetic acid in colourless, nearly rectangular prisms, which darkened but did not melt below  $310^{\circ}$  (Found: N, 15.8; MeO, 8.8.  $C_{11}H_6O_{10}N_4$  requires N, 15.8; 1MeO, 8.8%). This *trinitromethoxykynurenic acid* is moderately readily soluble in alcohol, acetone, or ethyl acetate, but is almost insoluble in other usual solvents. The solution in aqueous sodium carbonate is pale yellow, and the yellow solution in cold aqueous sodium hydroxide almost immediately deposits a yellow sodium salt.

A number of experiments were made on the exhaustive nitration of decarboxylated 7-methoxykynurenic acid and specimens undoubtedly containing 3 : 6 : 8-trinitro-7-methoxyquinoline were obtained. These did not show the characteristic behaviour of trinitrostrychol towards hot aqueous sodium hydroxide, and we are convinced that the trinitro-4 : 7-dihydroxyquinoline derivatives are more stable than trinitrostrychol.

*6-Nitrosalicylaldehyde (VII).*—Chloroform (24 c.c.) was added to a solution of *m*-nitrophenol (30 g.) in water (200 c.c.) and sodium hydroxide (40 g.), and the mixture refluxed for 1 hour. After removal of the excess of chloroform, the solution was acidified with sulphuric acid and distilled in steam. The pale yellow solid (yield,

3%) in the distillate crystallised from light petroleum or methyl alcohol in pale yellow prisms, m. p. 54–55° (Found: N, 8.6.  $C_7H_5O_4N$  requires N, 8.4%). The sodium salt was orange-red, and the ferric chloride coloration in alcoholic solution was reddish-brown. The salicylaldehyde configuration was confirmed by applying Dakin's reaction, a substance giving pyrocatechol-type reactions being obtained in small yield.

Methylation by means of methyl sulphate and sodium hydroxide yielded the *methyl* ether, which crystallised from carbon tetrachloride in colourless plates or needles, m. p. 111° (Found: C, 52.9; H, 3.9.  $C_8H_7O_4N$  requires C, 53.0; H, 3.9%). This methoxy-*o*-nitrobenzaldehyde gave a bulky, deep blue precipitate of dimethoxyindigotin (dark brownish-purple lustre) when cold aqueous sodium hydroxide was added to its solution in acetone.

### LIII.—*The Reaction between Cupric Chloride and Hydrazine Sulphate.*

By THOMAS IREDALE and CATHERINE ELEANOR MALLEN.

DOUBLE compounds of the salts of hydrazine and copper, both cuprous and cupric, have been described (Curtius and Jay, *J. pr. Chem.*, 1894, **50**, 311; Hofmann and Marburg, *Annalen*, 1899, **305**, 191, 222; Ranfaldi, *Atti R. Accad. Lincei*, 1906, **15**, ii, 95; Franzen and Lucking, *Z. anorg. Chem.*, 1911, **70**, 152; Ferratini, *Gazzetta*, 1912, **42**, i, 138), and copper salts have been used for the gasometric estimation of hydrazine (Purgotti, *ibid.*, 1896, **26**, 559; de Girard and de Saporta, *Bull. Soc. chim.*, 1904, **31**, 905; Rimini, *Atti R. Accad. Lincei*, 1905, **14**, i, 386; Ebler, *Z. anorg. Chem.*, 1905, **47**, 371). The cupric double compounds are usually formed without any chemical action other than perhaps a double decomposition. This is possible as a rule only in neutral or somewhat acid solutions; in alkaline solutions reduction to a cuprous salt, finally giving cuprous oxide, takes place, with evolution of nitrogen:  $8Cu^{++} + 2N_2H_5^+ + 10OH^- = 8Cu^+ + 10H_2O + 2N_2$ . According to Gutbier (*Z. anorg. Chem.*, 1902, **32**, 355), colloidal cuprous oxide may sometimes be formed in this way under certain conditions; with high concentrations of hydrazine, however, copper itself may be the final reduction product (Rimini, *loc. cit.*; Curtius and Jay, *Ber.*, 1887, **20**, 1632). Brown, amorphous solids of uncertain composition are sometimes precipitated which deposit copper on standing. On exposure to air they form basic copper carbonates.

By working under certain conditions, we have prepared from hydrazine sulphate and cupric chloride a new *compound* which is more complex than any hitherto described, and has some unusual properties.

#### EXPERIMENTAL.

*N*-Cupric chloride solution is run drop by drop into a mixture of 40 g. of hydrazine sulphate in 250 c.c. of water with 25 g. of potassium hydroxide (or the equivalent sodium hydroxide) in 250 c.c. of water. The solution turns blue at first, and then becomes brown, with evolution of nitrogen. A brown precipitate begins to form, and if the cupric chloride is run in slowly, a stage is reached where glistening brown plates separate. Further quantities of the chloride should be added cautiously in order to avoid formation of a blue solution due to excess of copper salt. The crystals are allowed to settle, filtered off as rapidly as possible on a Buchner funnel, washed with 95% alcohol and finally with absolute alcohol, kept over sulphuric acid in a vacuum desiccator, and analysed without further purification.

*Analysis.* (i) From the solution in hydrochloric acid, hydrogen sulphide precipitated copper sulphide; this was dissolved in nitric acid, and the metal estimated by the iodide method. (ii) The filtrate from the sulphide was freed from excess of hydrogen sulphide by a current of carbon dioxide, and the hydrazine was estimated in the solution by the iodine-bicarbonate method. (iii) Chlorine was estimated either by direct weighing as silver chloride, or by the Volhard method after an ammoniacal solution of the compound had been acidified with nitric acid. (iv) Sulphate was estimated as barium salt in the original hydrochloric acid solution (Found: Cu, 46.4; Cl, 12.1;  $N_2H_4$ , 21.1;  $SO_4$ , 18.0.  $2CuCl \cdot Cu_2SO_4 \cdot 4N_2H_4$  requires Cu, 46.3; Cl, 12.9;  $N_2H_4$ , 23.3;  $SO_4$ , 17.5%).

*Properties.* The *substance* is readily decomposed by cold water, but can be preserved for some time under anhydrous conditions. Hot water precipitates cuprous oxide, leaving a nearly neutral (methyl-orange) solution of hydrazine sulphate and chloride. The complex is insoluble in alcohol and in most organic solvents, but dissolves in formamide and pyridine to give straw-coloured solutions which rapidly become blue owing to oxidation; it also gives a similar solution in concentrated aqueous ammonia in an inert atmosphere, but access of oxygen rapidly produces the blue solution characteristic of cupric complexes. This rapid oxidation makes satisfactory recrystallisation from formamide difficult. Dilute sulphuric or nitric acid causes precipitation of copper, but hydrochloric acid at first yields a white precipitate which dissolves to a

colourless solution when the concentration of acid is increased, doubtless owing to the solubility of cuprous chloride in the concentrated acid.

The compound might simply be a double salt, but there appear to be at least three reasons for regarding it as fully co-ordinated: (1) the small number of acid radicals compared with hydrazine molecules and copper atoms; (2) the dark colour of the compound, probably indicating a large ion—the simpler double salts of cuprous copper are usually colourless, but the ammino-cuprous chlorides are brown (Lloyd, *J. Physical Chem.*, 1908, **12**, 398); (3) the ease with which it reacts with water to give cuprous oxide, suggesting the structure

Estimations of the molecular weight in pyridine and formamide were not satisfactory, owing to rapid oxidation and to the formation of other complexes.

Attempts to prepare related compounds have not been successful. When cupric sulphate is substituted for the chloride in the preparation, metallic copper separates.

We are indebted to Mr. W. J. Lawrence for checking some of the analyses.

ARMSTRONG COLLEGE, UNIVERSITY OF DURHAM, AND

UNIVERSITY OF SYDNEY. [Received, November 28th, 1929.]

### LIV.—Nitration of Phenyl Substituents of Heterocyclic Nuclei.

By ROBERT FORSYTH and FRANK LEE PYMAN.

NITRATION of 2-phenylglyoxaline by addition of the nitrate of the base to cold sulphuric acid and heating at 100° gave 2-*p*-, 2-*o*-, and 2-*m*-nitrophenylglyoxalines in yields of 50, 1·5, and 0·2% of the theoretical respectively (Pyman and Stanley, *J.*, 1924, **125**, 2484). In view of the poor total yield, the nitration has now been repeated, the mixture, however, being kept for 60 hours at the ordinary temperature instead of being heated: the result was but little better, 2-*p*-nitrophenylglyoxaline being obtained in a yield of 57% of the theoretical, and oxidation of the by-products gave a mixture of acids from which crude *m*-nitrobenzoic acid was isolated in 5% yield. Attempts to obtain a clearer picture of a similar nitration by employing 2-phenyl-1-methylglyoxaline were unsuccessful, for the only identifiable products in this case were the *p*-nitro-derivative in

39% yield and *p*-nitrobenzoic acid (by oxidation of the by-products) in 4.4% yield.

Whilst the above nitrations yield *p*-nitro-derivatives as main products, the nitration of 2-phenylglyoxaline-4 : 5-dicarboxylic acid (Pyman and Stanley, *loc. cit.*), 2-phenyl-4 : 5-dihydroglyoxaline, and benzamidine (Forsyth, Nimkar, and Pyman, J., 1926, 800) have been shown to yield predominantly *m*-nitro-derivatives. In the hope of throwing light on this difference in substitution, the nitration of a number of allied compounds has been studied, but experimental difficulties prevented anything more than an incomplete picture of the nitration being obtained in each case. 4-Hydroxy-2-phenyl-6-methylpyrimidine gave 50% of the *m*-nitro-compound, and oxidation of the mother-liquor gave a further 7% of *m*-nitrobenzoic acid : it thus resembles benzamidine rather than 2-phenylglyoxaline. The nitration of phenylacetamidine gave 75% of the *p*-nitro-derivative, just as the nitration of  $\beta$ -phenylethylamine gives mainly the *p*-compound, and 1-phenylglyoxaline also gave the *p*-nitro-compound (58%). On nitration, 4-phenylpiperidine gave the *p*-, *o*-, and *m*-nitro-compounds in yields of 52, 8, and 3% respectively : the proportion of *m*-compound is thus considerably less than in the nitration of 4-phenylpyridine, where the *p*-, *o*-, and *m*-compounds were isolated in yields of 38, 13, and 28% respectively.

We regret that in publishing our paper on the nitration of 2-, 3-, and 4-phenylpyridines (J., 1926, 2912) we overlooked the previous publication of Tschitschibabin and Schemjakina (*J. Russ. Phys. Chem. Soc.*, 1921, 53, 217) owing to the fact that no reference was made to it in our *Abstracts*, although it was abstracted in the *Chem. Zentralblatt*, 1923, ii, 1024. These authors, using different methods from ours, separated from the products of interaction of pyridine with diazotised *p*-nitroaniline two *p*-nitrophenylpyridines, m. p. 131—131.5° and 146—147° respectively. They proved that the first was 2-*p*-nitrophenylpyridine (for which we found m. p. 130.5—131.5°) and assumed that the second was 4-*p*-nitrophenylpyridine. In view of our results, however, it is clear that their second compound was 3-*p*-nitrophenylpyridine, for which we found m. p. 148—149°.

#### EXPERIMENTAL.

*Nitration of 2-Phenyl-1-methylglyoxaline.*—2-Phenyl-1-methylglyoxaline nitrate, described as needles, m. p. about 100°, but not analysed by Balaban and King (J., 1925, 127, 2701), crystallises from dry acetone in prismatic needles, m. p. 126—127° (corr.). It is anhydrous, readily soluble in water, and fairly readily soluble in alcohol or acetone (Found : C, 54.2; H, 5.3; N, 19.1.  $C_{10}H_{10}N_2.HNO_3$  requires C, 54.3; H, 5.0; N, 19.0%).

This salt (5 g.) was added to sulphuric acid (10 c.c.) below 0° and the solution was kept for an hour, heated at 100° for another hour, and diluted with ice-water. The colourless crystals which separated (0.56 g.; m. p. 167—168°) were rejected, as was also an ether-extract of the solution (0.38 g. of gummy crystals). When the aqueous solution was basified with sodium hydroxide, pale yellow crystals separated (2.4 g.; m. p. 90—100°); chloroform extracted from the mother-liquor 1.21 g. of syrupy bases. The precipitated base was converted into nitrate, which was crystallised from alcohol, giving pure 2-*p*-nitrophenyl-1-methylglyoxaline nitrate (2.05 g.; m. p. 184—185° [corr.]; yield, 34.1%); the mother-liquors gave a further 4.8% yield of the same substance rather less pure, and after oxidation with permanganate a 4.4% yield of crude *p*-nitrobenzoic acid.

The above nitrate and the base, m. p. 117—118° (corr.), and picrate, m. p. 214—215° (corr.), prepared from it were shown by the mixed melting-point method to be identical with the base and its salts prepared by the methylation of 2-*p*-nitrophenylglyoxaline, for which Balaban and King (*loc. cit.*) give the m. p.'s (nitrate) 186° (base) 116.5°, and (picrate) 212° (all corr.).

*Phenylacetamidine Nitrate*.—Phenylacetiminoethyl ether hydrochloride was prepared by the method of Luckenbach (*Ber.*, 1884, 17, 1421) in 92% yield; it had m. p. 99—100° (corr.; efferv.) after sintering from 97°. Luckenbach gives m. p. 85° after softening at 60°. This salt was converted into crude phenylacetamidine hydrochloride by means of alcoholic ammonia (Luckenbach, *loc. cit.*) and thence into the nitrate by means of silver nitrate. Phenylacetamidine nitrate was thus obtained in 93% yield. It crystallises from water in large rhombic prisms, m. p. 168—169° (corr.). Bernton (*Arkiv Kemi Min. Geol.*, 1918, 7, 1) gives m. p. 166—167°, but does not give an analysis of this salt. It is moderately easily soluble in water and sparingly soluble in alcohol (Found: N, 21.6.  $C_8H_{10}N_2.HNO_3$  requires N, 21.3%).

*Nitration of Phenylacetamidine*.—Phenylacetamidine nitrate (5 g.) was added to sulphuric acid (10 c.c.) below 0°. The solution was kept for one hour, heated at 100° for 2 hours, cooled, and diluted with ice-water. On extraction with ether, only a trace of material was removed. The aqueous solution was mixed with sufficient aqueous barium chloride to remove sulphate ions, filtered from barium sulphate, and concentrated to small bulk. Since the hydrochlorides obtained did not crystallise, they were dissolved in water and mixed with the equivalent quantity of silver nitrate. After removal of silver chloride and concentration, crude *p*-nitrophenylacetamidine nitrate separated (5.66 g.; m. p. 150°); the mother-liquor gave on evaporation a sticky residue (0.59 g.; m. p. 100—115°). Crystal-

lisation of the nitrate of higher m. p. from alcohol gave pure *p*-nitrophenylacetamidine nitrate (4.42 g.; m. p. 157° [corr.]; yield, 69.7%), which was identified with the synthetic product described below by the mixed melting-point method. Attempts to fractionate the remaining material by crystallisation as nitrate, or as picrate, or after oxidation as nitrobenzoic acids, were fruitless. Orientation of *p*-nitrophenylacetamidine was effected by its synthesis from *p*-nitrophenylacetonitrile.

*Synthesis of p-Nitrophenylacetamidine.*—A suspension of *p*-nitrophenylacetonitrile (16.2 g.) in dry ether (20 c.c.) and absolute alcohol (4.6 g.) was saturated with dry hydrogen chloride. After 3 days, the *p*-nitrophenylacetiminoethyl ether hydrochloride, which had separated as a colourless crystalline powder, was collected and washed with ether (yield, 21.6 g.; 88%). When heated slowly from the ordinary temperature, it softened at about 188° and melted at 191–192° (corr.: decomp.), but it decomposed when placed in a bath at 150° (Found: Cl, 14.2.  $C_{10}H_{12}O_3N_2 \cdot HCl$  requires Cl, 14.5%). This salt is fairly readily soluble in alcohol, but sparingly soluble in ether; it is decomposed by water.

To *p*-nitrophenylacetiminoethyl ether hydrochloride (10 g.), suspended in absolute alcohol (10 c.c.), absolute alcohol saturated with ammonia at 0° was added gradually until a slight excess of ammonia remained after prolonged shaking. After being kept at 30° for 2 days, the mixture was diluted with water, acidified faintly with hydrochloric acid, concentrated to remove alcohol, and extracted with ether. The aqueous liquor was mixed with sufficient aqueous silver nitrate to remove chlorine ions, filtered from silver chloride, and concentrated. *p*-Nitrophenylacetamidine nitrate [7.6 g.; m. p. 157° (corr.)] then separated, and the mother-liquor on concentration gave a further deposit which, after removal of non-basic material by ether, afforded a further 0.72 g. of the nitrate, m. p. 157° (corr.). Total yield, 81%.

*p-Nitrophenylacetamidine nitrate* crystallises from water or moist alcohol in colourless coarse needles which rapidly become pale yellow in contact with air. It contains  $\frac{1}{2}H_2O$ , which is lost slowly over sulphuric acid, and the dried salt has m. p. 157° (corr.). It is moderately easily soluble in water or alcohol. Its aqueous solution becomes intensely red on addition of alkali (Found in air-dried salt: loss over  $H_2SO_4$ , 3.6.  $C_8H_9O_2N_3 \cdot HNO_3 \cdot \frac{1}{2}H_2O$  requires  $\frac{1}{2}H_2O$ , 3.6%. Found in dried salt: C, 39.8; H, 4.3; N, 22.9.  $C_8H_9O_2N_3 \cdot HNO_3$  requires C, 39.7; H, 4.1; N, 23.1%). The picrate crystallises from water or alcohol in yellow needles, m. p. 210° (corr.). It is very sparingly soluble in both these solvents, but fairly readily soluble in acetone.

*Nitration of 4-Hydroxy-2-phenyl-6-methylpyrimidine.*—The pyrimidine (5 g.) was added to sulphuric acid (10 c.c.) below 0°, followed gradually by potassium nitrate (2.7 g.). The mixture was kept for 2 hours at the ordinary temperature, heated for 2 hours at 100°, cooled, and poured into water; crude 4-hydroxy-2-*m*-nitrophenyl-6-methylpyrimidine then separated (4.02 g.; m. p. 245–247°). After prolonged fractional crystallisation, this product gave 3.1 g. (yield, 50%) of the pure base, m. p. 257° (corr.), and small quantities (in all, 7%) of crude *m*-nitrobenzoic acid were obtained by oxidising the bases isolated from the mother-liquors. Orientation of the main product was effected by its oxidation and comparison of the oxidation product with *m*-nitrobenzoic acid, and by its identification with 4-hydroxy-2-*m*-nitrophenyl-6-methylpyrimidine prepared from *m*-nitrobenzamidine and ethyl acetoacetate. The base so prepared by us had m. p. 257° (corr.); Pinner (*Ber.*, 1895, 28, 485) gives m. p. 254°.

*Nitration of 4-Phenylpiperidine.*—4-Phenylpiperidine was prepared by the reduction of 4-phenylpyridine with sodium and alcohol after Bailly (*Ber.*, 1887, 20, 2590), and the base, which distilled mainly at 264–267° (corr.)/756 mm. (Bailly gives b. p. 255–257°/725 mm.), was converted into nitrate, the yield of pure nitrate being 67% of the theoretical calculated on the 4-phenylpyridine employed. 4-Phenylpiperidine nitrate crystallises readily from water in colourless, diamond-shaped, anhydrous plates, m. p. 139° (corr.) (Found: C, 58.8; H, 7.1.  $C_{11}H_{15}N, HNO_3$  requires C, 58.9; H, 7.1%).

4-Phenylpiperidine nitrate (30 g.) was added to concentrated sulphuric acid (60 c.c.) cooled with water, and the solution was heated for  $\frac{1}{2}$  hour at 100°. After being basified with sodium hydroxide, the product was collected by ether and mixed with 5*N*-nitric acid (28 c.c.); a crystalline nitrate (24 g.; m. p. 140–145°) then separated. The mother-liquor was evaporated to dryness and the residue was mixed with absolute alcohol and kept; it then deposited an oil which became partly crystalline. This product was separated into crystalline and oily nitrates. All the crystalline nitrates were recrystallised several times from water (3–4 parts) and gave 16.4 g. of pure 4-*p*-nitrophenylpiperidine nitrate. The mother-liquors from this were mixed with sodium iodide and gave a mixture of hydriodides from which 4-*m*-nitrophenylpiperidine hydriodide separated first on crystallisation from water. The hydriodide mother-liquors were basified and extracted with ether and the recovered base was converted into nitrate, a little more of the pure *p*-salt being obtained; the mother-liquors then yielded with sodium iodide a mixture of hydriodides from which more of the *m*-salt was obtained. The oily nitrates mentioned above gave with

sodium iodide in aqueous solution an oily hydriodide, which became partly crystalline, and the crystalline part on recrystallisation from water gave 4-*o*-nitrophenylpiperidine hydriodide. The yields were *p*-nitrate, 19.42 g. pure (52.5%); *m*-hydriodide, 1.17 g. pure + 0.2 g. of m. p. 225° (3.1%); *o*-hydriodide, 3.8 g. pure air-dried (8.1%).

The three bases were precipitated by sodium hydroxide from aqueous solutions of their salts as oils, and when these were collected by ether the *p*- and *m*-bases crystallised, melting without further purification at 95° and 77° respectively, whereas the *o*-base did not crystallise. All three bases readily absorbed carbon dioxide from the air, yielding crystalline carbonates. On oxidation with permanganate the three bases gave the corresponding nitrobenzoic acids, which were identified by the mixed m. p. method.

4-*p*-Nitrophenylpiperidine nitrate crystallises from water in very pale buff plates, m. p. 162—163° (corr.), which are anhydrous and sparingly soluble in cold water (Found: C, 49.1; H, 5.7.  $C_{11}H_{14}O_2N_2.HNO_3$  requires C, 49.1; H, 5.6%). The hydriodide crystallises from alcohol in deep yellow, anhydrous prisms, m. p. 189—190° (corr.), which are sparingly soluble in cold water or alcohol (Found: C, 39.9; H, 4.5.  $C_{11}H_{14}O_2N_2.HI$  requires C, 39.5; H, 4.5%).

4-*m*-Nitrophenylpiperidine hydriodide crystallises from water in flat, pale yellow needles, m. p. 236° (corr.). It is anhydrous and sparingly soluble in cold water (Found: C, 39.6; H, 4.5.  $C_{11}H_{14}O_2N_2.HI$  requires C, 39.5; H, 4.5%). The nitrate crystallises from water in cream-coloured prismatic needles, m. p. 205—206° (corr.), which are sparingly soluble in cold water.

4-*o*-Nitrophenylpiperidine hydriodide crystallises from water in almost colourless prismatic needles, containing 1H<sub>2</sub>O, which are sparingly soluble in cold water. After drying at 100°, it melts at 160—161° (corr.) (Found in air-dried salt: loss at 100°, 5.1.  $C_{11}H_{14}O_2N_2.HI.H_2O$  requires H<sub>2</sub>O, 5.1%. Found in dried salt: C, 39.5; H, 4.5%). The nitrate crystallises from water in almost colourless prisms, m. p. 131—132° (corr.), which are more readily soluble in water than the nitrates of the *p*- and *m*-isomerides.

*Nitration of 1-Phenylglyoxaline.*—When 1-phenylglyoxaline was dissolved in a slight excess of 5*N*-nitric acid, a solution was obtained which did not crystallise, but after addition of an excess of concentrated nitric acid and concentration of the solution under diminished pressure over sulphuric acid and sodium hydroxide, 1-phenylglyoxaline dinitrate crystallised in large prisms, m. p. 82—86° (corr.) (Found: C, 40.0; H, 3.7.  $C_9H_8N_2.2HNO_3$  requires C, 40.0; H, 3.7%). This salt (3.5 g.) was added gradually to concentrated

sulphuric acid (7 c.c.), cooled with water. The solution was kept for 2 hours, diluted with water (50 c.c.), filtered from a colourless non-basic precipitate (0.12 g.), and basified with aqueous sodium hydroxide; brown crystals (1.85 g.; m. p.  $195^{\circ}$  after sintering earlier) were then collected. The mother-liquor on extraction with ether gave only 0.1 g. of a brown oil, which became partly crystalline, but was neglected. When the brown crystals were extracted with hot dilute hydrochloric acid, some resin remained undissolved; the solution, after treatment with charcoal, was basified, 1-*p*-nitrophenylglyoxaline (1.6 g.; m. p.  $198-200^{\circ}$  after previous sintering) being precipitated. After crystallisation from alcohol, this gave 1.42 g. of the pure base (yield, 58%).

1-*p*-Nitrophenylglyoxaline crystallises from alcohol in cream-coloured prismatic needles, m. p.  $204-205^{\circ}$  (corr.) (Found: C, 56.9; H, 3.9.  $C_9H_7O_2N_3$  requires C, 57.1; H, 3.7%). It is insoluble in water and sparingly soluble in cold alcohol. The hydrochloride crystallises from dilute hydrochloric acid in almost colourless, elongated, anhydrous prisms, m. p.  $293-294^{\circ}$  (corr.; decomp.) (Found: Cl, 15.7.  $C_9H_7O_2N_3.HCl$  requires Cl, 15.7%).

In order to determine the orientation of the nitro-group, the base (0.75 g.) and methyl sulphate (0.75 c.c.) were heated for a few minutes at  $100^{\circ}$ ; a crystalline methosulphate was then formed. This was decomposed by boiling with aqueous sodium hydroxide; the *p*-nitroaniline (0.45 g.; m. p.  $132^{\circ}$ ) that separated gave 0.15 g. of the pure base (m. p.  $148^{\circ}$ , alone or mixed with pure *p*-nitroaniline) after purification.

## LV.—The Constitution of Cryptal.

By ARTHUR RAMON PENFOLD and JOHN LIONEL SIMONSEN.

It was shown some years ago (Penfold, J., 1922, 121, 266) that the aldehyde "aromadendral" described by Smith (*J. Roy. Soc. New South Wales*, 1900, 34, 286; *Pharm. J.*, 1905, 75, 356, 382; *Trans. Roy. Soc. South Australia*, 1916, 40, 485) was a mixture of cumin-aldehyde, phellandral, and a new aldehyde, *l*-cryptal, isomeric with phellandral. This aldehyde has now been found to be 4-isopropyl- $\Delta^2$ -cyclohexenal (I), since on oxidation with potassium permanganate in acetone solution it gives *d*- $\alpha$ -isopropylglutaric acid (III) in almost quantitative yield, oxidation evidently proceeding in accordance

with the following scheme, diosphenolcarboxylic acid (II) being formed as an intermediate product :

A number of experiments were made with the object of oxidising *l*-cryptal to the corresponding *cyclohexenecarboxylic acid*, but these were uniformly unsuccessful. The reaction with silver oxide proceeds smoothly, but, under all the conditions employed, the acid was a gum which showed no tendency to crystallise. This was possibly due to its being a mixture of  $\alpha\beta$ - and  $\beta\gamma$ -isomerides, but the quantity of material available was insufficient for a separation to be attempted. In another series of experiments, *l*-cryptaloxime was treated with acetic anhydride with the object of converting it into the nitrile: the reaction, however, proceeded abnormally and, although a little impure nitrile was obtained, the main product was a crystalline substance, m. p. 102–103°, which from its analysis appeared to have the formula  $\text{C}_{22}\text{H}_{30}\text{O}_2\text{N}_2$  or  $\text{C}_{22}\text{H}_{32}\text{O}_2\text{N}_2$ . It had the properties of a weak base, but its constitution was not determined.

The constitution which is now shown to be that of *l*-cryptal was assigned originally by Wallach (*Annalen*, 1905, 340, 15; 343, 34) to the tetrahydrocuminaldehyde formed by the action of dilute sulphuric acid on  $\beta$ -phellandreneglycol. This aldehyde was shown subsequently to be identical with phellandral (4-isopropyl- $\Delta^1$ -cyclo-

hexenal) (IV) (compare Schimmel's Report, 1909, October, p. 88). The occurrence in admixture with each other of the three aldehydes cuminaldehyde (V), phellandral (IV), and cryptal (I), is not without biogenetic interest, since they can all three arise very simply from  $\alpha$ -phellandrene (VI), the chief hydrocarbon constituent of the oils in which they occur.

#### EXPERIMENTAL.

The *l*-cryptal used in these experiments was the original specimen prepared by Penfold in 1922.

*l*-Cryptaloxime was readily obtained by the interaction of an alcoholic solution of cryptal with hydroxylamine hydrochloride in the presence of sodium acetate. After distillation in steam the oxime was obtained as a thick oil, b. p.  $150^{\circ}/17$  mm.,  $n_D^{20}$  1.5139; it did not crystallise even when cooled to a low temperature (Found: C, 71.7; H, 9.8.  $C_{10}H_{17}ON$  requires C, 71.8; H, 10.2%).

When the oxime was mixed with an excess of acetic anhydride in the presence of sodium acetate, heat was generated and the solution became yellow. After 30 minutes' boiling, a very vigorous reaction occurred and the solution became deep brown. When the cooled solution was poured into water, a viscid brown oil separated: this was dissolved in ether, the extract washed with sodium carbonate solution, dried, and evaporated, and the residual oil distilled under diminished pressure; the greater part boiled at  $200$ – $210^{\circ}/23$  mm., leaving a considerable residue. The distillate, which smelt strongly of a nitrile, crystallised almost completely on keeping. The solid, after being drained on porous porcelain, crystallised from light petroleum (b. p.  $60$ – $80^{\circ}$ ) in fine long needles, m. p.  $102$ – $103^{\circ}$  (Found: C, 74.1, 74.3; H, 8.8, 8.6; N, 8.4.  $C_{22}H_{30}O_2N_2$  requires C, 74.6; H, 8.5; N, 7.9.  $C_{22}H_{32}O_2N_2$  requires C, 74.1; H, 9.0; N, 7.9%). This substance, which was optically inactive, was not attacked by alkali even on prolonged boiling; it was soluble in concentrated mineral acids and precipitated on dilution with water.

*l*-Cryptalphenylhydrazone is an oil, but the *p*-nitrophenylhydrazone crystallised from alcohol in terra-cotta, highly iridescent, soft needles, m. p.  $167^{\circ}$  (Found: N, 14.9.  $C_{16}H_{21}O_2N_3$  requires N, 14.6%).

*Oxidation of l*-Cryptal.—To the aldehyde (10 g.), dissolved in acetone (200 c.c.) and cooled to  $0^{\circ}$ , potassium permanganate (25 g.) was gradually added. The oxidation proceeded rapidly at first but later became very slow. Water (50 c.c.) was then added and the oxidation completed by the addition of potassium permanganate (20 g.). The manganese dioxide sludge was separated and well washed with boiling water and the filtrate was evaporated to a small bulk in a current of carbon dioxide. After acidification the oxid-

ation product was extracted with ether (10 times), the extract dried, and the solvent evaporated. The residual oil (11 g.) crystallised on keeping and after draining on porous porcelain had m. p. 90°. It was recrystallised from hydrochloric acid, yielding small glistening plates, m. p. 93—94°, of *d*- $\alpha$ -isopropylglutaric acid (Found : C, 55.2; H, 7.9; *M*, 175. Calc. : C, 55.1; H, 8.0%; *M*, 174). In aqueous solution (*c* = 0.766),  $[\alpha]_{5461} + 14.2^\circ$  was observed. The anhydride crystallised from light petroleum in the curious soft needles, resembling cotton-wool, described by Perkin (J., 1896, 69, 1495); the anilic acid had m. p. 154—155°.

[Received, January 27th, 1930.]

## LVI.—Derivatives of 3-Keto-2 : 3-dihydrothionaphthen 1 : 1-Dioxide.

By AARON COHEN and SAMUEL SMILES.

CERTAIN members of this group were required in connexion with other experiments, but no systematic method of obtaining them was available. Treatment of 3-keto-2 : 3-dihydrothionaphthen with hydrogen peroxide gives the parent substance (II, R = H) in poor yield (Lanfry, *Compt. rend.*, 1912, 154, 1517), but the method is untrustworthy for the preparation of derivatives. Price and Smiles (J., 1928, 2860) prepared 3-keto-2-*p*-nitrophenyl-2 : 3-dihydrothionaphthen 1 : 1-dioxide (II, R = *p*-NO<sub>2</sub>·C<sub>6</sub>H<sub>4</sub>) from the sulphone ester (I, R = *p*-NO<sub>2</sub>·C<sub>6</sub>H<sub>4</sub>) derived from *o*-carboxybenzenesulphonic acid, and the carbethoxy-derivative (II, R = CO<sub>2</sub>Et) was obtained in a similar manner.

This mode of synthesis has now been further studied and, with certain limitations, has been found satisfactory; for instance, the *phenyl*, *o*-*nitrophenyl*, *acetyl*, and *benzoyl* derivatives (II, R = substituent) are readily obtained by reaction of the corresponding sulphone esters with sodium ethoxide.

The requisite sulphone esters (I) are often conveniently obtained in one operation from an alkali *o*-carboxybenzenesulphinate and the halogen derivative, but in cases (*e.g.*, I, R = Ph) where esterification does not proceed easily under the conditions it is more convenient to treat the ethyl ester of the sulphone acid (III) with sodium ethoxide,

admixture of the product with the ether (*e.g.*, IV) thus being avoided.

The structural conditions necessary to this closing of the ring are provided by the sulphone group (compare Troeger and Kroseberg, *J. pr. Chem.*, 1913, **87**, 67) and by the nature of R. For instance, in contrast with the corresponding sulphones, the ester of the benzyl sulphide (V, R = Ph) does not yield the ketodihydrothionaphthen with sodium ethoxide (Apitzsch, *Ber.*, 1913, **46**, 3092), the ester of *o*-carboxyphenylmethylsulphone (I, R = H) does not give the cyclic sulphone, and the *ethyl* ester of *ethylene di-o-carboxyphenylsulphone* (as III, R = CH<sub>2</sub>·) is not converted into the dicyclic sulphone by this method.

The stability conferred on the thionaphthen ring by the substituents phenyl, acetyl, benzoyl, and nitrophenyl is remarkable; the derivatives having these substituents in the 2-position dissolve in warm aqueous alkali hydroxide without fission, whereas the parent substance is attacked by the cold reagent, yielding *o*-carboxyphenyl-methylsulphone.

Very stable polycyclic systems are easily formed from derivatives of type (II): reduction of the *o*-nitrophenyl derivative leads directly to the *thionaphthindole dioxide* (VI), and the monophenyl-

hydrazones of the acetyl and benzoyl derivatives yield the thionaphthapyrazole dioxides (VII, R = Me and Ph, respectively).

The characters of 3-keto-2-benzoyl-2 : 3-dihydrothionaphthen and of the corresponding dioxide (II, R = CPh) have been contrasted in a few typical experiments: these indicate that the latter substance approaches more closely to the  $\beta$ -diketonic structure than the former, which behaves as a 2-hydroxy-ketone. For example, the thionaphthen is easily acetylated and yields only a monophenylhydrazone (Hart and Smiles, *J.*, 1924, **125**, 876), but the corresponding dioxide gives a *diphenylhydrazone* and cannot be acetylated under comparable conditions. The relationship is also well illustrated by the instability of the *borodiacetate* of the dioxide (VIII) in comparison with the stability of the characteristic derivative (VIII with S in place of SO<sub>2</sub>) of the thionaphthen. This relationship accords with

the observations of McClelland (J., 1929, 1590) that sulphur in the ortho-position to carbonyl favours enolisation of the latter by

increasing the negative character of the oxygen, whereas conversion of the sulphide into the sulphone lessens the activity of the sulphur as a source of electrons and thus moderates the enolic tendency of the carbonyl oxygen.

The halogen derivatives of this series exhibit interesting features. Bromination proceeds easily at the 2-position when available hydrogen is present. The parent substance (II, R = H) yielded the 2:2-dibromo-derivative, and the monobromo-derivative (IX) could be obtained only by decomposition of the unstable 2-bromo-2-carbethoxy-compound (IX with CO<sub>2</sub>Et in place of H); other bromine derivatives of the 2-substituted ring (II with Br in place of H) were more stable.

In accordance with the known character of the sulphone group and with the observations of Macbeth and his co-workers (J., 1922, 121, 892, 904, 1116) on substances of analogous type, the halogen in the 2-bromo-derivatives is removed as hypobromite by alkali hydroxide, being replaced by hydrogen, except in the mono- and di-bromo-compounds, where the process is modified by fission of the sulphone ring system. Moreover, in the monobromo-derivatives (IX, and II with Br in place of H) the halogen quantitatively liberates iodine from potassium iodide. These reactions appear to be characteristic of chlorine or bromine in the 2-position. Nitrous acid also attacks hydrogen in this position: in the parent substance replacement is complete, the nitroso-derivative undergoing further substitution (compare Friedländer, *Ber.*, 1908, 41, 227), but with the 2-phenyl derivative oxidation ensues, the oxide (X) being formed. This oxide is devoid of basic character and the corresponding 2-bromo-derivatives do not exhibit the properties of salts.

These facts give useful information concerning the structure of the product obtained by the action of excess of nitrous acid on the 2-*p*-aminophenyl derivative. The red crystalline material thus formed is basic in character and the chloride, from which the base is regenerated by hydrolysis, furnishes a *ferrichloride* and a *chloroplatinate*. In composition the base conforms with the structure (XI), but this arrangement, which involves the association of

hydroxyl with the 2-carbon atom, cannot be adopted, since the 2-oxide is entirely lacking in basic character. Similarly, the association of halogen with the 2-position of the thionaphthen nucleus (XI with Cl in place of OH) cannot be admitted in the case of the chloride or bromide; these salts are merely hydrolysed by water or

dilute alkalis and do not exhibit the characteristic behaviour of the 2-bromo-derivatives (IX, and II with Br in place of H), which liberate hypobromite on treatment with such agents. Moreover, a quinolide structure (XII) similar to that proposed by Gomberg (*J. Amer. Chem. Soc.*, 1913, **35**, 1035) for one of the isomeric forms of 4-hydroxytriphenylcarbinol and analogous substances is unacceptable, since removal of water from the base in question is effected only with difficulty, prolonged heating in a vacuum in presence of phosphoric oxide being necessary. On the other hand, the formation and properties of the base and salts are well expressed by the formula XIII (X = OH or Cl) in which the kation is formed by co-ordination of hydrogen with the carbonyl group of the quinone. This view accords with those of Pfeiffer (*e.g.*, *Annalen*, 1917, **413**, 328) on the nature of salts formed by substances containing the carbonyl group.

#### EXPERIMENTAL.

**3-Keto-2-benzoyl-2 : 3-dihydrothionaphthen 1 : 1-Dioxide** (II, R = C<sub>6</sub>H<sub>5</sub>).—(a) A concentrated solution of  $\omega$ -bromoacetophenone (23 g.) was added to an alcoholic solution of *o*-carboxybenzenesulphonic acid (10 g.) (*J.*, 1928, 2860) which had been neutralised with concentrated aqueous potassium hydroxide. When the mixture was boiled, potassium bromide separated ( $\frac{1}{2}$  hour); the cooled liquid yielded a further quantity of this salt together with *phenacyl-o-carbophenacylphenylsulphone* (I, R = C<sub>6</sub>H<sub>5</sub>). This substance (70% yield) separated from acetone-alcohol in needles, m. p. 164° (Found : C, 65.1; H, 4.5; S, 7.5. C<sub>23</sub>H<sub>18</sub>O<sub>6</sub>S requires C, 65.4; H, 4.3; S, 7.6%). A solution of this ester (8 g.) in alcohol (50 c.c.) in which sodium (0.4 g.) had been dissolved was boiled for 30 minutes and the solvent was then evaporated after the addition of water. Benzoylcarbinol was removed by solution in ether and the aqueous liquid was mixed with an excess of dilute sulphuric acid. **3-Keto-2-benzoyl-2 : 3-dihydrothionaphthen 1 : 1-dioxide**, which separated in 66% yield, crystallised from benzene in plates, m. p. 188° (Found : C, 62.6; H, 3.6; S, 11.0. C<sub>15</sub>H<sub>10</sub>O<sub>4</sub>S requires C, 62.9; H, 3.5; S, 11.2%).

(b) 3-Keto-2-benzoyl-2 : 3-dihydrothionaphthen (0.5 g.), suspended in acetic acid (10 c.c.) to which hydrogen peroxide (1 c.c. of 30%) had been added, dissolved after 2 days and the oxidation product, which was identical with the substance obtained as described above, separated.

The substance was recovered unchanged from 10% sodium hydroxide solution after 3 hours' boiling and attempts to obtain an acetyl or benzoyl derivative by the usual methods were unsuccessful. The *diphenylhydrazone*, m. p. 243° after crystallisation from alcohol, was obtained from the substance (1 mol.) and phenylhydrazine (3 mols.) in boiling concentrated benzene solution (Found : N, 12.2.  $C_{27}H_{22}O_2N_4S$  requires N, 12.0%).

When the preparation of a monophenylhydrazone of 3-keto-2-benzoyl-2 : 3-dihydrothionaphthen 1 : 1-dioxide was attempted by boiling an alcoholic solution containing phenylhydrazine (1 mol.), 1 : 3-*diphenylthionaphthapyrazole* 5 : 5-dioxide (VII, R = Ph) was obtained : this crystallised from acetone in prisms, m. p. 225°, which were insoluble in alkali and responded to Knorr's pyrazole test (*Ber.*, 1893, 26, 100) (Found : N, 8.2; S, 8.8.  $C_{21}H_{14}O_2N_2S$  requires N, 7.8; S, 8.9%).

The *borodiacetate* (VIII) separated in lemon-yellow needles, m. p. 220° (decomp.), when a boiling solution of the substance (II, R = Ph) in acetic anhydride containing boroacetic anhydride was cooled. It was easily decomposed by cold water, yielding the parent substance (II); analysis was made by weighing this product (Found :  $C_{15}H_{10}O_4S$ , 68.9.  $C_{19}H_{15}O_6SB$  requires  $C_{15}H_{10}O_4S$ , 69.2%). For comparison, the *borodiacetate* of 3-keto-2-benzoyl-2 : 3-dihydrothionaphthen (VIII with S in place of  $SO_2$ ) was prepared in a similar manner : it formed red prisms which were very slowly decomposed by boiling water (Found :  $C_{15}H_{10}O_2S$ , 67.1.  $C_{19}H_{15}O_6SB$  requires  $C_{15}H_{10}O_2S$ , 66.7%).

3-Keto-2-phenyl-2 : 3-dihydrothionaphthen 1 : 1-Dioxide (II, R = Ph).—(a) Alcohol (50 c.c.) which contained benzyl chloride (6.8 g.) and the potassium salt of *o*-carboxybenzenesulphinic acid (14.2 g.) was boiled for 3 hours. When the potassium chloride had been removed, the sparingly soluble potassium salt (7.8 g.) of *o*-carboxyphenylbenzylsulphone (III, R = Ph) separated. The acid, liberated in the usual manner, crystallised from water in needles, m. p. 126—128° after dehydration at 100° (Found : C, 60.8; H, 4.3;  $H_2O$ , 6.2.  $C_{14}H_{12}O_4S.H_2O$  requires C, 61.1; H, 4.0;  $H_2O$ , 6.1%). The methyl ester (1 mol.), prepared from the silver salt, was heated for 20 minutes with alcohol which contained sodium ethoxide (1 mol.); the solvent was then evaporated, and an aqueous extract of the residue treated with an excess of dilute sulphuric acid. 3-Keto-2-phenyl-2 : 3-di-

*hydrothionaphthen 1 : 1-dioxide*, obtained in 60% yield, crystallised from acetone-alcohol in prisms, m. p.  $174^{\circ}$  (Found : C, 65.0; H, 3.9.  $C_{14}H_{10}O_3S$  requires C, 65.1; H, 3.9%). The yellow alkaline solution yielded unaltered material after 2 hours' boiling.

(b) This phenyl derivative was also obtained by boiling a solution of potassium *o*-carboxybenzenesulphinate (1 mol.) in alcohol which contained benzyl chloride (2 mols.) and treating the resulting solution with sodium ethoxide as usual. When the solvent and other volatile materials had been removed in steam, the remaining aqueous alkaline solution gave the 2-phenyl derivative in 15% yield on treatment with acid. An equal quantity of material which was insoluble in the alkali was identified with the *benzyl ether* (IV) of 3-hydroxy-2-phenylthionaphthen 1 : 1-dioxide synthesised from the 2-phenyl derivative (II, R = Ph) and benzyl chloride in alkaline solution : it separated from acetone-alcohol in prisms, m. p.  $146^{\circ}$  (Found : C, 72.4; H, 4.6; *M*, 357.  $C_{21}H_{16}O_3S$  requires C, 72.4; H, 4.6%; *M*, 348).

*3-Keto-2-acetyl-2 : 3-dihydrothionaphthen 1 : 1-Dioxide* (II, R = CO·CH<sub>3</sub>).—Alcohol (75 c.c.) which contained monochloroacetone (15 g.) and the potassium salt prepared from *o*-carboxybenzenesulphinic acid (15 g.) was boiled for 5 hours. The solution, which contained the sulphone ester (I, R = CO·CH<sub>3</sub>), was treated with sodium ethoxide in the usual manner. Half the volume of solvent was evaporated and the material which separated from the cooled residue was purified from water (charcoal). The required *product* was liberated from the aqueous solution by dilute mineral acid; it separated from benzene-ligroin in prisms, m. p.  $164^{\circ}$  (Found : C, 53.5; H, 3.7.  $C_{10}H_8O_4S$  requires C, 53.6; H, 3.6%). The ketone was recovered unchanged from a boiling alkaline solution. Attempts to prepare the substance by oxidation of 3-keto-2-acetyl-2 : 3-dihydrothionaphthen with hydrogen peroxide were unsuccessful, the chief product being "thioindigo."

The *monophenylhydrazone* was obtained by boiling an alcoholic solution of the ketone with phenylhydrazine (slightly more than 1 mol.) for 3 hours. It crystallised from alcohol in yellow needles, m. p.  $210^{\circ}$ , which were soluble in aqueous alkali (Found : C, 61.1; H, 4.8; N, 9.2.  $C_{16}H_{14}O_3N_2S$  requires C, 61.1; H, 4.8; N, 8.9%). When a solution of the phenylhydrazone in acetic acid containing a few drops of sulphuric acid was warmed at  $90^{\circ}$  for 1 hour, dehydration was effected and 1-phenyl-3-methylthionaphthapyrazole 5 : 5-dioxide (VII, R = CH<sub>3</sub>) was produced. This, isolated from the fluorescent solution by dilution, formed prisms, m. p.  $180^{\circ}$ , which were insoluble in alkali or acid (Found : N, 9.7.  $C_{16}H_{12}O_2N_2S$  requires N, 9.5%). The substance responded to Knorr's pyrazole test.

*3-Keto-2-o-nitrophenyl-2 : 3-dihydrothionaphthen 1 : 1-Dioxide* (II,  $R = o\text{-NO}_2\cdot\text{C}_6\text{H}_4$ ).—The *o*-nitrobenzyl ester (I,  $R = o\text{-NO}_2\cdot\text{C}_6\text{H}_4$ ) of *o*-carboxyphenyl-*o*-nitrobenzylsulphone was prepared from *o*-nitrobenzyl chloride and potassium *o*-carboxybenzenesulphinate in the usual manner; it separated from aqueous acetone in plates, m. p.  $156^\circ$  (Found: C, 55.1; H, 3.7; N, 5.9.  $\text{C}_{21}\text{H}_{16}\text{O}_8\text{N}_2\text{S}$  requires C, 55.3; H, 3.5; N, 6.1%). A solution of this substance (5 g.) in alcohol (100 c.c.) in which sodium (0.25 g.) had been dissolved was boiled ( $\frac{1}{2}$  hour); the solvent was then evaporated, and the residue treated with water and ether. The latter solvent removed *o*-nitrobenzyl alcohol. The aqueous solution on treatment with excess of dilute acid yielded *3-keto-2-o-nitrophenyl-2 : 3-dihydrothionaphthen dioxide* (2 g.), which crystallised from acetone in prisms, m. p.  $187^\circ$  (Found: C, 55.3; H, 3.2.  $\text{C}_{14}\text{H}_9\text{O}_5\text{NS}$  requires C, 55.5; H, 3.0%).

Zinc dust was added to a boiling solution of the nitro-compound in acetic acid. The product, separated from the cooled liquid and crystallised from alcohol, gave *thionaphthindole dioxide* (VI) in needles, m. p.  $220^\circ$  (Found: C, 65.6; H, 3.6; S, 12.4.  $\text{C}_{14}\text{H}_9\text{O}_2\text{NS}$  requires C, 65.9; H, 3.5; S, 12.6%). This substance was also prepared by oxidation of thionaphthindole obtained by McClelland in another manner (J., 1929, 1589).

*3-Keto-2-p-aminophenyl-2 : 3-dihydrothionaphthen 1 : 1-Dioxide* (II,  $R = p\text{-NH}_2\cdot\text{C}_6\text{H}_4$ ).—A concentrated aqueous solution of sodium hydrosulphite was added to a warm ( $70^\circ$ ) alkaline solution (200 c.c.) of the sodium salt (3 g.) of the 2-*p*-nitrophenyl derivative (J., 1928, 2862) until the red colour of the latter was discharged. When dilute acetic acid was added to the cooled mixture, the required amino-derivative (1.5 g.) was liberated. This separated from alcohol in yellow prisms, m. p. *ca.*  $180^\circ$ , which were too unstable for further purification. It was characterised by the *acetyl* derivative, which formed plates, m. p.  $226^\circ$ , from acetic acid (Found: C, 60.6; H, 4.3.  $\text{C}_{16}\text{H}_{13}\text{O}_4\text{NS}$  requires C, 60.9; H, 4.1%).

*Ethylenedi-o-carboxyphenylsulphone* (as III,  $R = \text{CH}_2$ ).—Alcohol (50 c.c.) which contained ethylene dibromide (5 g.) and the potassium salt derived from 10 g. of *o*-carboxybenzenesulphinic acid was boiled (4 hours). The solvent was then evaporated and ethylene dibromide was removed from the residue by a current of steam. The aqueous solution (charcoal) was mixed with excess of sulphuric acid (60%). The *product* liberated (40% yield) crystallised from acetone in needles, m. p.  $250^\circ$  (Found: C, 47.8; H, 3.7.  $\text{C}_{16}\text{H}_{14}\text{O}_8\text{S}_2$  requires C, 48.2; H, 3.5%). Boiling thionyl chloride converted it into the chloride, from which the *ethyl* ester was obtained in good yield. This formed plates from alcohol and had m. p.  $150^\circ$  (Found:

C, 52.7; H, 5.0; S, 14.2.  $C_{20}H_{22}O_8S_2$  requires C, 52.8; H, 4.8; S, 14.1%.

*2-Bromo-derivatives.*—These substances, except the monobromo-derivative of the parent compound, were obtained by the direct action of the necessary amount of bromine in a suitable solvent, usually acetic acid, and were isolated by dilution with water.

*2 : 2-Dibromo-3-keto-2 : 3-dihydrothionaphthen 1 : 1-dioxide* (IX with Br in place of H) crystallised from alcohol in needles, m. p. 148°. It liberated iodine from acidified aqueous potassium iodide. Halogen was determined in this manner (a) and also by the usual method (b) [Found : Br, (a) 47.2, (b) 47.1.  $C_8H_4O_3Br_2S$  requires Br, 47.1%]. The substance dissolved in warm aqueous alkali and the solution was found to contain carboxylic acids, evidently produced by rupture of the thionaphthen ring system.

*2-Bromo-3-keto-2 : 3-dihydrothionaphthen 1 : 1-dioxide* (IX). A suspension of the 2-carbethoxy-derivative (Feist, *Ber.*, 1925, 58, 2311) (2 g.) in acetic acid was heated together with a solution of bromine (1.4 g.) in the same solvent for 1½ hours, carbon dioxide being liberated. The product, isolated in the usual manner, crystallised from benzene in needles, m. p. 149–150° [Found : C, 36.9; H, 2.0; Br, (a) 30.7, (b) 30.2.  $C_8H_5O_3BrS$  requires C, 36.8; H, 1.9; Br, 30.6%]. It was decomposed by warm aqueous alkali, the ring suffering fission and bromine being eliminated.

*2-Bromo-3-keto-2-benzoyl-2 : 3-dihydrothionaphthen 1 : 1-dioxide* (IX with CPh in place of H) crystallised from alcohol in needles, m. p. 168° (Found : Br, 22.1.  $C_{15}H_9O_4BrS$  requires Br, 21.9%). It dissolved in warm aqueous sodium acetate, and acid liberated the original 2-benzoyl compound from the solution.

*2-Bromo-3-keto-2-phenyl-2 : 3-dihydrothionaphthen 1 : 1-dioxide* (IX with Ph in place of H) formed plates, m. p. 170°, from which aqueous sodium acetate removed halogen, replacing it by hydrogen (Found : Br, 23.7.  $C_{14}H_9O_3BrS$  requires Br, 23.8%).

*2-Bromo-3-keto-2-p-nitrophenyl-2 : 3-dihydrothionaphthen 1 : 1-dioxide* (as IX) formed plates, m. p. 155°, from acetic acid. The substance behaved in the usual manner with warm sodium acetate solution (Found : Br, 20.8.  $C_{14}H_8O_5NBrS$  requires Br, 20.9%). None of these bromine derivatives yielded perbromides or additive compounds with metallic bromides.

*The 2-Oxide of 3-Keto-2-phenyl-2 : 3-dihydrothionaphthen 1 : 1-Dioxide* (X).—(a) Concentrated hydrochloric acid (3 c.c.) was slowly added to alcohol (25 c.c.) which contained 3-keto-2-phenyl-2 : 3-dihydrothionaphthen dioxide (1 g.) and ethyl nitrite (2.7 c.c. of 15% solution) and the mixture was warmed at 90° for ¼ hour. The product (0.8 g.), obtained on cooling, separated from benzene, on

addition of light petroleum, as a microcrystalline powder, m. p.  $220^{\circ}$  (Found: C, 63.5; H, 3.7; *M*, 515.  $C_{28}H_{18}O_7S_2$  requires C, 63.4; H, 3.4%; *M*, 530).

(b) Chromic acid (0.25 g.) was added to acetic acid (15 c.c.) which contained the above phenyl derivative (1.1 g.), and the mixture was warmed and then diluted with water. After purification, the product (1 g.) was identified with that obtained in (a).

When 3-keto-2:3-dihydrothionaphthen 1:1-dioxide was treated with an excess of nitrous acid under similar conditions to the above, a substance was obtained in almost quantitative yield. It formed plates, which decomposed at  $173^{\circ}$ , and gave a red solution in cold aqueous alkali; in the warm reagent, decomposition took place, *o*-carboxybenzenesulphinic acid being formed (compare Friedländer, *loc. cit.*) (Found: C, 42.3; N, 9.4; S, 14.0.  $C_{16}H_9O_9N_3S_2$  requires C, 42.5; N, 9.3; S, 14.1%). From these data the substance appears to be a *nitroso-oximino* derivative containing the structure  $>C(NO) \cdot N(OH) \cdot C(NO)<$  formed by complete replacement of the 2-hydrogen atoms in the parent substance (II, R = H).

3-Keto-2-benzoyl-2:3-dihydrothionaphthen 1:1-dioxide was not attacked by nitrous acid.

3-Keto-2-*p*-quino-2:3-dihydrothionaphthen 1:1-Dioxide Hydroxide (XIII, X = OH).—A solution of sodium nitrite (1 g. in 10 c.c.) was slowly added to a cold solution of 3-keto-2-*p*-aminophenyl-2:3-dihydrothionaphthen 1:1-dioxide (4 g.) in concentrated hydrochloric acid (10 c.c.). The crystalline material which separated was washed with aqueous sodium acetate, with water, and with ether. It formed deep red plates, which decomposed at  $123^{\circ}$  (Found: C, 58.1; H, 3.3;  $H_2O$ , 6.1.  $C_{14}H_8O_4S \cdot H_2O$  requires C, 57.9; H, 3.4;  $H_2O$ , 6.2%). The substance dissolved in warm concentrated hydrochloric acid, and when chloroplatinic acid was added to the solution the *chloroplatinate* was precipitated in the crystalline state [Found: Pt, 19.9.  $(C_{14}H_8O_4S \cdot HCl)_2PtCl_4$  requires Pt, 20.4%]. The *ferrichloride* was obtained in orange crystals by a similar method (Found: Fe, 12.6.  $C_{14}H_8O_4S \cdot HCl \cdot FeCl_3$  requires Fe, 11.9%). Both salts were unstable in presence of moisture and decomposed when heated. When a solution of the chloride was diluted, the hydroxide was produced.

LVII.—*The Interaction of Ethyl l-Mandelate and Thionyl Chloride in the Presence of Pyridine. The Mechanism of the Replacement of Hydroxyl by Chlorine by Means of Thionyl Chloride.*

By JOSEPH KENYON, ALFRED GEORGE LIPSCOMB, and  
HENRY PHILLIPS.

WHEN a laevorotatory hydroxy-acid or its ester is treated with thionyl chloride, the chloro-acid or ester produced is dextrorotatory; e.g., ethyl *l*-malate is converted into ethyl *d*-chlorosuccinate (McKenzie and Barrow, J., 1911, 99, 1910):

McKenzie and Clough (J., 1910, 97, 2564) discovered, however, that thionyl chloride behaves differently towards hydroxy-acids (and esters) containing a phenyl group directly attached to the asymmetric carbon atom, since from these compounds it produces chloro-acids (and esters) with the same sign of rotation as the parent hydroxy-compound; e.g., ethyl *l*-mandelate is converted into ethyl *l*-phenylchloroacetate (McKenzie and Barrow, *loc. cit.*). It has now been found that if ethyl *l*-mandelate is first dissolved in a tertiary base (pyridine, quinoline, or *isoquinoline*) and then treated with thionyl chloride, ethyl *d*-phenylchloroacetate is obtained instead of ethyl *l*-phenylchloroacetate. The following changes have therefore been realised:

These results are the more surprising since *l*-β-octanol is converted into *d*-β-chloro-octane by thionyl chloride both in the absence (Levene and Mikeska, *J. Biol. Chem.*, 1924, 59, 45) and in the presence of pyridine (McKenzie and Tudhope, *ibid.*, 1924, 62, 551):

There can be little doubt that the mechanism of the interaction of thionyl chloride with hydroxy-compounds is modified by the presence of a tertiary base. The work now described suggests, however, that such modification only determines the sign of rotation of the resulting chloro-compound when a phenyl group is directly attached to the asymmetric carbon atom.

In the paragraphs below, the results of the experiments are briefly described and then the mechanisms of the chlorination

reaction of thionyl chloride in the presence and in the absence of pyridine are discussed. An explanation is also put forward to account for the difference in behaviour of hydroxy-compounds which contain an aromatic radical.

*Results of the Experiments.*—Thionyl chloride (1 or 2 mols.) was added slowly to an ice-cold solution of ethyl *l*-mandelate and the tertiary base (1 or 2 mols.) in about five volumes of dry ether. After the initial vigorous reaction had ceased, the reaction mixture was warmed on a steam-bath for 30 minutes. Water was then added, and the product extracted with ether. The ethereal extract was washed with dilute hydrochloric acid and dried, and the product isolated and distilled. The ethyl *d*-phenylchloroacetate obtained was sometimes contaminated with ethyl *l*-mandelate, particularly in those experiments in which the *l*-ester was dissolved in only one molecular proportion of the tertiary base. This was most probably due to incomplete reaction under the mild experimental conditions employed, which were chosen to minimise the interaction between the chloro-ester produced and the tertiary base.

In Table I are recorded the rotatory powers of the ethyl *d*-phenylchloroacetate and of the mixtures of ethyl *d*-phenylchloroacetate and ethyl *l*-mandelate which were isolated. The percentages of *d*-chloro-ester in the mixtures were calculated from the percentages of chlorine which they were found to contain. For purposes of comparison, the rotatory power of the ethyl *l*-phenylchloroacetate prepared by McKenzie and Barrow (*loc. cit.*) is also included in the Table. The observed rotatory power of this *l*-ester ( $[\alpha]_{5461}^l$ ,  $l = 1.0$ ) was calculated from the recorded value ( $[\alpha]_{5893}^l$ ,  $l = 1.0$ ) by aid of the dispersion ratio  $\alpha_{5893}/\alpha_{5461}$  0.816, which was determined for this purpose.

TABLE I.

*The Observed Rotatory Powers of Ethyl Phenylchloroacetate prepared from Ethyl l-Mandelate by Means of Thionyl Chloride in the Presence of Tertiary Bases.*

Tertiary base used.	Observed rotatory power, $[\alpha]_{5461}^l$ ( $l = 1.0$ ).	% Ethyl phenylchloro- acetate in the product.	% Cl in the product.*
None (McKenzie and Barrow) .....	— 91.3°	100.0	—
Pyridine.			
1 mol.; SOCl <sub>2</sub> , 1 mol. ....	+ 41.2	63.3	11.3
2 mols.; SOCl <sub>2</sub> , 2 mols. ....	+ 122.0	100.0	18.0
Quinoline.			
1 mol.; SOCl <sub>2</sub> , 1 mol. ....	+ 107.2	83.3	14.9
2 mols.; SOCl <sub>2</sub> , 2 mols. ....	+ 116.2	100.0	17.7
isoQuinoline.			
1 mol.; SOCl <sub>2</sub> , 1 mol. ....	+ 114.4	100.0	18.2
2 mols.; SOCl <sub>2</sub> , 2 mols. ....	+ 73.0	88.4	15.8

\* Ethyl phenylchloroacetate contains 17.9% Cl.

It will be seen that the magnitudes of the rotatory powers of the ethyl *d*-phenylchloroacetate obtained in these experiments were higher than that of the *l*-ester obtained by means of thionyl chloride alone. They are also greater than the rotatory power of the *d*-ester obtained by Walden (*Ber.*, 1895, **28**, 1287) by the action of phosphorus pentachloride on a solution of ethyl *l*-mandelate in chloroform. The rotatory power of this ester was  $[\alpha]_{5893} + 25.19^\circ$ , from which it can be calculated that it had  $\alpha_{5461} + 37.0^\circ$  ( $l = 1.0$ ).

*The Interaction of Thionyl Chloride with 1-β-Octanol and Ethyl l-Mandelate in the Presence of Pyridine.*—The reaction between thionyl chloride and an alcohol takes place in two stages. The alcohol is first converted into a chlorosulphinic ester, and this ester then loses sulphur dioxide and forms the chloride. In the case of *d*-amyl alcohol, McKenzie and Clough (*J.*, 1913, **103**, 698) were able to isolate the *d*-amyl chlorosulphinate and showed that by heating to  $120^\circ$  it was converted into *d*-amyl chloride. Similarly, Frankland and Garner (*J.*, 1914, **105**, 1101) have isolated ethyl *d*-α-chlorosulphinoxypionate. Attempts made in these laboratories to isolate *l*-β-octyl chlorosulphinate from the product of the interaction of *l*-β-octanol and thionyl chloride have been unsuccessful, the sole product obtained in every experiment being *d*-β-chloro-octane. Nevertheless, it is probable that this reaction, as with *d*-amyl alcohol, also occurs in two stages, and that the chlorosulphinic ester, which is the product of the first stage of the reaction, is difficult to isolate owing to its instability.

If pyridine were present, it could take part in both stages of the reaction. It could facilitate the formation of the chlorosulphinate, and also aid its decomposition by combining with it to form the unstable intermediate complex (I), a pyridinium chloride.

A similar unstable pyridinium chloride (II) might also arise during the reaction between ethyl *l*-mandelate and thionyl chloride in the presence of pyridine. The constitutions assigned to (I) and (II) involve few, if any, assumptions. It is also considered that they emphasise certain important characteristics of the unstable intermediate complexes the formation of which can be postulated in many reactions which lead to a Walden inversion. In previous

papers two reactions have been described which are known, with some degree of certainty, to take place with a Walden inversion. One is the conversion of *p*-toluenesulphonic esters into carboxylic esters (Phillips, J., 1923, **123**, 44; 1925, **127**, 2566; Kenyon, Phillips, and Turley, *ibid.*, p. 399; Gough, Hunter, and Kenyon, J., 1926, 2052), and the other the conversion of *l*- $\beta$ -octyl *p*-toluenesulphinate into *d*- $\beta$ -octanol (Houssa, Kenyon, and Phillips, J., 1929, 1700). The results obtained with the *p*-toluenesulphinate and the *p*-toluenesulphonate of *l*- $\beta$ -octanol were as follows:

It was also found (Houssa, Kenyon, and Phillips, *loc. cit.*) that *d*- $\beta$ -chloro-octane could be obtained either by the action of chlorine on the *l*-sulphinic ester or by the action of lithium chloride on the *l*-sulphonic ester. It was considered highly probable that these reactions were also accompanied by an inversion, since they were similar to the corresponding reactions with hypochlorous acid and potassium acetate. On this assumption, *d*- $\beta$ -chloro-octane has the same configuration as *d*- $\beta$ -octanol. Houssa, Kenyon, and Phillips (*loc. cit.*), abandoning the  $\alpha$ -hydrogen hypothesis of Phillips (*loc. cit.*), made use of the revised structural formulæ for *p*-toluenesulphinic esters (Phillips, *loc. cit.*, p. 2552) and sulphonic esters (Sugden, Reed, and Wilkins, J., 1925, **127**, 1525), and suggested that during the reactions, mentioned above, which lead to the formation of *d*- $\beta$ -chloro-octane, the intermediate complexes (III) and (IV) were formed.

On comparing the constitutions assigned to these two complexes, the decomposition of which is accompanied by a Walden inversion, with those assigned to the complexes (I) and (II), certain striking similarities are found. In all four the group about to sever its union with the asymmetric carbon atom has become preponderantly

positive in character. Further, the chlorine atom, about to unite with the asymmetric carbon atom, exists in each case as a negative ion. It is also noteworthy that intermediate complexes possessing these two characteristics may also be formed during two other reactions, by the aid of which, and according to the conclusions of Houssa, Kenyon, and Phillips (*loc. cit.*), *l*- $\beta$ -octanol can be converted into *d*- $\beta$ -chloro-octane. These are the interaction of *l*- $\beta$ -octanol and hydrogen chloride (V) (Pickard and Kenyon, J., 1911, 99, 45) and the interaction of *l*- $\beta$ -octyl chlorocarbonate and pyridine (Houssa and Phillips, J., 1929, 2510) (VI).

By the interaction of *l*- $\beta$ -octanol and thionyl chloride, in the presence of pyridine (I), *d*- $\beta$ -chloro-octane is produced and therefore this reaction can also be assumed to take place with inversion of configuration. It thus appears that in all the reactions by which *l*- $\beta$ -octanol, *l*- $\beta$ -octyl *p*-toluenesulphonate or *p*-toluenesulphinate can be converted into  $\beta$ -chloro-octane a Walden inversion occurs. Moreover, each of these reactions and also those by which *l*- $\beta$ -octyl *p*-toluenesulphonate is converted into carboxylic esters of *d*- $\beta$ -octanol, and *l*- $\beta$ -octyl *p*-toluenesulphinate into *d*- $\beta$ -octanol, all pass through a phase in which unstable intermediate complexes, possessing certain notable characteristics in common, are produced.

It will be assumed that since, during the reaction between ethyl *l*-mandelate and thionyl chloride in the presence of pyridine, the formation of an intermediate complex of the same type may also be postulated, this reaction is accompanied by a Walden inversion: in other words, that ethyl *l*-phenylchloroacetate has the same configuration as ethyl *l*-mandelate. It follows, therefore, on this assumption, that the interaction of ethyl *l*-mandelate and phosphorus pentachloride is also attended by a configurative change. It is significant that here again the same type of intermediate complex (VII) may arise.

A general idea underlying most of the theories of the Walden inversion (Fischer, *Annalen*, 1911, 381, 132; Werner, *Ber.*, 1911, 44, 881; Pfeiffer, *Annalen*, 1911, 383, 123; Gadamer, *Chem. Ztg.*, 1912, 36, 1327; Lowry, *Deuxième Conseil de Chimie. Solvay*, 1925, 40) is that in such reactions the entering group attaches itself to

the opposite side of the asymmetric molecule to that occupied by the group to be displaced. It is essential, therefore, for the occurrence of a Walden inversion that the entering group should be free to take up this position. In the unstable intermediate complexes of the inversion reactions described in this paper, the entering group, the chlorine anion, is always available to assume this favourable position in the molecular complex, before the groups to be displaced leave the asymmetric carbon atoms.

*The Interaction of Thionyl Chloride with l-β-Octanol and Ethyl l-Mandelate in the Absence of Pyridine.*—With l-β-octanol. Levene and Mikeska (*loc. cit.*) have shown that the action of thionyl chloride on l-β-octanol in the absence of pyridine leads to the formation of d-β-chloro-octane; hence a Walden inversion occurs, since it has been concluded that d-β-chloro-octane has the same configuration as d-β-octanol. Furthermore, since the inversion is unlikely to occur during the first stage of the reaction (as the bonds of the asymmetric carbon atom are not disturbed), it follows that it takes place when the l-β-octyl chlorosulphinate decomposes.

It has been found that the interaction of thionyl chloride and l-β-octanol in the presence of potassium carbonate also leads to the formation of d-β-chloro-octane. This result indicates that the d-β-chloro-octane obtained in the absence of potassium carbonate does not arise from the interaction, as shown in (IX), of the chlorosulphinate with the hydrogen chloride produced in the first stage of the reaction.

It seems reasonable to assume that when the various intermediate complexes, which have been postulated, decompose, the asymmetric carbon atoms necessarily acquire a positive charge, since, ultimately, they each unite with a negative chlorine ion. It is therefore possible that, when l-β-octyl chlorosulphinate decomposes, it splits up into a carbonium kation, sulphur dioxide, and a chlorine anion, and that the d-β-chloro-octane is formed by the union of the carbonium ion with the chlorine ion :

Experimental evidence, however, is still wanted which will show whether the formation of a carbonium kation is attended with a

a negative ion and a positively charged group (the nitrogen molecule) about to leave the asymmetric carbon atom.

*With ethyl l-mandelate.* McKenzie and Barrow (*loc. cit.*) have shown that thionyl chloride, in the absence of pyridine, converts ethyl *l*-mandelate into ethyl *l*-phenylchloroacetate. It has been suggested that these two compounds have the same configuration and therefore that the reaction is not accompanied by a Walden inversion. As in the study of the interaction of *l*- $\beta$ -octanol and thionyl chloride, an experiment was made to prove that the ethyl *l*-phenylchloroacetate was not formed by the interaction of the products of the first stage of the reaction, namely, hydrogen chloride and ethyl *l*-mandelylchlorosulphinate. It was found that potassium carbonate (*in marked contrast to pyridine*) had no influence on the sign of rotation of the ethyl phenylchloroacetate obtained. There appear to be two possible mechanisms (A and B) by which the decomposition might take place.

Of these two alternatives, only (B) sharply differentiates the decomposition of ethyl *l*-mandelylchlorosulphinate from that of *l*- $\beta$ -octyl chlorosulphinate and assigns a definite function to the phenyl group. This function is to confer on the asymmetric carbon atom the power to retain electrons during the decomposition. A phenyl group can function in this way, since it is strongly electron-attracting, whereas purely aliphatic groups, such as methyl and *n*-hexyl, are electron-donating groups, which, therefore, when attached to an asymmetric carbon atom, weaken its power to retain electrons. This mechanism also gives a satisfactory explanation of the power of pyridine to change the sign of rotation of the product of this decomposition. The interaction of pyridine with the chlorosulphinate produces a pyridinium chloride (II) in which the positive character of the chlorosulphinoxy-group has been augmented and its electron-retaining power therefore increased. Hence, when the chlorosulphinate decomposes in the presence of pyridine, the increased electron-retaining power of the chlorosulphinoxy-group enables it to overcome the electron-retaining power conferred on the asymmetric atom by the phenyl group, with the result that the asymmetric carbon atom loses two electrons during the further stages of the decomposition, which now leads to a Walden inversion.

## EXPERIMENTAL.

*l*-Mandelic acid, isolated from amygdalin (Freudenberg and Markert, *Ber.*, 1925, 58, 1753), was converted into ethyl *l*-mandelate by the method of Fischer and Speier.

*The Interaction of Thionyl Chloride with Ethyl l-Mandelate and d-β-Octanol in the Presence of Potassium Carbonate.*—With ethyl *l*-mandelate. Thionyl chloride (2.97 g.) in ether (10 c.c.) was added to a solution of ethyl *l*-mandelate (4.5 g.) in ether (50 c.c.) containing recently ignited potassium carbonate (10.4 g.). The mixture was heated under reflux for  $\frac{1}{2}$  hour, the potassium carbonate and chloride were removed by filtration, and the ether was distilled from the filtrate. The residue on distillation gave a mixture of ethyl *l*-mandelate and ethyl *l*-phenylchloroacetate, b. p. 136–138°/18 mm., with  $\alpha_{5461} -30.94^\circ$  ( $l = 0.25$ ) (Found: Cl, 7.7%). The mixture therefore contained 43% of the chloro-ester. 1.14 G. of ethyl *l*-mandelate were dissolved in 0.86 g. of ethyl *dl*-phenylchloroacetate. This solution had  $\alpha_{5461} -20.98^\circ$  ( $l = 0.25$ ) and hence the ethyl phenylchloroacetate in the mixture isolated in the above experiment was laevorotatory.

*With d-β-octanol.* *d*-β-Octanol (2.9 g.) in ether (30 c.c.) was added slowly to an agitated solution of thionyl chloride (10 g.) in ether (30 c.c.) containing potassium carbonate (12 g.). After 12 hours, the ether was removed by distillation, and the residue extracted with ether. In this manner the reaction was completed in the presence of potassium carbonate. The ethereal extract, on evaporation, gave *l*-β-chloro-octane (2.5 g.), b. p. 60–61°/14 mm. and  $\alpha_{5461} -5.05^\circ$  ( $l = 0.25$ ).

The authors wish to express their thanks to the Government Grant Committee of the Royal Society and to Imperial Chemical Industries, Ltd., for grants which have defrayed the cost of this investigation.

[Received, December 5th, 1929.]

LVIII.—*Synthesis of Alkyl Naphthalenes. Part I.*  
5-, 6-, and 7-Ethyl-1-methylnaphthalenes.

By JOHN HARVEY, ISIDOR MORRIS HEILBRON, and  
DONALD GRAHAM WILKINSON.

IN connexion with the study now being carried out in this laboratory of the structure of the naphthalene hydrocarbon  $C_{13}H_{14}$  obtained by dehydrogenation of tetracyclosqualene with sulphur (Harvey, Heilbron, and Kamm, J., 1926, 3136) it became desirable to have,

for reasons which will be explained in a later communication, information regarding the properties of the methylethynaphthalenes containing a methyl group in position 1 and the ethyl radical in the second benzene ring. The present communication deals with the synthesis of the three isomerides indicated above.

**1-Methyl-7-ethylnaphthalene.**—*o*-Tolualdehyde and ethyl  $\alpha$ -bromobutyrate were condensed together in presence of zinc, whereby ethyl  $\beta$ -hydroxy- $\beta$ -*o*-tolyl- $\alpha$ -ethylpropionate (I) was obtained. The hydroxy-ester was converted into ethyl *o*-methyl- $\alpha$ -ethylcinnamate (II) by treatment with phosphorus tribromide and subsequent removal of hydrogen bromide by heating with diethylaniline. Reduction of the unsaturated ester by Bouveault's method gave the alcohol (III), which was converted through the bromide and nitrile (compare Ruzicka, *Helv. Chim. Acta*, 1922, 5, 934) into  $\gamma$ -*o*-tolyl- $\beta$ -ethylbutyric acid (IV). Ring closure was brought about by the action of aluminium chloride on the acid chloride of (IV), an almost theoretical yield of the cyclic ketone (V) being obtained. The ketone was reduced by Clemmensen's method to 1-methyl-7-ethyl-5:6:7:8-tetrahydronaphthalene (VI), and this on treatment with selenium (compare Diels, Gädke, and Körding, *Annalen*, 1927, 459, 1) gave 1-methyl-7-ethylnaphthalene.

**1-Methyl-5-ethylnaphthalene.**—*o*-Tolualdehyde was condensed with ethyl acetate in presence of sodium, as described by Young (*Ber.*, 1892, 25, 2102), to ethyl *o*-methylcinnamate (VII), which was reduced with sodium and alcohol, in the apparatus described by Rupe and Länger (*Helv. Chim. Acta*, 1920, 3, 272), to  $\gamma$ -*o*-tolylpropyl alcohol (VIII). The alcohol was converted through the bromide and the nitrile into  $\gamma$ -*o*-tolylbutyric acid (IX), from which 5-keto-1-methyl-5:6:7:8-tetrahydronaphthalene (X) was obtained by the action of aluminium chloride on the acid chloride. The ketone on treatment with magnesium ethyl iodide yielded the hydroxy-compound (XI), which, on distillation or on heating with acetic anhydride, lost

water, giving 1-methyl-5-ethyl-7:8-dihydronaphthalene (XII). Dehydrogenation of this hydrocarbon by means of selenium gave the required 1-methyl-5-ethylnaphthalene.

1-Methyl-6-ethylnaphthalene.—2-Methylstyryl ethyl ketone (XIII), prepared by the condensation of *o*-tolualdehyde with methyl ethyl ketone in presence of alkali, on hydrogenation in presence of colloidal palladium, gave  $\beta$ -*o*-tolyl-diethyl ketone (XIV), and this on reduction with sodium gave a satisfactory yield of  $\gamma$ -*o*-tolyl- $\alpha$ -ethylpropyl alcohol (XV), from which  $\gamma$ -*o*-tolyl- $\alpha$ -ethylbutyric acid (XVI) was readily obtained in the usual manner. The acid was converted into its acid chloride, which on treatment with aluminium chloride gave an almost quantitative yield of 5-keto-1-methyl-6-ethyl-5:6:7:8-tetrahydronaphthalene (XVII). On reduction of the ketone by Clemmensen's method 1-methyl-6-ethyl-5:6:7:8-tetrahydronaphthalene (XVIII) was formed, and this was dehydrogenated with selenium, giving 1-methyl-6-ethylnaphthalene. A somewhat better yield of the alkylnaphthalene is obtained by reducing (XVII) with sodium and alcohol, whereby a mixture of carbinol and unsaturated hydrocarbon is produced which, without further purification, is treated with selenium.

## EXPERIMENTAL.

*Ethyl  $\beta$ -Hydroxy- $\beta$ -o-tolyl- $\alpha$ -ethylpropionate* (I).—A mixture of ethyl  $\alpha$ -bromobutyrate (72 g.) and freshly distilled *o*-tolualdehyde (45 g.) was added gradually to pure zinc turnings (26 g.) covered with dry benzene, in a flask fitted with a reflux condenser. After the addition of 20 c.c. of the mixture the flask was warmed on a steam-bath in order to start the reaction. The remainder was then added in small quantities at a time so as to regulate the reaction, and the whole refluxed for 4 hours. The product was decomposed with ice-cold dilute hydrochloric acid and the benzene layer was separated, washed with water, and dried over calcium chloride. After removal of the benzene the *hydroxy-ester* was fractionated in a vacuum and obtained as a thick oil (65 g.), b. p. 164–166°/12 mm. (Found: C, 70.8; H, 8.5.  $C_{14}H_{20}O_3$  requires C, 71.2; H, 8.5%).

*Ethyl o-Methyl- $\alpha$ -ethylcinnamate* (II).—A solution of the hydroxy-ester (65 g.) in dry benzene (100 c.c.) was heated on a water-bath with phosphorus tribromide (85 g.) until the evolution of hydrogen bromide had practically ceased (5 hours). The excess of phosphorus tribromide was decomposed with alcohol (with ice-cooling), the solution poured into water, and the benzene layer separated and dried over calcium chloride. After removal of the solvent, the bromo-ester was obtained as a heavy oil (82 g.) with an irritating effect on the eyes. Without further purification, it was mixed with diethylaniline (70 g.) and heated at 180° for 4 hours. Water was added, the whole extracted with ether, and the excess of diethylaniline removed by repeated washing with dilute hydrochloric acid. The residual unsaturated ester was fractionated under reduced pressure, practically the whole distilling at 144°/15 mm.

*$\gamma$ -o-Tolyl- $\beta$ -ethylpropyl Alcohol* (III).—A solution of the above ester (45 g.) in absolute alcohol (300 c.c.) was placed in a flask fitted with a sealed stirrer, a reflux condenser, and a short wide inlet tube. The stirrer was set in rapid motion and sodium (65 g.), cut into small strips, was added gradually through the inlet tube to the boiling solution. During the course of the reduction (1½ hours) more alcohol (200 c.c.) was added from time to time to assist the solution of the sodium. The liquid was diluted with water, the alcohol distilled, and the residual alkaline solution extracted with ether. The ethereal solution, after being washed with water, dried, and evaporated, gave 19–20 g. of the crude alcohol. When the aqueous solution was rendered acid,  *$\beta$ -o-tolyl- $\alpha$ -ethylpropionic acid* was precipitated as an oil. After being extracted in ether, it distilled as a thick oil, b. p. 173–175°/12 mm., which gradually solidified, and then separated from light petroleum in large colourless prisms, m. p. 53–54° (Found: C, 75.0; H, 8.5.  $C_{12}H_{16}O_2$  requires C,

75.0; H, 8.3%). The acid was esterified and reduced as described above; a further quantity of  $\gamma$ -o-tolyl- $\beta$ -ethylpropyl alcohol was then obtained. The whole was distilled, and the pure alcohol collected as a colourless viscous liquid, b. p. 145°/15 mm. (Found: C, 81.2; H, 10.2.  $C_{12}H_{18}O$  requires C, 80.9; H, 10.1%).

*$\gamma$ -o-Tolyl- $\beta$ -ethylpropyl Bromide.*—The alcohol (25 g.) was heated under pressure with a 30% solution of hydrogen bromide in glacial acetic acid (250 g.) at 100° for 16 hours. The cooled liquid was poured into water; the bromide then separated as a heavy oil, which was extracted with ether. The ethereal solution was washed and dried, and the residual bromide distilled, b. p. 136—138°/12 mm. Yield, quantitative (Found: Br, 32.7.  $C_{12}H_{17}Br$  requires Br, 33.2%).

*$\gamma$ -o-Tolyl- $\beta$ -ethylbutyric Acid (IV).*—A solution of the bromide (31 g.) in alcohol (500 c.c.) was boiled with potassium cyanide (25 g. in 70 c.c. of water) for 20 hours. The alcohol was then removed, and the residue diluted with water; the nitrile separated as an oil, which was directly hydrolysed by boiling for 40 hours with concentrated alcoholic potash (30 g. KOH). The crude acid was precipitated from the diluted alkaline solution, extracted with ether, and distilled,  *$\gamma$ -o-tolyl- $\beta$ -ethylbutyric acid* being obtained as a thick oil (21 g.), b. p. 186°/13 mm. (Found: C, 75.4; H, 8.8.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%).

The acid chloride, prepared by treatment of the acid with thionyl chloride, was obtained as a colourless mobile oil, b. p. 149—150°/12 mm.

*5-Keto-1-methyl-7-ethyl-5:6:7:8-tetrahydronaphthalene.*—A solution of  $\gamma$ -o-tolyl- $\beta$ -ethylbutyryl chloride (19.5 g.) in petroleum (20 c.c., b. p. 80—100°) was gradually added to freshly prepared aluminium chloride (17 g.) covered with the same solvent. After the initial vigorous reaction had ceased, the mixture was heated on a steam-bath for 2 hours, and the product decomposed with ice-cold dilute hydrochloric acid. The ketone was extracted with ether and fractionated in a vacuum; a colourless oil, b. p. 165°/12 mm., was obtained which gradually solidified. On crystallisation from aqueous methyl alcohol, *5-keto-1-methyl-7-ethyl-5:6:7:8-tetrahydronaphthalene* (17 g.) separated in small needles, m. p. 38° (Found: C, 82.7; H, 8.7.  $C_{13}H_{16}O$  requires C, 83.0; H, 8.5%).

*1-Methyl-7-ethyl-5:6:7:8-tetrahydronaphthalene.*—The ketone (15 g.) was reduced by boiling with concentrated hydrochloric acid and amalgamated zinc (100 g.). When the greater part of the zinc had dissolved, the liquid was steam-distilled and the distillate extracted with ether. The crude tetrahydronaphthalene was fractionated, giving a mobile oil (6 g.), b. p. 129—131°/14 mm.

1-*Methyl-7-ethylnaphthalene*.—The tetrahydro-derivative was heated with powdered selenium (6 g.) at 300° for 24 hours. The reaction product was distilled over sodium, yielding a colourless oil (4.8 g.), b. p. 134–138°/14 mm., which was directly treated with warm alcoholic picric acid solution. The crude *picrate* which separated on cooling was recrystallised from alcohol, giving long, silky, golden-yellow needles (5 g.), m. p. 97° (Found : C, 56.7; H, 4.3; N, 10.7.  $C_{19}H_{17}O_7N_3$  requires C, 57.1; H, 4.3; N, 10.5%).

The *picrate* was decomposed with ammonia, and the hydrocarbon extracted with ether. 1-*Methyl-7-ethylnaphthalene* was obtained as a colourless oil, b. p. 133°/12 mm.,  $n_D^{20}$  1.5970, which failed to crystallise (Found : C, 91.4; H, 8.2.  $C_{13}H_{14}$  requires C, 91.8; H, 8.2%).

*Ethyl o-methylcinnamate* (VII) was prepared as detailed by Young (*loc. cit.*) from *o*-tolualdehyde and ethyl acetate in presence of sodium. The pure ester, which does not appear to have been described, was obtained as a highly refractive liquid, b. p. 157°/25 mm. (Found : C, 75.8; H, 7.6.  $C_{12}H_{14}O_2$  requires C, 75.8; H, 7.4%).

$\gamma$ -*o*-Tolylpropyl alcohol (VIII), obtained by reduction of the above ester (25 g.) as described under  $\gamma$ -*o*-tolyl- $\beta$ -ethylpropyl alcohol, formed a thick colourless oil (4 g.) with a sweetish odour, b. p. 136°/15 mm. The *urethane* formed long needles, m. p. 58°, from light petroleum (Found : N, 4.9.  $C_{17}H_{19}O_2N$  requires N, 5.2%).

$\beta$ -*o*-Tolylpropionic acid, which formed the main product (14 g.) in the Bouveault reduction, separated when the aqueous alkaline solution was rendered acid. It melted at 105°; Young (*loc. cit.*) gives m. p. 102° (Found : C, 73.1; H, 7.4. Calc. for  $C_{10}H_{12}O_2$  : C, 73.3; H, 7.3%). The acid was esterified, yielding 14 g. of the ethyl ester, b. p. 141°/22 mm., which was reduced to furnish a further quantity of the alcohol.

$\gamma$ -*o*-Tolylpropyl bromide formed a heavy, sweet-smelling liquid, b. p. 124°/17 mm. Yield, quantitative (Found : Br, 37.7.  $C_{10}H_{13}Br$  requires Br, 37.5%).

$\gamma$ -*o*-Tolylbutyric Acid (IX).—A solution of the bromide (25.5 g.) in alcohol (450 c.c.) was boiled with potassium cyanide (20 g. in 80 c.c. of water) for 24 hours. After removal of the alcohol the liquid was diluted with water and the nitrile then separated as an oil. It was extracted with ether and hydrolysed with alcoholic potash (26 hours), and the diluted solution acidified;  $\gamma$ -*o*-tolylbutyric acid was then precipitated as an oil which quickly solidified. On crystallisation from light petroleum it separated in needles (20 g.), m. p. 60° (Found : C, 74.3; H, 7.9.  $C_{11}H_{14}O_2$  requires C, 74.2; H, 7.9%). The acid chloride was obtained as a colourless mobile liquid, b. p. 143°/17 mm.

5-Keto-1-methyl-5:6:7:8-tetrahydronaphthalene (X) was prepared as described under (V). The reaction product was decomposed with ice-cold dilute hydrochloric acid, and the liquid steam-distilled. The distillate was extracted with ether; the ketone was then obtained as a crystalline solid. It separated from light petroleum in large crystals, m. p. 50—51° (yield, 5 g. from 7.5 g. of the acid chloride) (Found: C, 82.7; H, 7.7.  $C_{11}H_{12}O$  requires C, 82.5; H, 7.5%).

1-Methyl-5-ethyl-7:8-dihydronaphthalene (XII).—A solution of the ketone (6 g.) in dry ether (25 c.c.) was added gradually to a well-cooled solution of magnesium ethyl iodide, prepared from magnesium (3.3 g.), ethyl iodide (20 g.), and dry ether (100 c.c.). The reaction mixture was heated under reflux for 4 hours and then decomposed with ice-cold dilute hydrochloric acid. The ethereal layer was washed with water and dried over sodium sulphate. After removal of the solvent the viscous carbinol was directly converted into the hydrocarbon by boiling with acetic anhydride (30 c.c.) under reflux for 1 hour. The acetic anhydride was decomposed with hot water and the hydrocarbon was extracted with ether and purified by distillation over sodium under reduced pressure; it was then obtained as a colourless mobile liquid (4.5 g.), b. p. 130—131°/12 mm.

1-Methyl-5-ethylnaphthalene.—The dihydro-compound (8 g.) was heated with selenium (4.2 g.) at 300° for 24 hours. The solid reaction product was distilled over sodium; the main portion, b. p. 133°/10 mm., was directly converted into picrate by treatment with warm alcoholic picric acid solution. On cooling, the *picrate* crystallised in small orange needles (13 g.), m. p. 97° (Found: C, 56.8; H, 4.4; N, 10.5.  $C_{19}H_{17}O_7N_3$  requires C, 57.1; H, 4.4; N, 10.5%).

1-Methyl-5-ethylnaphthalene was regenerated by treating the picrate, suspended in ether, with dilute aqueous ammonia. It crystallised from alcohol in plates, m. p. 40°, closely resembling naphthalene in appearance and odour;  $n_D^{30}$  1.600.

2-Methylstyryl Ethyl Ketone (XIII).—A solution of *o*-tolualdehyde (46 g.) and methyl ethyl ketone (52 g.) in 50% alcohol (800 c.c.) was treated with 2*N*-sodium hydroxide solution (20 c.c.), and the whole left over-night; 2-methylstyryl ethyl ketone then separated as a heavy yellow oil. After dilution with water the liquid was extracted with ether, and the ethereal solution dried over sodium sulphate. The residual oil was distilled, the main fraction passing over at 145—160°/14 mm. After further fractionation the ketone was obtained as a pale yellow oil (19 g.), b. p. 150—153°/14 mm.

The *semicarbazone*, prepared in the usual manner, crystallised from acetone in colourless needles, m. p. 176—178°; it exhibited

phototropic properties, becoming bright yellow on exposure to sunlight (Found: N, 18.2.  $C_{13}H_{17}ON_3$  requires N, 18.2%).

*β-o-Tolyldiethyl Ketone* (XIV).—2-Methylstyryl ethyl ketone (18 g.) was dissolved in dry ether (200 c.c.) and hydrogenated at room temperature in presence of palladium-black. After the absorption of hydrogen had ceased, the ether was removed and the residual oil distilled, the *ketone* being obtained as a pale yellow liquid (17 g.), b. p. 140–143°/16 mm. (Found: C, 81.4; H, 8.9.  $C_{12}H_{16}O$  requires C, 81.8; H, 9.1%). The *semicarbazone* crystallised from alcohol in plates, m. p. 160° (Found: C, 66.6; H, 8.2; N, 18.2.  $C_{13}H_{19}ON_3$  requires C, 66.9; H, 8.2; N, 18.0%).

*γ-o-Tolyl-α-ethylpropyl Alcohol* (XV).—A solution of the above ketone (15.2 g.) in boiling absolute alcohol (150 c.c.) was reduced by means of sodium (20 g.), added in small quantities at a time. The reaction mixture was diluted with water and extracted with ether. After removal of the solvent the alcohol was distilled in a vacuum, forming a colourless viscous oil (12.5 g.), b. p. 145–146°/14 mm. (Found: C, 80.7; H, 10.2.  $C_{12}H_{18}O$  requires C, 80.9; H, 10.1%).

*γ-o-Tolyl-α-ethylpropyl bromide*, prepared as already described (p. 427), formed a colourless mobile liquid, b. p. 149–151°/18 mm. (Found: Br, 32.6.  $C_{12}H_{17}Br$  requires Br, 33.2%).

*γ-o-Tolyl-α-ethylbutyric Acid* (XVI).—A solution of the bromide (12.5 g.) in alcohol (200 c.c.) was boiled with potassium cyanide (15 g. in 40 c.c. of water) for 30 hours. The alcohol was removed, and after dilution with water, the residue was extracted with ether. The crude product was distilled under reduced pressure, and yielded together with the nitrile fraction, b. p. 150–165°/16 mm. (6 g.), a lower-boiling fraction consisting of unsaturated hydrocarbons (3 g.). The nitrile was hydrolysed with amyl-alcoholic potash (potassium hydroxide, 10 g., in 100 c.c. of amyl alcohol) for 15 hours, and the amyl alcohol removed with steam. When the solution was acidified, *γ-o-tolyl-α-ethylbutyric acid* was precipitated as an oil, which was extracted with ether and distilled. The acid was collected as a viscous oil, b. p. 195–196°/18 mm., which solidified after some days. It crystallised from light petroleum in large prisms (4.5 g.), m. p. 51° (Found: C, 75.6; H, 8.8.  $C_{13}H_{18}O_2$  requires C, 75.7; H, 8.7%). The acid chloride was obtained as a colourless liquid, b. p. 158–160°/18 mm.

*5-Keto-1-methyl-6-ethyl-5 : 6 : 7 : 8-tetrahydronaphthalene* (XVII) was prepared from the acid chloride (9 g.) as described on p. 427. The pure ketone (8 g.) was a colourless oil, b. p. 172°/19 mm. (Found: C, 82.9; H, 8.6.  $C_{17}H_{16}O$  requires C, 83.0; H, 8.5%).

*1-Methyl-6-ethylnaphthalene*.—A portion of the ketone (3.7 g.)

was reduced by Clemmensen's method, giving 2 g. of 1-methyl-6-ethyl-5 : 6 : 7 : 8-tetrahydronaphthalene, b. p. 130°/16 mm. The remainder of the ketone (4.5 g.) was dissolved in alcohol and heated with sodium (7 g.) at 130°. After removal of the alcohol the liquid was diluted with water and extracted with ether. The residual oil was distilled, the greater part (2.4 g.) passing over at 110—160°/20 mm. It was unsaturated towards bromine, and was probably a mixture of unsaturated hydrocarbon and carbinol. The products from both experiments were mixed together and heated with an equal weight of selenium at 300° for 24 hours. The oil was diluted with ether, filtered from unchanged selenium, and purified by distillation over sodium. The crude hydrocarbon (3.1 g.), b. p. 145—152°/20 mm., was converted into the *picrate*, which crystallised from alcohol in small yellow needles, m. p. 82° (Found : C, 56.8; H, 4.4; N, 10.4.  $C_{19}H_{17}O_7N_3$  requires C, 57.1; H, 4.3; N, 10.5%).

1-Methyl-6-ethylnaphthalene, which was regenerated from the pure picrate, formed a colourless, highly refractive liquid having a faint naphthalene-like odour; b. p. 140°/12 mm.,  $n_D^{20}$  1.598 (Found : C, 91.4; H, 8.3.  $C_{13}H_{14}$  requires C, 91.8; H, 8.2%).

Grateful acknowledgment is made to the Department of Scientific and Industrial Research for grants which have enabled this investigation to be carried out.

# LIX.—*The Nature of the Alternating Effect in Carbon Chains. Part XXXII. The Directive Influence of $\psi$ -Basic Systems in Aromatic Substitution. Nitration of Benzylidene-m-nitroaniline.*

By JOHN WILLIAM BAKER and CHRISTOPHER KELK INGOLD.

THE study of orientation by neutral and by ionic substituents has a natural sequel in the consideration of directive action by the intermediate class of "ionogenic" groups, that is, neutral systems which tend to acquire an ionic charge by interaction with the reagent employed for further substitution. This category comprises not only simple acidic and basic substituents with a single potentially ionic centre (e.g., OH,  $NR_2$ ), but also  $\psi$ -acidic and  $\psi$ -basic groups, the ionic forms of which are regarded as possessing a distributed charge; and in Part XXXI (Baker, J., 1928, 2257) it was shown, by reference to the nitration of some  $\psi$ -acidic phenylnitromethanes, that the anionic charges, which are developed in the side chains of these

"Intensely yellow" is certainly a correct description; but the base itself is almost colourless and forms colourless solutions in dry alcohol. It is true that Flürscheim and Holmes prepared a "colourless" solid hydrochloride by precipitation with hydrogen chloride in dry benzene, but this might well be a non-ionised form, such as a  $\psi$ -salt,  $\text{Ph}\cdot\text{CHCl}\cdot\text{NHR}$ , which (like triphenylchloromethane and many other substances) might develop colour in suitable ionising solvents (see below); it does, indeed, form a strongly yellow solution in dry alcohol. Our experiments lead us to suggest that, on the contrary, the free base, for all practical purposes, is absent, and that the compound exists entirely as a sulphate in the sulphuric acid medium. This conclusion is based largely on partition experiments. When a solution of the base in ligroin is shaken with the acid, the whole of the base passes into the acid (with development of the usual strong colour). When a saturated solution of the base in the acid is shaken repeatedly with ligroin, or even with carbon tetrachloride, in which the base is very soluble, none is removed.\* Finally, when a warm concentrated solution of the base in the acid is cooled to the ordinary temperature and kept, the *hydrogen sulphate* separates. This salt, when dry, is almost colourless; but it gives the usual strong colour on solution in sulphuric acid.

Flürscheim and Holmes's second argument is that the high proportion of *m*-isomeride cannot be due to nitration of the ammonium kation, which "fact," according to them, is "established" by the observations that the *m*-ratio remained nearly the same when ammonium sulphate was added to the nitration solvent, whereas in the nitration of diethylbenzylamine (*idem*, J., 1926, 1569), admittedly a reaction of the kation, the addition of ammonium sulphate caused the *m*-ratio to be strongly depressed. Our observations compel us to challenge this conclusion also. It is true that, under the conditions used by Flürscheim and Holmes for the nitration of the Schiff's base, the addition of ammonium sulphate makes no great difference to the proportion of *m*-isomeride; but we find that precisely the same is true of the nitration of diethylbenzylamine. Furthermore, although careful observation shows that there is a small difference, which will be considered later, between the two cases, the direction of the disparity is the opposite of that suggested by Flürscheim and Holmes.

\* Neither is benzaldehyde extracted, which proves the absence of hydrolysis, since added benzaldehyde is readily removed. Indeed, if benzaldehyde and *m*-nitroaniline are brought together in the solvent, rapid combination occurs with formation of the anhydro-base, which, since it is present as sulphate, cannot be partitioned with neutral solvents, but can be recovered in good yield by pouring the acid solution into excess of ice-cold sodium hydrogen carbonate solution.

In seeking confirmatory evidence of the theory that nitration of the Schiff's base proceeds through the salt, we first studied its nitration with a nearly neutral reagent, namely, acetyl nitrate, the expectation being that salt formation would occur only to a small extent or not at all, and that, consequently, the proportion of *m*-isomeride would be found to be below the value, 79%, given by benzaldehyde in mixed acids. This was confirmed, the proportion found being 41%; but it soon transpired that the result could not justly be regarded as evidence on the question at issue, since at least one derivative of the Schiff's base other than its salt was almost certainly present in the nitration medium. From a solution of *m*-nitrobenzylidene-*m*-nitroaniline in this medium we have isolated an unstable crystalline compound which may have the constitution (VI), and it is possible, therefore, that nitration of benzylidene-*m*-nitroaniline takes place at least partly through a similar addition compound with acetyl nitrate. In this connexion the following analogy also seems to have some value: when benzaldehyde was nitrated with acetyl nitrate in excess of acetic anhydride, it was found possible to isolate the *p*-nitro-additive compound (VII); and the proportion of *m*-nitro-product in the mononitro-compounds was only 37%.

We therefore resumed the comparative study of the nitration of benzyldiethylamine and the Schiff's base in sulphuric acid with and without ammonium sulphate, on the basis of the following considerations. First, we concur with Flürscheim and Holmes in assuming that, *if* the Schiff's base is nitrated essentially as such, the depression in the *m*-ratio caused by sulphate ions should be negligible in comparison with that observed in a corresponding experiment with benzyldiethylamine, in which it is known that nitration occurs through the kation of the salt and that sulphate ions cause electrostriction equivalent to a certain amount of change in the direction, dissociated kation  $\longrightarrow$  undissociated salt; this difference, *if established*, would, we agree, constitute strong evidence that the azomethine is nitrated as base. Secondly, we suggest that if, on the other hand, the Schiff's base, like benzyldiethylamine, is nitrated through the kation of its salt, then, if there is any observable difference of behaviour, it should be the Schiff's base which should exhibit the larger repression of *m*-substitution when nitrated in the presence of sulphate ions. The reason is that the Schiff's base is a pseudo-base and that any association of the ions of the true (electrovalent) salt should be succeeded by partial conversion of this into

the pseudo-(covalent) salt; in other words, whilst any depression of the *m*-ratio in the nitration of benzyldiethylamine is dependent on the loss of *m*-orienting power represented by the change, ion  $\rightarrow$  salt, *i.e.*, pole  $\rightarrow$  dipole, in the case of the Schiff's base a further *m*-repressing influence exists in the second stage of the change, ion  $\rightarrow$  salt  $\rightarrow$   $\psi$ -salt, *i.e.*, pole  $\rightarrow$  dipole  $\rightarrow$  neutral form. A difference in this direction would therefore be strong evidence in favour of the theory that the nitration of the azomethine, leading to the high proportion of *m*-isomeride, takes place through the ion of the salt. The details of our nitrations are given in the experimental portion, but Table I constitutes a summary of the results relating to the point at issue. The figures represent the mean values of the percentage of *m*-isomeride, together with the mean deviations from the mean to give an indication of consistency.

TABLE I.

Diethylbenzylamine.		Benzylidene- <i>m</i> -nitroaniline.	
Conditions.	meta (%).	Conditions.	meta (%).
Without (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> ...	61.0 $\pm$ 1.3	Without (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> ...	89.1 $\pm$ 0.3
With (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> ...	61.9 $\pm$ 0.3	With (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> ...	83.7 $\pm$ 0.2
Diff. ...	+0.9 $\pm$ 1.6	Diff. ...	-5.4 $\pm$ 0.5

The difference here recorded for benzyldiethylamine is within the experimental error; no importance can be attached to it, and the only possible conclusion is that any alteration of the *m*-ratio caused by ammonium sulphate cannot be detected in the experiments we have conducted. On the other hand, the difference for benzylidene-*m*-nitroaniline, although not large, is well beyond the limits of precision, and affords clear evidence of nitration through the kation of the salt, confirming the indications of the experiments described earlier in this paper.

Thus it transpires that a reinvestigation of this crucial nitration reverses the theoretical situation in the direction favourable to those theories of aromatic substitution which are directly or indirectly related to the electronic theory of valency; and the same investigation shows that the theory of the distributed charge in  $\psi$ -basicity, as well as in  $\psi$ -acidity, is to be seriously regarded in its application to orientation by ionogenic systems.\*

#### EXPERIMENTAL.

*Materials.*—The benzylidene-*m*-nitroaniline employed had m. p. 72°, and was almost colourless (very pale greenish-yellow) (Found :

\* The application of this theory to the nitration of benzylidene-*m*-nitroaniline was made by the undersigned shortly after the appearance of Flürscheim and Holmes's publication, despite their claim to have proved the contrary (*Ann. Reports*, 1928, 25, 140).—C. K. I.

C, 68.8; H, 4.2. Calc.: C, 69.0; H, 4.4%). Following Flürscheim and Holmes's procedure, the sulphuric acid used for nitration contained a small excess of sulphur trioxide as a precaution against hydrolytic fission; for the same reason, the nitric acid employed was rendered anhydrous by distillation with excess of sulphuric acid.

*Salts of Benzylidene-m-nitroaniline.*—The base formed a colourless solution in alcohol dried with calcium, but a yellow solution in concentrated or fuming sulphuric acid. The hydrochloride, prepared by Flürscheim and Holmes's method, gave a yellow solution in calcium-dried alcohol and a yellow solution in concentrated or fuming sulphuric acid. The *hydrogen sulphate* was obtained as follows: The base (3.5 g.) was added in small portions with shaking to sulphuric acid (10 g.) containing 2.7% excess sulphur trioxide. The warm suspension was filtered through asbestos with precautions against access of moisture from the atmosphere, and the saturated solution of the sulphate kept in a sealed vessel at the ordinary temperature for several days, crystals slowly separating; these were collected and washed with ethyl sulphate and dry ether successively, or with ether only. A further quantity was precipitated from the mother-liquor by dilution with dry ether. The salt (Found:  $\text{SO}_4''$ , 32.4.  $\text{C}_{13}\text{H}_{10}\text{O}_2\text{N}_2 \cdot \text{H}_2\text{SO}_4$  requires  $\text{SO}_4''$ , 29.6%) is very pale yellow, is comparatively stable in air, has m. p.  $225^\circ$  (decomp.) with previous darkening, and gives a yellow solution in fuming sulphuric acid.

*Partition Experiments.*—The ligroin (b. p.  $110$ – $120^\circ$ ) and carbon tetrachloride used were purified by repeated and prolonged shaking, first with concentrated and finally with fuming sulphuric acid (5% sulphur trioxide). The solvent for the second phase was sulphuric acid containing 2.7% excess of sulphur trioxide. The temperature was that of the room and the mixtures were shaken for periods varying from 1 to 24 hours. The results are summarised in the introduction.

*Formation of Azomethines in Sulphuric Acid.*—The acid used as solvent and condensing agent contained 2.7% excess of sulphur trioxide. The formation and isolation of benzylidene-*m*-nitroaniline have already been described; a similar experiment with *m*-nitrobenzaldehyde in place of benzaldehyde yielded *m*-nitrobenzylidene-*m*-nitrobenzylamine, which was similarly isolated. The product in each case was identified by m. p. and mixed m. p. with authentic specimens.

*Side-chain Transformations of an Azomethine and of Benzaldehyde with Nitric Acetic Anhydride.*—(Nitration 3). Benzylidene-*m*-nitroaniline (2.3 g.) was added in small portions at  $35^\circ$  to a mixture

prepared at 0° of absolute nitric acid (6.0 g.) and acetic anhydride, and the mixture was kept at room temperature over-night. The product was poured on ice and excess of potassium hydrogen carbonate and extracted with ether and benzene after decomposition of the acetic anhydride. Qualitative separation of the residue showed that substances other than nitrobenzylidene-*m*-nitroanilines were present, but the mixture was too complex to admit of the isolation of a pure individual. The whole process was therefore repeated with *m*-nitrobenzylidene-*m*-nitrobenzylamine in place of the original azomethine, except that the separation by means of ether and alkali was replaced by evaporation to constant weight at the ordinary temperature in an oil-pump vacuum with passage of a limited stream of dry air. The gain in weight was 42.4%, whereas the gain required for the addition of 1 mol. of acetyl nitrate is 38.8%. The material was not crystalline, but a product which remained crystalline for a short time was obtained as follows. A moderately concentrated solution of *m*-nitrobenzylidene-*m*-nitroaniline in a similarly prepared mixture of nitric acid and acetic anhydride was cooled in liquid ammonia for several hours; the liquid then became filled with a mass of colourless crystals. These rapidly dissolved if the temperature was raised, and were therefore collected at -30° in jacketed apparatus and washed with ethyl nitrate and ligroin at the same temperature. The crystals had m. p. 50—55° (decomp.) when rapidly heated in a sealed tube, but quickly decomposed at the ordinary temperature, either in the air or in sealed tubes, giving nitrous gases and a red gum. The freshly prepared crystals when warmed with dilute sulphuric acid gave nitric acid (nitron precipitate) in addition to the normal hydrolysis products. These experiments are regarded as proving the formation, rather than the constitution, of an addition product of the azomethine with the reagent used.

(Nitration 5). Benzaldehyde (5.0 g.) was added during 2 hours at 35° to a nitration solution prepared at 0° from absolute nitric acid (18 g.) and acetic anhydride (30 c.c.). After being kept over-night, the mixture was poured on ice and excess of potassium hydrogen carbonate, and, after decomposition of the acetic anhydride, extracted twice with ether and once with benzene. The residue obtained after removal of the solvents partly crystallised, and the crystals were drained and washed with ether-ligroin. They then had m. p. 118—120°, and one crystallisation from ether raised this to 125—127°, alone or in admixture with an authentic specimen of *p*-nitrobenzylidene diacetate.

*Nitration of Benzylidene-m-nitrobenzylamine and of Benzaldehyde in Acetic Anhydride.*—The numerical particulars, except analyses,

relating to these nitrations are given in Table II; the analytical details and results are in Table IV.

The products of the nitration of the azomethine were isolated as described for nitration 3 above, and hydrolysed by boiling with dilute sulphuric acid. The aldehydes were isolated by extraction with ether and benzene successively, and oxidised with permanganate to acids, which were isolated and analysed by reduction and bromination as usual.

The nitration product of benzaldehyde was isolated in the same way, and the subsequent treatment was the same except for the omission of the hydrolysis.

TABLE II.

Nitr- ation No.	Substance nitrated.	Weight taken (g.).	HNO <sub>3</sub> (g.).	Ac <sub>2</sub> O (g.)	Temp.	Time (hrs.).	Pro- duct (g.).	Treated (g.).	Acids (g.).
1	PhCH:NR	2.00	6.08	25	{ 0° room	{ 2.2 0.8 }	2.68	2.18	0.916
2	"	2.29	7.0	11.5	{ 35° room	{ 2.5 24.0 }	2.640	2.037	1.002
4	PhCH:O	4.98	18.0	30	{ 35° room	{ 2.0 20.0 }	10.40	4.682	2.480

The heading "Treated" should be interpreted, "Product hydrolysed and oxidised" for nitrations 1 and 2, and "Product oxidised" for nitration 4.

In nitration 1 the azomethine was previously dissolved in half the acetic anhydride, and the solution was slowly added to a mixture of the nitric acid and the other half.

In nitration 2 the solid azomethine was added in small portions to the nitration mixture.

In nitration 4 the benzaldehyde was run into the nitration solution. Part of the solution of the acids obtained by oxidation was lost and the weight recorded is that of the residue from the remaining solution.

*Nitration of Benzyl-diethylamine and Benzylidene-m-nitroaniline in Sulphuric Acid with and without Addition of Ammonium Sulphate.*—The numerical particulars, except analyses, relating to these nitrations are recorded in Table III; the analytical details and results will be found in Table IV.

The benzyl-diethylamine, b. p. 105–107°/20 mm., was in all cases run into the nitration solution. The product was poured on ice, basified with potassium hydroxide, and extracted with chloroform. Owing to the difficulty of removing the last traces of this solvent from the residual oil, some of the recorded yields of nitro-bases may be slightly too high. The products were oxidised, and the acids analysed, as usual.

The solid benzylidene-*m*-nitroaniline was in all cases added little

by little without solvent to the nitration solution. The product was poured on ice and excess of potassium hydrogen carbonate and extracted successively with ether and benzene. The material obtained was subjected to the usual routine of hydrolysis, oxidation, reduction, and bromination.

TABLE III.

Nitr ation No.	Sub- stance nitrated.	Weight taken (g.).	Am. SO <sub>4</sub> (g.).	HNO <sub>3</sub> (g.).	H <sub>2</sub> SO <sub>4</sub> (g.).	SO <sub>3</sub> % in H <sub>2</sub> SO <sub>4</sub> .	Temp.	Time (hrs.).	Pro- duct (g.).	Alde- hydes (g.).	Treated (g.).	Acids (g.).
6	PhCH <sub>2</sub> -NEt <sub>2</sub>	3.00	—	3.06	66	1.5	0° room	2.0 2.0	2.817	—	2.268	1.321
7	"	2.66	—	1.50	38	2.7	0° room	1.5 2.0	3.253	—	2.005	1.173
8	"	3.01	—	1.60	20	5.0	0° room	2.0 2.0	3.795	—	3.131	0.908
9	"	3.00	35	3.06	66	1.5	0° room	2.0 2.0	3.581	—	2.654	1.209
10	"	3.98	26	2.00	57	2.7	0° room	1.5 2.0	4.751	—	3.379	2.380
11	"	3.08	6	1.8	20	5.0	0° room	2.0 2.0	3.795	—	2.843	1.414
12	PhCH <sub>2</sub> NR	3.00	—	2.45	71	1.5	35-40° room	4.0 22.0	—	1.824	1.824	1.321
13	"	3.00	—	0.60	16.5	2.7	10° room	1.0 21.0	3.410	—	2.254	1.198
14	"	3.00	21	2.40	40	2.7	40° room	3.0 21.0	—	1.968	1.968	1.062
15	"	3.00	21	2.40	40	2.7	35-40° room	4.0 20.0	—	1.601	1.601	1.264

The heading "Treated" should be interpreted "Product oxidised" for nitrations 6—11, "Product hydrolysed and oxidised" for nitration 13, and "Aldehydes oxidised" for nitrations 12, 14, and 15. The corresponding figures for nitrations 6—11 may be somewhat too high owing to the difficulty, mentioned above, of completely freeing the oily nitration product from chloroform.

In nitration 8, part of the solution of the acids obtained by oxidation was lost and the weight recorded is that of the residue from the remainder.

In nitration 13, the 2.254 g. of nitration product yielded 1.645 g. of aldehydes and the whole of this was oxidised.

In nitrations 12, 14, and 15, the nitration products were hydrolysed without weighing, but the aldehydic product was weighed and the whole of it oxidised.

*Analytical Results relating to the Nitrations.*—The analytical data and the proportions of isomeride calculated therefrom are given in Table IV.

Table I (p. 435) shows the mean values (and mean deviations) of the proportion of *m*-nitro-isomeride formed from benzyldiethylamine and from benzylidene-*m*-nitroaniline in mixed acids, together with difference figures indicating the effect of ammonium sulphate on the meta-ratio; in the latter case, the mean deviations are obtained by subtracting one from another the individual results taken in pairs.

It should be stated that the experimental conditions (temperature,

proportions of reagents, etc.) relating to the individual nitrations of which the results are averaged are not exactly the same (Table III); nevertheless, the internal consistency of the results of each of the several sets so treated is such as to show that any differences due to the varied conditions referred to are too small to be detected by the experiments here recorded.

THE UNIVERSITY, LEEDS.

[Received, February 4th, 1930.]

### LX.—Primary and Associated Results of Replacement of Hydrogen directly attached to 4-Co-ordinated Carbon.

By WESLEY COCKER, ARTHUR LAPWORTH, and ARTHUR WALTON.

THE substituents  $NO_2$ ,  $CN$ ,  $COR$ , and  $SO_2R$  in attachment to phenyl are meta-directive. In position X, in  $X\cdot CHR_1R_2$ , these substituents render the hydrogen atom labile and, moreover, the compound  $X\cdot CHR_1R_2$  is able to exist in two "tautomeric" forms. These relations were recognised nearly thirty years ago (compare J., 1901, 79, 1901).

It is not easy to state when the idea was first advanced that enolisation of a ketonic form originates in a minute degree of ionisation of the hydrogen atom which is attached to the carbon atom in the  $\alpha$ -position. It was certainly no later than 1902, when definite schemes based on this idea were proposed for reversible desmotropic changes belonging to the type now commonly called prototropic (J., 1902, 81, 1508). References were given in this

paper to still earlier suggestions, in which conceptions of dissociation had been applied to such phenomena by Brühl, Thiele, and Henrich, and the names of Kekulé, Williamson, Euler, Goldschmidt, Knorr, and others should have been mentioned in any exhaustive treatment.

The conception of the acceleratory influence of an alkali on enolisation as due to the attack of hydroxyl ion on an "incipiently ionised" hydrogen atom in direct attachment to carbon on the ketonic form was formulated in 1920 (*Mem. Manchester Phil. Soc.*, 1921, 64, 13 and 14).

The above ideas are now widely used, but few of those who have adopted them as working hypotheses appear to be aware that even the most recent of them took definite shape nearly nine years ago.

On the view above described, expressed in terms of current theory, compounds of the type  $X\cdot CHR_1R_2$  ( $X$  being defined as above) are themselves very feeble acids—too feeble, as a rule, to yield their protons to the very weak base, water, but able to yield them to more potent acceptors.

With the introduction of electronic conceptions it followed naturally, as Lewis himself pointed out, that the affinity of an acid must be associated with the degree of restraint on the bonding electrons of the atom to which the acidic hydrogen, or proton, is attached. Hence, if the above ideas are sound, it follows as a matter of course that each of the substituents  $NO_2$ ,  $CN$ ,  $COR$ , and  $SO_2R$  must exercise some special restraint on the electrons of an attached carbon atom; the case is only one of many covered by scheme 7, in the paper by Allan, Oxford, Robinson, and Smith (J., 1926, 404), in which scheme carbonyl was evidently used to typify all substituents which come in the above category (compare *ibid.*, p. 403, line 8 from bottom). The connexion between electron-restraining properties and meta-directive power had previously been a strong plank in the platform of supporters of "polarity theories" and a passing reference to Robinson's discerning extrapolation from this general basis and his own experiments to the prediction of meta-directive effects in benzylamine salts may serve as a reminder of this. It may therefore be maintained that no date later than that of the paper by Allan, Oxford, Robinson, and Smith may properly be assigned to the complete association of all the above ideas, although much of real novelty has since been written in connexion with the same topics and numerous important extensions have been suggested.

It is, however, not enough to attribute to any given substituent an "inherent" electron-attractive or electron-repulsive power, and then to assume that the apparent contradictions are due to covalency adjustments which are inseparable from a completed chemical

change. The present authors are convinced that the idea of interior electron displacements formulated by Lewis (compare "Valence and the Structure of Atoms and Molecules," G. N. Lewis, American Chemical Society Monographs, 1923), though acceptable in many applications and in particular to the strengths of the hydroxides of the elements as bases and acids (*loc. cit.*, p. 138), does not admit of the extension suggested by Lewis himself in his attempt to account for the high ionisation constants of  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -chloro-derivatives of saturated aliphatic acids (*loc. cit.*, p. 139). A number of workers have accepted the lead given by Lewis on this point; but it may be noted that in certain schools of thought the mass of indications pointing to the existence of some transmission of effects by interior means is ignored and distances of points from poles are calculated apparently on the assumption that the disturbances are propagated solely through the medium (compare Larsson and Holmberg, *Z. anorg. Chem.*, 1929, **183**, 30).

Insufficient attention has been paid to the possibility, already partly recognised, that even in the resting state of a molecule the effect of a substituent at a given point, even at a considerable distance from the substituent, may be the resultant of at least two simultaneous influences, one reaching the point from the exterior and the other from the interior, that is *via* the electronic system of the adjacent atom, the condition of which, in its turn, is likely to be determined by the resultant of interior and exterior influences. The exterior and interior forces at a given point may operate either in harmony or in opposition according to the nature of the substituent, and possibly also according to other circumstances, and obviously may affect one another to a greater or less extent throughout the whole range of collateral transmission.

It is almost certainly erroneous to suppose that the net effect of a substituent, Y, in say,  $Y \cdot CHR_1R_2$ , on the electrons of the carbon atom to which it is directly attached is always in the same sense as its net effect on the electrons of more remote atoms. It so happens that, if attention be restricted to the meta-directive substituents above specified, no glaring discrepancy is revealed, for not only does each of these substituents exercise, in the light of the above ideas expressed in terms of Lewis's theory of proton expulsion, a marked restraining effect on the electrons of any carbon atom to which it is directly attached, but it also displays consistent restraining effects on the electrons of atoms more remote, as shown by the large ionisation constants of all carboxylic acids in which these substituents occur. With a number of other substituents, however, and more especially with some of the powerfully ortho-para directive ones, no such consistency obtains.

Discussion of even the most elementary issues involved in this complicated question requires a clear understanding as to the implication of terms used. In view of this, the electropolar effect of a substituent is now defined for the present purpose and without references to any particular hypothesis, as that effect which, when the substituent occurs at the  $\alpha$ -,  $\beta$ -,  $\gamma$ - and more remote positions in a saturated aliphatic acid, leads consistently to a rise or consistently to a fall in the ionisation constant of the acid, and diminishes as the distance from the substituent increases. The rate of diminution in the series of saturated fatty acids is given approximately by Derick's logarithmic rule (*J. Amer. Chem. Soc.*, 1911, **33**, 1152).\*

The authors prefer to use the description "electropolar" effect or factor, due to Flürscheim, rather than "electron affinity" (Lewis), because the latter expression has been applied (a) to the restraint which an atom exercises over its own electrons, (b) to interior electron displacements consequent thereon, and (c) to true electropolar effects, which, in the view of the present authors, have often been confused with (b). The description "general polar," originally suggested (1921) as equivalent to Flürscheim's "electropolar," has since been used to specify not only true electropolar effects but also effects of interior electron displacements as conceived by Lewis.

Significant connexions which have appeared from the work of Bjerrum and others between electropolar effects and dipole moments, combined with the circumstances that electropolar effects make themselves felt at considerable distances from their point of origin even when a long saturated chain of carbon atoms intervenes, lead the authors to accept the view that the electropolar effect of a substituent, Y, is essentially the manifestation of a change in the electrical fields immediately exterior to the chains of atoms on the molecule. They imagine that the substitution ordinarily produces a change in the external field which is equivalent to the superposition of a new external field on the original one, and that this superimposed field increases in intensity as the substituent is approached from distant parts of the molecule. At some point, at a very small distance (measured in atomic diameters) from the point of substitution, it is, however, presumed that the superimposed field may be extremely complex, so that neither its intensity nor its sign can be deduced from a knowledge of the distribution of that field at points more remote—or at least not until that knowledge is far more exact than can be claimed at the present time. The precise distance at which the exterior effects may be treated as

\* Admittedly the criterion can strictly be applied only when the influence of "steric" factors has been eliminated.

mathematically separable from the primary and its interiorly transmitted effects is likely to remain as an outstanding difficulty; but on the view advanced by Lapworth and Manske (J., 1928, 2536, 2537) its point must be somewhere *beyond* the atom at which substitution takes place. Assuming, for simplicity, that this point in saturated systems lies immediately beyond the electrons of the atom in question and that "steric" effects may be treated as irregularities in an otherwise regularly diminishing, exterior field beyond this point, the opposite electropolar factors of  $\text{O}\cdot\text{CH}_3$  and  $\text{CH}_3$  may be suggested by the arrows placed above the two figures

To the left of these two upper arrows it is postulated, not that an exterior field is non-existent, but that, whatever its direction may be, it is, by definition (J., 1928, 2536), only one of the factors in the primary effect,  $\Sigma\text{---}\text{CH}_2\text{---}$ , of the substituent on the electrons of the carbon atom to which it is directly attached, and may not be counted twice.

This interpretation of the facts, however, demands that in the two cases just specified, the displacements implied by the  $\text{---}$  signs are very small, which is consistent with remarks which are made later in this paper on transmission by a single bond in a saturated carbon system (p. 450). The sign  $z$  is used to imply that the value,  $>$ , is almost zero.

Proton is admittedly unique; and there is strong physical evidence, largely but not wholly spectroscopic, that proton can enter very deeply into the electronic systems of other atoms (compare Knorr, *Z. anorg. Chem.*, 1923, **129**, 109; Müller, *Z. Elektrochem.*, 1924, **30**, 493; 1925, **31**, 46, 143; Lederle and Rieche, *Ber.*, 1929, **62**, 2576). The presence of hydrogen in direct combination with another non-metallic atom may then be equivalent to an increase in the central restraining charge of that atom, and this would lead, algebraically, to a corresponding decrease in restraint when the hydrogen is replaced. This factor is doubtless not the only one operative, and electrostatic attraction between the nucleus of one atom and the electrons, especially if "unshared," of another atom in the sense of theories previously used by Stark, Robinson, Lapworth and others is consistent with numerous data and is not excluded by electronic theory. It remains, however, as a striking fact that, with the exception of some, like  $\text{NMe}_3^+$ , which themselves contain an additional positive charge, and others, like  $\text{NO}_2$ , which contain a qualitatively equivalent dipole, nearly all the familiar substituents produce, on 3-co-ordinated carbon, chemical effects

which correspond with those to be anticipated from a virtual decrease in the central charge of the carbon atom (compare Lapworth and Manske, J., 1928, 2536). Examples of this include such diverse substituents as  $\text{NH}_2$ ,  $\text{NMe}_2$ ,  $\text{OMe}$ ,  $\text{Cl}$ , and  $\text{Alk}$ , some (*e.g.*,  $\text{Cl}$ ) with electron-restraining and others (*e.g.*,  $\text{Alk}$ ) with electron-releasing electropolar factors.

On the evidence of the ionisation constants of substituted acetic, propionic and butyric acids, the electropolar factors for  $\text{OH}$  and  $\text{O}\cdot\text{CH}_3$  attached to 4-co-ordinated carbon are definitely *electron-restraining*; moreover, *m*-hydroxybenzoic acid is stronger than benzoic acid, and there is strong evidence that the electropolar effect is usually the dominant one in the meta-position (compare, *inter alia*, J., 1929, 2547, lines 7—9). Nevertheless,  $\text{OH}$ , or  $\text{O}\cdot\text{CH}_3$ , when replacing  $\text{H}$  attached to an aromatic nucleus, confers on some electrons of the nucleus a greatly *decreased* restraint; and when  $\text{OH}$  replaces the  $\text{H}$  of the kation,  $\text{H}\cdot\text{CO}_2\ominus$ , of formic acid, the product,  $\text{HO}\cdot\text{CO}_2\ominus$ , has a very greatly increased affinity for proton, connoting a greatly *decreased* restraint on the electrons of the carboxyl oxygens. In these two cases, however, the  $\text{OH}$  has replaced  $\text{H}$  attached to 3-co-ordinated carbon and the view has already been expressed by Lapworth and Manske (J., 1928, 2536), that this occurrence is undoubtedly associated, in the case of  $\text{OH}$ , with a greatly decreased restraint on the carbon electrons, which restraint can be transmitted in turn, by electron displacements (Lewis), to other atoms in the molecule, the intensity and extent of transmission varying very greatly with structural conditions.

It is perhaps desirable at this juncture to state that the present view accommodates the case of initiation of electron displacement at points remote from the substituent by the operation of the electropolar effect on a plastic system, such as a double bond, a 1 : 3-diene system, or a carbon-halogen linkage. The slight polarisation of the ethylenic linkage in stearolic acid, demonstrated by Robinson and Robinson (J., 1926, 2204), is regarded by the present authors as a case coming within this category; such effects might suitably be called "imported," in contrast to "transmitted."

A 1 : 3-diene, or an aromatic, system, when acted upon either by an imported or a transmitted strain, may display "alternate effects" of several kinds. The problem of the mechanism of "static" alternate effects such as those indicated by study of dissociation constants of aromatic carboxylic acids and cyanohydrins must be approached from the standpoint of a sound theory of the more elementary phenomena associated with substitution.

The question whether a given substituent operates on 4-co-ordinated (or "saturated") carbon in the same mode as it operates

on 3- and 2-co-ordinated carbon was touched on very lightly by Lapworth and Manske, in view of the paucity of convincing evidence bearing thereon (*loc. cit.*, p. 2537). The substituents  $\text{NO}_2$ ,  $\text{CN}$ ,  $\text{COR}$ , and  $\text{SO}_2\text{R}$  offer no difficulty from the qualitative point of view, their primary interior factors (*ibid.*, p. 2536) and electropolar factors being, as previously stated, clearly and consistently electron-restraining, no matter to which type of carbon atom they are attached. It has been shown in the preceding pages that the conjunction of Lewis's theory with the idea of incipient ionisation in the derived systems,  $\text{X}\cdot\text{CHR}_1\text{R}_2$ , implies that these substituents exercise a restraining effect on the electrons of 4-co-ordinated carbon, thus facilitating the removal of the hydrogen atom as proton by suitable acceptors. In the following pages an attempt is made to show that some of the more powerfully ortho-para directive substituents exert precisely the opposite effect on the electrons of directly attached, 4-co-ordinated carbon, so that when the latter is also associated with an atom or group, which either *per se* or by association with a suitable acceptor, can act as an anion, a state of "incipient ionisation" is brought about in the sense opposed to that induced by the meta-directive substituents  $\text{NO}_2$ ,  $\text{CN}$ ,  $\text{COR}$  and  $\text{SO}_2\text{R}$ , when occupying similar positions.

It is well known that the halogen in  $\alpha$ -chloroalkyl oxides such as monochlorodimethyl ether,  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl}$ , is exceptionally labile. Contrasting  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl}$  with  $\text{H}\cdot\text{CH}_2\text{Cl}$ , it may be said with confidence that the replacement of H by  $\text{O}\cdot\text{CH}_3$  does not lead to any of the results to be anticipated from a virtual increase in the central charge of the carbon atom of the  $\text{CH}_2$  group. Such results would be, for example, a more ready reducibility of the chloro-compound to the hydride, or a tendency to react with water in accordance with the scheme  $\text{R}\cdot\text{Cl} + \text{HOH} \longrightarrow \text{R}\cdot\text{H} + \text{HOCl}$  (compare the properties of  $\text{NCl}_3$  and  $\text{NH}_2\text{Cl}$  with those of chloro-derivatives of methane). On the contrary, there is observed a greatly increased tendency for the halogen atom to appear as chloridion; moreover, the group  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2$  has apparently so small an affinity for its bonding electrons that it can replace proton, even in presence of free hydrochloric acid, as in the facile reaction of the chloride  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl}$  with methyl alcohol :

(Henry, *Ber.*, 1893, 26, 933, *Ref.*).

The extraordinary facility of the transformations of this chloride and the consistent relative "polarities" of its two parts,  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2$  and  $\text{Cl}$ , as well as the comparatively small heat changes involved, are well illustrated by its behaviour towards water, alkali and con-

centrated hydriodic acid respectively. In each case hydrolysis occurs quickly, the chloro-ether, at first insoluble, dissolves within a few seconds when shaken vigorously with the cold aqueous liquid. In the case of the strong, aqueous hydriodic acid, the heat display is so small that, with equal volumes of acid and chloro-ether, the rise of temperature is only about 7°. No free iodine is liberated even if the compound is added to the hot acid. From the work of Henry (*loc. cit.*) and others there is good reason to conclude that in each of the three cases the change which takes place is simply a reversal of that on which the ordinary method of preparing the ether is based:

Monochlorodimethyl ether acts almost instantaneously on tertiary bases (Litterschied, *Annalen*, 1901, **316**, 161), forming quaternary salts:

The present authors have observed that although, as found by Litterschied, these salts are also formed almost instantaneously in presence of an alcoholic solvent, such as amyl alcohol or *cyclohexanol*, they may subsequently react with the alcohol on warming in presence of excess of the tertiary base, the methoxymethyl residue evidently leaving the nitrogen atom and replacing the proton of some of the alcohol. Thus with pyridine and amyl alcohol:

It may be worth while to point out that these reactions do not seem to differ in any essential feature from those which occur during the well-known process, due to Einhorn, for acylation of alcohols by means of acyl chlorides and tertiary amines (*Annalen*, 1898, **301**, 95), though the yields obtained are less satisfactory, owing in some cases to less complete reaction and in others to formation of products of higher molecular weight in which methoxyl has been replaced. In both cases quaternary salts are formed in the first instance by direct union of amine and acid chloride (compare Dennstedt and Zimmermann, *Ber.*, 1886, **19**, 75) and there is no sufficient reason to assume that there is an essential distinction between the two mechanisms. The authors infer that both acyl groups and  $\alpha$ -alkyloxymethyl groups can function much as protons do; that is to say, while probably not capable of separate existence in solution as kations, they are readily detached from their bonding

electrons and thus, in the same sense as such protons, occur in the state frequently described as "incipient ionisation."

In the authors' view the conditions which give rise to the modes of reaction of monochlorodimethyl ether are to be regarded as pre-existent in the resting molecules,  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl}$ , and it is not necessary to assume complete conversion of the molecules into desmotropic forms prior to interaction with the agents. Oxonium chemistry certainly indicates that reversible changes such as  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl} \leftrightarrow \text{CH}_3\cdot\text{O}^+\cdot\text{CH}_2\text{Cl}^-$  might take place readily; but the

existence of such reversible relations in itself connotes comparatively small free energy differences between the molecular configurations in the two isomeric forms, and such forms are probably subject to similar interior distortions, demanding comparatively small "activation" increments of energy for transformation in either direction. It is on this basis, and not on the hypothesis of one ion common to both forms, that the authors would approach the theory of isodynamic isomerism; the observations of Leuchs (*Ber.*, 1913, 46, 2438) and of Kuhn and Albrecht (*Ber.*, 1927, 60, 1297), with optically active compounds, strongly support the idea that the ions of the so-called "pseudo-acid" forms have individual existence.

The present authors would represent the interior effects which they believe to be produced by the conversion of  $\text{H}\cdot\text{CH}_2\text{Cl}$  into  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl}$ , by the strain-symbol,  $\text{CH}_3\cdot\text{O}-\text{CH}_2-\text{Cl}$ , where,

in contrast to the case of  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$  (p. 444), the transmitted effect is considerable (in the plastic  $\text{C}-\text{Cl}$  bond) and has more influence on the properties of the compound than has the electropolar effect

The extremely variable lability of CN directly attached to carbon seems strongly to support the general ideas above advanced. Ordinarily, CN directly attached to carbon cannot be removed as cyanidion. Even cyanohydrins  $\text{HO}\cdot\text{CR}_2\cdot\text{CN}$  are mostly quite stable in this respect at the ordinary temperature, providing that appreciable ionisation of the hydroxyl hydrogen be prevented, as by addition of a trace of mineral acid (Lapworth, *J.*, 1901, 79, 1268; 1906, 89, 948; Ultée, *Rec. trav. chim.*, 1909, 28, 248, 257); on the other hand, partial breaking down, with attainment of equilibrium, takes place extremely quickly at the ordinary temperature if the conditions are on the alkaline side, thus permitting of a small amount of ionisation of the acidic cyanohydrin (*J.*, 1904, 85, 1206):

The instability of  $\alpha$ -amino-nitriles is well known, and the authors have observed that the compound  $\text{NEt}_2\cdot\text{CH}(\text{CH}_3)\cdot\text{CN}$  decomposes at the ordinary temperature in presence of water; free hydrogen cyanide is formed and if this be allowed to escape from the system complete decomposition takes place ultimately at the ordinary temperature. The reactions involved are again reversals of those followed during the ordinary method of preparing the compound:

(not necessarily by way of the desmotropic form  $\text{NEt}_2\cdot\text{CH}(\text{CH}_3)\cdot\text{CN}^\ominus$ ).

The compound  $\text{NEt}_2\cdot\text{CH}(\text{CH}_3)\cdot\text{OH}$  then breaks down much in the same way as a cyanohydrin does, giving  $\text{NEt}_2$  and  $\text{CH}(\text{CH}_3)\cdot\text{O}$ . The case of cyanodihydroberberine is closely comparable with this (compare Robinson and Robinson, J., 1917, 111, 966).

Compounds having the structure  $\text{CH}_3\cdot\text{O}\cdot\text{CR}_1\text{R}_2\cdot\text{CN}$ , unlike cyanohydrins themselves and unlike  $\alpha$ -amino-nitriles, are exceedingly stable compounds, and do not yield their cyanidion under most drastic treatment.

It seems clear, therefore, that in respect to their efficiencies in promoting the withdrawal of CN from the same carbon atom, the order of four important substituents is  $\ominus\text{O}$ ,  $\text{NAlk}_2$ ,  $\text{OH}$ ,  $\text{O}\cdot\text{CH}_3$ . The last of these is here quite ineffective, and even  $\text{OH}$  is usually effective only at temperatures above the ordinary, in which circumstances almost any ketone cyanohydrin can lose hydrogen cyanide; menthone cyanohydrin when exposed cannot be prevented from doing so slowly even at the ordinary temperature and in presence of stabilising hydrogen chloride (Lapworth, Manske, and Robinson, J., 1927, 2054). It may be noted that the order of the four substituents above deduced is the same as that accepted for ortho-para directive powers, which order, however, is not necessarily always the same as that for "static" or average primary effects. Aromatic substitution, as Robinson has constantly maintained, is no doubt very largely a phenomenon connected with specially energised molecules in the system and not with the average molecules, and the nitroso-group affords a striking example of a substituent the "static" primary effect of which on carbon is in one sense (electron-restraining, like  $\text{CO}\cdot\text{R}$  or  $\text{NO}_2$ ) and nevertheless does not too effectively oppose the formation of energised forms in which it is in effect operating in the opposite sense (ortho-para directive and electron-releasing) (compare Robinson, *Chem. and Ind.*, 1925, 456). Such an associated function may be termed a "permissive" property of the substituent.

When alcoholic potassium cyanide acts on polynitro-derivatives

of the aromatic series, the group  $\text{O}\cdot\text{CH}_3$  enters the molecule at the carbon atom from which the  $\text{NO}_2$  radical is displaced; the group  $\text{CN}$ , when it enters, is found on a carbon atom to which  $\text{H}$  was originally attached (Bruyn and others; compare Kenner, J., 1914, 105, 2730). The opposite primary interior effects of  $\text{O}\cdot\text{CH}_3$  and  $\text{CN}$  are doubtless here foreshadowed or utilised in some way at intermediate stages,

$\ominus\text{NO}_2$  being "loosened" in the former case and  $\oplus\text{H}$  in the latter (compare "Summary" of present paper).

On considering all the evidence now available it seems clear that the statement made by Lapworth and Manske to the effect that the influence of substituents on 4-co-ordinated carbon is "certainly small" (J., 1928, 2537) was unfortunate, and a more accurate statement would have been that the changes produced by substitution of  $\text{H}$  attached to 4-co-ordinated carbon are "certainly more difficult to detect" than with 3-co-ordinated carbon.

This difficulty seems to be due in the main to the circumstance that changes in the restraint on the electrons of 4-co-ordinated carbon are transmitted, if at all, only to a very feeble extent to another carbon atom; thus even the considerable effect of the substituent  $\text{O}\cdot\text{CH}_3$ , which is manifest in the properties of  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\text{Cl}$ , does not suffice to cause loss of the  $\text{CN}$  group from  $\text{CH}_3\cdot\text{O}\cdot\text{CH}_2\cdot\text{CN}$  or  $\text{CH}_3\cdot\text{O}\cdot\text{CH}(\text{CH}_3)\cdot\text{CN}$  (compare Robinson, on resistance offered by a saturated carbon atom, *Chem. and Ind.*, 1925, 118).

Owing to the difficulty of detection and comparison of static primary effects on 4-co-ordinated carbon, except in special cases such as those above discussed, it would be premature to maintain that the sequence of substituents in this connexion is the same as the sequence for static primary effects on 3-co-ordinated carbon. On *a priori* grounds it would seem possible that such might be the case, at least for substituents which contain no double-bonded structure adjacent to the point of attachment. Comparison of the properties of  $(\text{Cl})\cdot\text{CH}_2\text{Cl}$  and  $(\text{CH}_3)\cdot\text{CH}_2\text{Cl}$  with those of  $(\text{H})\cdot\text{CH}_2\text{Cl}$  clearly indicates that the "primary" influence of  $\text{Cl}$  or  $\text{CH}_3$  on 4-co-ordinated carbon is very much smaller than that of  $\text{O}\cdot\text{CH}_3$ , and this again is broadly in agreement with effects already deduced on 3-co-ordinated carbon. Whatever may transpire hereafter, it now seems beyond reasonable doubt that when substituents are arranged in the order of their "static" (or average) primary effects on directly attached, 4-co-ordinated carbon, that order will

be quite different from the electropolar sequence (order of "electron affinities") and will correspond much more closely with Flürscheim's "quantitative" sequence, though, as already explained (p. 449), with certain modifications connected with the mechanism of aromatic substitution. It is doubtful whether the precise order, even if there be such, for static primary effects of substituents can be deduced from chemical reactions, but the authors assume that facile and reversible reactions provide the most trustworthy indications. The study of equilibrium constants furnishes a basis for comparing average free energies over a large number of molecules; but "primary" effects are not the only factors involved.

There is yet another complication, as there is reason to believe that with certain substituents which have comparatively small primary effects, even the sense of their primary effects is not wholly independent of the nature of the other substituents present on the same atom. Thus the successive replacement of hydrogen atoms in ammonia by methyl groups causes at the first step a rise and at the last a fall in the basic affinity constant. Again the capacity of the  $\text{CCl}_3$  group to pass, together with its bonding electrons, from one state of combination to another (as from proton in chloroform to depleted carbon in acetone) suggests that the joint primary (*i.e.*, totalised) effect of the three chlorine atoms on the carbon is electron-restraining, whereas the primary effect of Cl on carbon of the aromatic nucleus or of carbonyl appears consistently electron-releasing (compare J., 1928, 2547); on the other hand, a "permissive" effect might be concerned here.

## Section II.

This section deals only with observations of which a more detailed account than has been given in the preceding pages seems desirable.

(1) *Action of Methoxymethylpyridinium Chloride on Hydroxy-compounds.*—(a) *Benzyl alcohol.* Chlorodimethyl ether (40 g.) was slowly added to purified pyridine (100 c.c.) dissolved in dry ether (500 c.c.) cooled in ice-water, the crystalline quaternary salt which at once separated being then collected rapidly on a Buchner funnel, washed with ether, and transferred to a dry flask. A small sample of the chloroplatinite was prepared and had m. p.  $180\text{--}182^\circ$  (efferv.) (compare Litterschied, *Annalen*, 1901, **316**, 168). The bulk of the salt was heated with dry benzyl alcohol (54 g.) and pyridine (80 c.c.) at  $90\text{--}95^\circ$  for 6 hours, after which time addition of ether to a sample of the cooled mixture led to precipitation of pyridine hydrochloride (chloroplatinite, m. p.  $238\text{--}240^\circ$ ). In working up the product, the latter was cooled and mixed with water, made slightly acid, and extracted twice with ether (400 c.c. in all), which was then washed

with dilute hydrochloric acid and water successively, dried over sodium sulphate, and evaporated. From the residual liquid, a main portion (40 g.), b. p. 205—215°, and a less volatile portion (5 g.) were obtained. To remove benzyl alcohol, the former was shaken repeatedly with a concentrated aqueous solution of sodium salicylate\* until it suffered no further appreciable diminution in bulk and was then refractionated. A fraction (25 g.), b. p. 208—211°, was obtained, consisting of *methoxymethyl benzyl ether*,  $C_6H_5 \cdot CH_2 \cdot O \cdot CH_2 \cdot O \cdot CH_3$ .

The ether is obtained in better yield (about 36 g.) by simply mixing benzyl alcohol (54 g.), chlorodimethyl ether (40 g.), and dry pyridine (50 g.) slowly but without special cooling, and working up the product as before. It is a colourless oily liquid, b. p. 208—211°/756 mm., having a fragrant fruity odour (Found: C, 70.8; H, 7.9.  $C_9H_{12}O_2$  requires C, 71.1; H, 8.0%).

In each of the following cases, the alcohol was warmed with the mixture of chlorodimethyl ether and pyridine for several hours, and the product worked up as above.

(b) *cycloHexanol*. The yield of *methoxymethyl cyclohexyl ether* was so poor that a homogeneous product could not be isolated. Most of the alcohol was recovered unchanged, and from 50 g. of *cyclohexanol* only 1.8 g. of oil (b. p. 190—210°) were obtained (Found: C, 67.3; H, 11.2.  $C_8H_{16}O_2$  requires C, 66.6; H, 11.2%). About 2.5 g. of higher-boiling product (b. p. 255—274°) accompanied this.

(c) *sec.-β-Octyl alcohol*. From 65 g. of this alcohol were obtained 5 g. of *methoxymethyl sec.-octyl ether*, as a liquid with a fragrant odour; b. p. 188—190° (Found: C, 69.2; H, 12.7.  $C_{10}H_{22}O_2$  requires C, 69.0; H, 12.6%).

(d) "*Amyl alcohol*." A commercial amyl alcohol, b. p. 131—132°, being used (44 g.), a fraction representing *methoxymethyl "amyl" ether* was obtained in fair yield (15 g.). This product had a very powerful, not unpleasant odour, reminiscent of amyl alcohol (Found: C, 63.5; H, 12.2.  $C_7H_{16}O_2$  requires C, 63.6; H, 12.7%).

The action of *methoxymethylpyridinium chloride* on amyl alcohol appears to be much less energetic than on benzyl alcohol. In the latter case the heat disengaged in admixture is sufficient to ensure completion of the reaction, but in the former it was found that most of the amyl alcohol is recovered unchanged unless the mixture is heated on the steam-bath before it is worked up. No special trials were made to find the minimum time necessary.

(e) *Phenol*. No reaction appeared to take place with the quater-

\* A solution of sodium salicylate seems to have been used in industry for the separation of alcohols from mixtures of these with non-alcoholic compounds.

nary pyridinium salt, and no neutral product boiling above 100° was detected. A sample of the recovered phenolic material was carefully fractionated in order to ascertain whether any alkylation in the nucleus had taken place, but nothing boiling appreciably higher than phenol could be isolated. The expected ether,  $C_6H_5 \cdot O \cdot CH_2 \cdot O \cdot CH_3$  boils at 188—189°/760 mm. (compare *Centr.*, 1909, I, 1681).

This inertness of phenol is doubtless associated with its acid character, having a parallel in the difficulty which is experienced in the alkylation of nitrophenols or carboxylic acids by means of aqueous alkali and methyl sulphate.

The order of the hydroxy-compounds examined as to the facility with which they react with methoxymethylpyridinium chloride appears to be: benzyl alcohol, amyl alcohol, *sec.*-octyl alcohol, cyclohexanol, phenol, and a close relation with the order of their acidities may be suspected.

(2) *Observations on some  $\alpha$ -Substituted Nitriles.*—(a)  *$\alpha$ -Diethylaminopropionitrile.* This compound, which has already been made by Klages (*J. pr. Chem.*, 1902, **65**, 196), is readily produced by slowly mixing diethylamine with a slight excess of acetaldehyde and liquid hydrogen cyanide in the required proportion. There is considerable heat development and careful cooling is therefore necessary. The product, after exposure in a vacuum for a short time, forms a mobile liquid, stable in absence of water at the ordinary temperature (Found: N, 21.9. Calc. for  $C_7H_{14}N_2$ : N, 22.2%).

A sample so prepared was added to a solution of silver nitrate acidified with nitric acid and yielded silver cyanide corresponding with 1.3% of free hydrogen cyanide, the nitrile itself (or rather its salt) being stable to this reagent. The total CN present in the same sample was determined by shaking with excess of dilute sodium hydroxide solution and silver hydroxide and then adding excess of dilute nitric acid. The total CN found was 23.1%; hence the combined CN was 21.8% (theory requires CN, 20.4%).

On distillation of the nitrile under reduced pressure, a portion, b. p. 72—77°/17 mm., amounting to about at least 60% of the whole is obtained. This appears to consist mainly of the original nitrile, but is decidedly more viscous, and some decomposition products are probably present.

The nitrile can also be obtained, though in smaller yield (about 30% of the theoretical), by adding diethylamine and acetaldehyde in equimolecular proportion to a concentrated aqueous solution of potassium cyanide and extracting the product with a large bulk of ether. Here potassium hydroxide must be formed:

When the amino-nitrile is left with water, the odour of hydrogen cyanide becomes perceptible within a few minutes. If the hydrogen cyanide formed is continuously removed by exposure of the vessel in a vacuum desiccator over a solution of sodium hydroxide, the layer of oily nitrile gradually disappears and, after several days, only a scum of tarry product can be seen on the surface of the water, though even then a faint odour of hydrogen cyanide is perceptible.

The picrate is best made from the nitrile before distillation, a solution of picric acid in cold dry ether being used. It is deposited as long prisms, m. p.  $99.5-102^\circ$ ; Klages (*loc. cit.*) gives m. p.  $102^\circ$ . As its melting point was appreciably lowered by recrystallisation, the crude salt was analysed (Found: C, 44.2; H, 4.8; N, 22.3, 19.7. Calc. for  $C_{13}H_{17}O_7N_5$ : C, 43.9; H, 4.8; N, 19.7%).

(b) *Methoxyacetoneitrile*. This was made by the method of Polstorff and Meyer (*Ber.*, 1912, 45, 1911) from formaldehyde, potassium cyanide, and methyl sulphate. Its identity was confirmed by its boiling point ( $120-122^\circ$ ) and other properties (Found:  $CH_3 \cdot O$ , 42.7. Calc. for  $CH_3 \cdot O \cdot C_2H_2N$ :  $CH_3 \cdot O$ , 43.6%), as well as by the properties and composition of the methoxyacetamide prepared from it; needles, m. p.  $96.5-97^\circ$  (Found:  $CH_3 \cdot O$ , 34.8. Calc. for  $CH_3 \cdot O \cdot C_2H_4ON$ :  $CH_3 \cdot O$ , 34.8%).

The nitrile does not yield detectable traces of hydrogen cyanide or metallic cyanide when heated alone, with alkalis, with solid sodium hydroxide at its boiling point, with potassium in boiling toluene, or with silver nitrate and dilute nitric acid.

(c) *Methoxypropionitrile*. This compound is most readily made by the method used by Polstorff and Meyer in preparing the lower homologue, the formaldehyde being replaced by an equivalent amount of acetaldehyde. It has previously been made by Gautier from the corresponding chloro-ether (*Ann. Chim. Phys.*, 1909, 16, 315).

The product obtained by the present authors had b. p.  $128-130^\circ/758$  mm. (Found:  $CH_3 \cdot O$ , 30.0. Calc. for  $CH_3 \cdot O \cdot C_3H_4N$ :  $CH_3 \cdot O$ , 30.1%). It was readily converted into the corresponding amide (needles, m. p.  $83^\circ$ , from light petroleum) by means of alkaline hydrogen peroxide. It yielded no hydrogen cyanide nor metallic cyanide under the most drastic treatment.

### Summary.

The electron displacement theory of G. N. Lewis, in its application to phenomena associated with results of introducing substituents into the molecules of carbon compounds, is accepted only in part.

It is shown that there is good reason to believe that the substituents  $\ominus O$ ,  $NAlk_2$ ,  $OH$  and  $O \cdot CH_3$ , in descending order of

efficiency, greatly increase the electron fugacity of directly attached, 4-co-ordinated carbon, and thus form a group in complete contrast to the carbonyl and nitro-radicals.

There is no simple relation between such effects ("primary" effects) and the so-called electron affinities ("electropolar" factors) of substituents. There is a close general connexion, however, between the former and the ortho-para directive powers ("quantitative" factors).

The tendency of a radical to enter into combination with a given carbon atom or/and to replace another radical attached thereto, is influenced not only by the nature of the radicals already attached to the carbon atom but also by those properties of the entrant radical which determine what the sign and the magnitude of the "primary" effect of that radical will be after such combination has taken place.

Evidence is cited that, at least with a substituent which has a comparatively small "primary" effect, even the sign of that effect is not always independent of the nature of the other radicals attached to the atom.

## LXI.—*Substituted Diaryl Ethers. Part III. A New Synthesis of Substituted Xanthhydryls.*

By JOSEPH REILLY and PETER J. DRUMM.

IN a recent communication (J., 1927, 2814) the authors showed that di-*p*-tolyl ether yields only monosubstituted derivatives in the Friedel-Crafts reaction. The product of interaction of benzoyl chloride and di-*p*-tolyl ether was assigned the constitution of an ortho-substituted diaryl ether (I) because it was converted into 9-phenyl-2:7-dimethylxanthen (II) and also because its solutions in acetic and sulphuric acids were yellow, indicating xanthhydryl formation through ring closure. The non-formation of a phenyl-hydrazone was attributed to steric hindrance by the tolyloxy-radical in the ortho-position to the carbonyl group. The supposed ketone (I) has now been found to be the isomeric 9-phenyl-2:7-dimethylxanthhydryl (III), which has also been obtained by the action of magnesium phenyl bromide on 2:7-dimethylxanthone.

This interaction constitutes a simple method of producing substituted xanthhydrols in good yield from readily accessible materials. Ordinarily, xanthhydrols are prepared from the corresponding xanthenes by the Grignard reaction (compare Ullmann and Engi, *Ber.*, 1904, **37**, 2370). This method is unsuitable in the case of the above xanthhydrol, since the preparation of 2 : 7-dimethylxanthone from *p*-cresotic acid is not satisfactory.

9-Phenyl-2 : 7-dimethylxanthhydrol, when boiled with acetic acid, gave 9-phenyl-2 : 7-dimethylxanthen (*loc. cit.*), which was also prepared by Feuerstein and Lipp (*Ber.*, 1902, **35**, 3255) by distillation of 6 : 6'-dihydroxy-3 : 3'-dimethyltriphenylmethane. In Part II (J., 1927, 2815) it was suggested that Feuerstein and Lipp's compound might be a fluorene on the ground that acetic acid is not usually a reducing agent. The xanthen constitution is more in line with the experimental facts, reduction of the xanthhydrol having been brought about by the presence of reducing agents in the acetic acid used : reduction does not take place with specially purified acid. The constitution assigned by Feuerstein and Lipp was confirmed by the re-conversion of their 9-phenyl-2 : 7-dimethylxanthen into the corresponding xanthhydrol by oxidation with lead peroxide.

It has been shown by Schmidlin and Garcíá Banús (*Ber.*, 1912, **45**, 3188) that triphenylcarbinol is readily reduced to triphenylmethane by heating with alcoholic sulphuric acid, and Kauffmann and Pannwitz (*ibid.*, p. 766) have shown that a similar reduction takes place by boiling with alcoholic hydrogen chloride. The present authors have obtained similar results with these reagents in the case of 9-phenyl-2 : 7-dimethylxanthhydrol and comparative experiments have shown that the latter is reduced much more readily than triphenylcarbinol. Formic acid also is an effective but less vigorous reducing agent.

By the action of hydrogen chloride on 9-phenylxanthhydrol in chloroform solution, Bünzly and Decker (*Ber.*, 1904, **37**, 2935) obtained a coloured chloride. With hydrogen chloride, 9-phenyl-2 : 7-dimethylxanthhydrol forms a coloured *chloride hydrochloride* which readily loses a molecule of hydrogen chloride, giving the colourless chloride (compare Gomberg and Cone, *Annalen*, 1909, **370**, 142). Work on the application of the above synthesis to the preparation of substituted thioxanthhydrols is in progress.

#### EXPERIMENTAL.

*9-Phenyl-2 : 7-dimethylxanthhydrol.*—Finely powdered 2 : 7-dimethylxanthone (6 g.) was gradually added to a cooled solution prepared from bromobenzene (10 g.), magnesium (1 g.), and anhydr-

ous ether (50 c.c.). A vigorous reaction ensued and a yellow magnesium double compound separated. After addition of benzene (10 c.c.) the mixture was heated on a water-bath for 1 hour. The solvent was removed, and the residue decomposed by careful addition of ice-cold water. Just sufficient dilute sulphuric acid was then added to dissolve basic magnesium salts. On addition of alcohol to the mixture the precipitated oil quickly solidified (yield, 6.2 g.). The product was crystallised from ethyl alcohol-ethyl acetate, 9-phenyl-2:7-dimethylxanthhydrolyd being obtained in colourless rhombohedra which, alone or when mixed with the product of interaction of benzoyl chloride and di-*p*-tolyl ether, melted at 185—186°.

*4'-Diethylamino-9:9-diphenyl-2:7-dimethylxanthen.*—Diethyl-aniline (1 g.) and 9-phenyl-2:7-dimethylxanthhydrolyd (1 g.) were heated under reflux in acetic acid solution for 30 minutes. The product, which separated on cooling, was obtained from alcohol-ethyl acetate in colourless needles, m. p. 183—184° (Found by the micro-method: C, 85.5; H, 7.0.  $C_{31}H_{31}ON$  requires C, 85.9; H, 7.1%). *4'-Diethylamino-9:9-diphenyl-2:7-dimethylxanthen* is readily soluble in chloroform and ethyl acetate and slightly soluble in ethyl alcohol.

*9-Phenyl-2:7-dimethylxanthhydrolyd chloride hydrochloride* was obtained on saturating a solution of 9-phenyl-2:7-dimethylxanthhydrolyd in anhydrous ether (containing a few drops of acetyl chloride) with dry hydrogen-chloride. It separated slowly in well-defined, reddish-orange prisms, m. p. 147—149° (Found: Cl, 20.3.  $C_{21}H_{17}OCl.HCl$  requires Cl, 19.9%). The chloride hydrochloride is readily soluble in chloroform and acetic acid and insoluble in benzene and ether. It is very susceptible to traces of moisture, being decomposed immediately by water. Heated in a vacuum over quicklime at 130°, it loses a molecule of hydrogen chloride, giving the colourless chloride (Found:  $HCl$ , 10.8. Calc. for  $C_{21}H_{17}OCl: HCl$ , 10.2%). The latter is very unstable, turning red on exposure to air. Its double salt with ferric chloride is identical in all respects with the *ferrichloride* prepared from 9-phenyl-2:7-dimethylxanthhydrolyd by addition of anhydrous ferric chloride to a solution of the xanthhydrolyd in glacial acetic acid previously saturated with hydrogen chloride, which crystallised from glacial acetic acid, containing hydrogen chloride, in reddish-orange rectangular plates, m. p. 181° (Found: Cl, 30.0.  $C_{21}H_{17}OCl.FeCl_3$  requires Cl, 29.4%). It is stable in the air (not showing any signs of decomposition after 2 days), but is slowly decomposed by cold, and more readily by hot water. It dissolves readily in chloroform, nitrobenzene and acetone, but is sparingly soluble in cold acetic acid and insoluble in benzene

and ether. The mercuric chloride and gold chloride double salts were prepared in a similar manner, the former consisting of reddish prisms soluble in chloroform and the latter of golden-yellow needles.

Addition of a solution of bromine in acetic acid to a solution of the xanthhydrol in the same solvent saturated with dry hydrogen bromide gave a precipitate of the tribromide, which formed short reddish-orange prisms, m. p. 145–146° (decomp.) (Found: Br, 46.1.  $C_{21}H_{17}OBr_3$  requires Br, 45.7%). The tribromide is readily soluble in chloroform, nitrobenzene and acetone, but is sparingly soluble in benzene and ether. Water slowly decomposes it with regeneration of the carbinol base.

*9-Phenyl-2:7-dimethylxanthen.*—Zinc dust was gradually added to a boiling solution of 9-phenyl-2:7-dimethylxanthhydrol (1 g.) in 80% acetic acid (50 c.c.). At first a reddish-orange solution was obtained, the colour of which was completely discharged after 10 minutes' boiling. The solid which separated from the hot filtrate was obtained from glacial acetic acid in colourless needles, which melted, alone or when mixed with the 9-phenyl-2:7-dimethylxanthen of Feuerstein and Lipp (*loc. cit.*), at 195–196°. Contrary to the statement of these authors, sulphuric acid in contact with the above xanthen does not develop a yellow colour. On heating, however, a yellow solution with a green fluorescence is obtained, owing probably to partial oxidation of the xanthen to the xanthhydrol by the acid.

*Oxidation of 9-Phenyl-2:7-dimethylxanthen.*—To a hot solution of the xanthen (3 g.) in 80% acetic acid (100 c.c.) was added, during 1 hour, with stirring, freshly prepared lead peroxide (1 mol.) made into a paste with acetic acid. The solution, at first colourless, gradually assumed a deep orange colour. The solid obtained on dilution of the filtrate with water was collected, washed with hot water, dried, and redissolved in glacial acetic acid. The ferri-chloride was identical with that from 9-phenyl-2:7-dimethylxanthhydrol.

UNIVERSITY COLLEGE, CORK.

## LXII.—Photomicrographic Methods applied to Two-component Salt Mixtures.

By WALTER MATTHEW MADGIN.

DISCUSSING the deduction of the type of a two-component system, Freeth (*J. Physical Chem.*, 1925, 29, 497) states that the methods of thermal analysis are not conclusive in many cases. Such methods

would be expected to be most inconclusive in systems where the melting point of each component is lowered by addition of the second component and where the solids are wholly or partially miscible: in both of these systems cooling curves may be misleading, *e.g.*, when the rate of cooling is too rapid and gives rise to cored structure, and the systems may be mistaken for simple eutectic systems. The very successful application of photomicrographic methods to the study of metallic alloys suggests that similar methods might be of value in the cases discussed above, and, in fact, Schemtschuschny (*Z. anorg. Chem.*, 1908, 57, 267) has thereby obtained useful data as to the miscibility or otherwise of potassium chloride with potassium chromate, potassium dichromate, or silver chloride.

From the results of thermal analysis, Guthrie (*Phil. Mag.*, 1884, 17, 462) concluded that the salt pair potassium nitrate-lead nitrate formed a simple eutectic system, but he did not prove the non-existence of limited solid miscibility. Accordingly a photomicrographic study of this system has been undertaken, and the results afford confirmation of Guthrie's. In addition, they point to the conclusion, which would be difficult to deduce from thermal data, that the components of the system show little or no solid miscibility.

Pure lead nitrate is not fusible without decomposition, but with potassium nitrate it forms fusible mixtures of low melting point which are stable provided they do not contain more than 70% of lead nitrate (Guthrie, *loc. cit.*). The melting point of this limiting mixture is given as 335°, which is therefore the highest working temperature permissible and is practically the melting point of pure potassium nitrate (330°; Briscoe and Madgin, J., 1923, 123, 1608). This restricted working temperature is an important consideration when synthetic mixtures are being prepared as described below.

#### EXPERIMENTAL.

The materials used were supplied as of pure quality and were recrystallised until analysis showed at least 99.9% purity.

Mixtures of potassium nitrate and lead nitrate in various proportions and cast in a suitable form for polishing were prepared in ordinary glass test-tubes ( $\frac{5}{8}$ " diameter) by weighing an amount of lead nitrate in a tube and adding a weighed amount of potassium nitrate, which was always on top of the lead salt. The test-tube was placed in an electric heater similar to that described by Briscoe and Madgin (*loc. cit.*) but sufficiently large to cover most of the tube. By this procedure no decomposition of lead nitrate ever occurred,

since the temperature never exceeded  $335^{\circ}$ , and no lead nitrate could ever be left undissolved, being always below the potassium nitrate.

When complete fusion had occurred, the heater was slowly cooled by altering the external resistance, and the rate of cooling was adjusted so as to secure the growth of large crystals. The composition of the various mixtures used is shown below as % of potassium nitrate by weight, No. 4 being the eutectic mixture:

Mixture No. ....	1	2	3	4	5
KNO <sub>3</sub> , % .....	89.6	77.8	65.5	48.6	35.9

Mixtures at or near the eutectic composition (Nos. 3, 4, and 5) required very slow cooling, *viz.*,  $10^{\circ}$  per hour, in order to yield moderately large crystals. Nos. 1 and 2 were cooled much more rapidly, being completely solidified in one hour (a fall of  $130^{\circ}$ ); otherwise the primary crystals of potassium nitrate were much too large and the enclosed eutectic solid was difficult to detect.

The eutectic composition given above differs slightly from that given by Guthrie (*loc. cit.*) and was therefore redetermined as a preliminary to the present work. Further details of this determination will be published elsewhere.

The solidified mixtures obtained as described above were of such an amount as to fill the test-tubes to a depth of 1 inch. After removal from the test-tubes, the castings were sawn into pieces about  $\frac{1}{2}$ " in length and the fresh-cut surfaces were polished.

*Polishing of Specimens.*—The surfaces were filed smooth, rubbed on emery cloth, and then on three grades of emery paper of increasing fineness. This gave a moderate polish but left scratches readily visible under the microscope; further polishing was therefore done on Selvyt cloth on a rotating wheel.

The result of these various treatments was a highly polished but flowed surface, with little or no structure visible, and as ordinary etching reagents could not be employed to remove this surface, 96% alcohol was tried (compare Schemtschuschny, *loc. cit.*). Polished specimens were placed in warm 96% alcohol for about 1 minute, then removed and repolished on the Selvyt cloth. Two or three repetitions of this treatment gave a highly polished surface which showed the structure of the specimen very clearly when examined under the microscope with vertical illumination. It was concluded that the small amount of water in the alcohol had been sufficient to remove the flowed surface and etch lightly the surface beneath.

Microscopic examination showed the existence of two distinct crystalline substances, one white and the other dark grey. Since the specimens were white, this difference is attributed to alteration

cooling between two plane glass surfaces, where complex capillary forces would exist, and this does not provide a convenient method for examining structure.

*Results.*—The photomicrographs show that potassium nitrate and lead nitrate mixtures containing between 89.6% and 36% of the former afford no evidence of solid miscibility and form a eutectic system; banded eutectic structure is easily recognisable in all cases, and staining with hydrogen sulphide enables the two components to be differentiated readily. However, the possibility of partial solid miscibility is not excluded in mixtures of compositions outside the above range. Mixtures containing less than 36% of potassium nitrate would have melting points above 335° and therefore could not be examined. On the other hand, microscopic examination of specimens containing 93, 96, and 98% of potassium nitrate showed the presence of the usual eutectic structure in all cases and, after the specimens had been stained with hydrogen sulphide, the presence of banded eutectic areas between large primary crystals was much more easily recognisable. The photomicrographs of these specimens are not included, as they did not show any fundamental differences from the specimens illustrated.

The stained specimens (Figs. 5, 6, and 7) provide valuable evidence of the absence of solid miscibility. If solid lead nitrate was in any way miscible with potassium nitrate, lead sulphide staining should penetrate throughout the white crystals of potassium nitrate. The absence of such penetration (*e.g.*, Fig. 5) is evidence that the two components are immiscible in the solid state.

Figs. 2, 4, and 7 show that lead nitrate, the constituent in excess, tends to form dendrites much more than potassium nitrate appears to do. It is seen in Fig. 4 that the primary crystals of lead nitrate are surrounded by dark-coloured bands which do not appear to contain any of the lead salt. According to Huntington and Desch (*Trans. Faraday Soc.*, 1908, 4, 51) this phenomenon is due to segregation, large crystals growing at the expense of small crystals when both are in contact with a saturated solution, and it may be in some way related to the tendency of lead nitrate to exhibit dendritic growth. Similar phenomena were not observed in mixtures containing excess of potassium nitrate. It was thought that the formation of these bands surrounding primary crystals might be the outcome of supercooling, since Guthrie (*loc. cit.*) has shown that the eutectic mixture and also those mixtures containing excess of lead nitrate exhibit pronounced supercooling, whereas mixtures containing excess of potassium nitrate do not manifest such supercooling. However, Lamplough and Scott (*Proc. Roy. Soc.*, 1914, 90, A, 600) have confirmed the conclusions of Huntington and Desch.

and have shown that these bands surrounding primary crystals may be formed without supercooling and may be absent when supercooling occurs.

*Summary.*

(1) A method of preparing etched and polished surfaces of mixtures of lead and potassium nitrates is described, and such surfaces are illustrated by photomicrographs.

(2) Hydrogen sulphide reacts with the lead nitrate in these mixtures, and in the photomicrographs the resulting lead sulphide enables the structure to be seen very clearly.

(3) It is concluded that solid potassium nitrate and lead nitrate are completely immiscible when the former exceeds 35% by weight in any mixture. Mixtures containing more than 65% of lead nitrate cannot be investigated.

(4) The results are in agreement with Guthrie's thermal analysis of the same system.

### LXIII.—*The Interaction between Alkyl Grignard Reagents and Antimony Trichloride.*

By WILFRED JAMES CECIL DYKE, WALTER CULE DAVIES, and  
WILLIAM JACOB JONES.

ON treating magnesium ethyl bromide in ethereal solution with excess of antimony trichloride, Auger and Billy (*Compt. rend.*, 1904, 139, 599) obtained a mixture which they supposed to contain ethyl-dichloro- and -dibromo-stibine. Using equivalent weights of magnesium, methyl iodide, and antimony trichloride, Hibbert (*Ber.*, 1906, 39, 160) prepared trimethylstibine (which he isolated as dibromide representing a yield of 60–70%), together with high-boiling by-products, which were not further examined. Subsequently, Hibbert's method was employed both by Hantzsch and Hibbert (*Ber.*, 1907, 40, 1512), and by Morgan and Yarsley (*J.*, 1925, 127, 184), who devised a special form of apparatus in which the trimethylstibine was purified by distillation of its dibromide with zinc in an inert atmosphere. Morgan and Yarsley also used triethyl- and tri-*n*-butyl-stibine in attempts to prepare bisalkylstibinedichloroplatinums, but they do not describe the properties of the butylstibine. The reactions of the substituted chloro- and iodo-stibines with alkyl Grignard reagents have been investigated by Grüttner and Wiernik (*Ber.*, 1915, 48, 1484, 1759), by Grüttner and

Krause (*Ber.*, 1916, 49, 437), and by Ingold, Shaw, and Wilson (*J.*, 1928, 1283).

The purpose of the present work was twofold, *viz.*, (1) to investigate the character and yields of products other than tertiary stibines, and (2) to characterise the tertiary stibines and investigate their general properties.

In all cases hydrocarbon, formed by the synthetic action of the magnesium on the alkyl bromide, was isolated by exhaustively treating the first runnings, obtained in the isolation of the stibine, with concentrated sulphuric acid.

No evidence of any considerable formation of alkylhalogenostibine, such as that supposed by Auger and Billy (*loc. cit.*), was obtained. Moreover, no higher-boiling product than the stibine (compare Hibbert, *loc. cit.*) was produced in appreciable amount, except the stibine oxide, which, in spite of careful exclusion of air, was always formed to a slight extent.

Interaction between alkyl Grignard reagents and antimony trichloride is always accompanied by separation of finely divided antimony. Direct experiment has proved that on mixing alkylstibines with antimony trichloride there is immediate reduction to antimony.

The total yield of stibine in a preparation, determined iodometrically (see Experimental), was generally 60–70% of the theoretical, in agreement with that found by Hibbert in the case of trimethylstibine, but for triethylstibine the yield was 80–85%.

In view of the ease of oxidation of the trialkylstibines, special precautions were taken to exclude air, both during reactions and in the subsequent separation and manipulation of the products.

Trimethylstibine (Landolt, *Annalen*, 1851, 78, 91) and triethylstibine (Löwig and Schweizer, *ibid.*, 1850, 75, 315, 327) have long been known, but, excepting the preparation of tri-*n*-butylstibine by Morgan and Yarsley (*loc. cit.*), no preparations of higher trialkylstibines have been recorded since 1856, when Berl   (*Annalen*, 1856, 97, 316) prepared a triamylstibine.

The higher trialkylstibines are clear liquids of peculiar odour. Their density falls regularly as the series is ascended, whilst their boiling points rise. When distilled under reduced pressure, the lower members pass over undecomposed, but tri-*n*-hexylstibine is partly decomposed. When cooled to the temperature of liquid air, they crystallise. They are only slightly miscible with water, but at the ordinary temperature they mix in all proportions with alcohol, ether, benzene, and carbon disulphide.

Trialkylstibines combine vigorously with oxygen, which causes an immediate clouding of the originally clear liquid, considerable

heat being evolved. The avidity for oxygen, however, falls off with increased molecular weight. Stibines readily ignite when warmed in the air, burning with the greyish-green flame characteristic of antimony and evolving clouds of antimonous oxide. When allowed to fall on filter paper, they cause charring and, if in quantity, ignition. Chlorine, bromine, and iodine readily combine with the stibines, dihalides being formed quantitatively. In contradistinction to the phosphines, trialkylstibines combine only lethargically with methyl and other alkyl iodides, and with carbon disulphide they yield no coloured compounds. They reduce mercuric salts in cold aqueous solution, and, on warming, auric and silver salts also, to the metal.

Antimony was determined in the stibines by heating the compound with sodium carbonate in a stream of oxygen in a combustion tube. The contents of the tube were dissolved in 10% hydrochloric acid and antimony trisulphide was precipitated from the boiling solution by the passage of hydrogen sulphide for  $\frac{1}{2}$  hour. An equal volume of hot water was then added to the liquid, and the stream of hydrogen sulphide was continued for 5 minutes. The precipitate was collected on a Gooch crucible, washed, and dried for 2 hours at  $130^{\circ}$  and for 2 hours at  $280\text{--}300^{\circ}$  in carbon dioxide.

#### EXPERIMENTAL.

The apparatus consisted of a wide-necked bottle, of 1 litre capacity, fitted with a rubber stopper carrying a mercury-sealed stirrer, a dropping funnel, a reflux condenser, an inlet tube for hydrogen, and a siphon whereby liquid layers could be withdrawn and separated in absence of air. The exterior limb of the siphon was fitted with a tap and it slid smoothly through a glass jacket fixed in the stopper of a separating funnel (see fig.). Air-tightness was secured by stretching rubber tubing over both the jacket and the limb of the siphon. The other limb of the siphon passed into the reaction bottle by a similar device, which permitted adjustment of the siphon to any desired level. The separating funnel was provided with two tubes with taps to serve either as inlet and outlet, respectively, for carbon dioxide, or for the application of suction.

The Grignard solution was prepared by dropping the freshly prepared alkyl halide, dissolved in 150 c.c. of ether, on 12.1 g. of magnesium turnings immersed in 150 c.c. of ether to which a granule of iodine had been added. Throughout the preparation of this

solution and its interaction with antimony trichloride, pure dry hydrogen was passed over the liquid. The liquid was then cooled to  $0^{\circ}$  and 38.1 g. of freshly redistilled antimony trichloride in 100 c.c. of ether were added drop by drop. After the addition was complete the mixture was warmed for  $\frac{1}{2}$  hour, again cooled to  $0^{\circ}$ , and then treated with ammonium chloride solution. The separating funnel was now filled with pure dry carbon dioxide, and the ethereal layer was transferred from the reaction bottle into the funnel. In this way an unclouded solution was obtained.

In the estimation of the total yield of stibine a standard solution of iodine in ether, or of bromine in carbon tetrachloride, was run into the funnel through the inlet tube until the colour persisted, indicating quantitative conversion into the dihalide.

In cases where the stibine was isolated, the ethereal solution was dried with anhydrous sodium sulphate, the ether distilled off in an atmosphere of carbon dioxide, and the residue fractionally distilled under reduced pressure. A  $2^{\circ}$  fraction containing the stibine was collected in a pycnometer-receiver with a tubular neck and ground-glass stopper. The stibine was thus obtained as a clear liquid.

Triethylstibine was prepared by the addition of the equivalent of antimony trichloride in ether to the Grignard solution prepared from 55 g. of ethyl bromide. The total yield of stibine in the ethereal solution was 80–85%.

*Tri-n-propylstibine*, obtained by the addition of antimony trichloride to magnesium *n*-propyl bromide prepared from 62 g. of the alkyl bromide, has b. p.  $100^{\circ}/25$  mm.,  $113^{\circ}/39$  mm.;  $d_4^{25}$  1.241 (Found: C, 43.2; H, 8.5; Sb, 48.1.  $C_9H_{21}Sb$  requires C, 43.1; H, 8.4; Sb, 48.5%). The total yield of stibine was 60–70%, and the yield of purified material 11 g. The stibine possesses a penetrating, alliaceous odour.

The residue after removal of ether in the case of the interaction between antimony trichloride and magnesium *isopropyl* bromide, on being heated under reduced pressure, continuously emitted gaseous decomposition products. This result is comparable with that obtained in the interaction between various phosphorus chlorides and the Grignard reagent of *isopropyl* bromide (Davies, Pearse, and Jones, J., 1929, 1268).

From the products of the interaction between magnesium *n*-butyl bromide (from 69 g. of *n*-butyl bromide) and its equivalent of antimony trichloride, a first fraction containing *n*-octane was obtained. From this, 5 g. of the purified hydrocarbon, b. p.  $125^{\circ}/760$  mm., were isolated. The distillation was continued under reduced pressure, whereupon there were obtained 11 g. of *tri-n-butylstibine*,

b. p.  $131^{\circ}/12$  mm.;  $d_4^{25}$  1.191 (Found: C, 48.8; H, 9.9; Sb, 40.5.  $C_{12}H_{27}Sb$  requires C, 49.2; H, 9.3; Sb, 41.5%).

*Triisobutylstibine*, b. p.  $135^{\circ}/31$  mm.,  $d_4^{25}$  1.323 (Found: Sb, 41.8.  $C_{12}H_{27}Sb$  requires Sb, 41.5%), was prepared (yield, 11 g.) by the interaction between the antimony halide and magnesium *isobutyl* bromide made from 69 g. of the alkyl bromide. The first runnings furnished 6 g. of  $\beta$ -dimethylhexane, b. p.  $109^{\circ}/760$  mm. The butylstibines possess a mixed alliaceous-butylic odour. The *isobutylstibine* is distinctly yellow.

The preparation of *tri-n-amylstibine* was effected by adding antimony trichloride to the Grignard reagent obtained from 76 g. of *n*-amyl bromide; yield, 15 g., b. p.  $168^{\circ}/16$  mm.,  $d_4^{25}$  1.136 (Found: C, 53.8; H, 9.3; Sb, 37.2.  $C_{15}H_{33}Sb$  requires C, 53.7; H, 9.9; Sb, 36.3%). In the preparation of this stibine there were obtained 8 g. of *n*-decane, b. p.  $88^{\circ}/50$  mm. (Krafft, *Ber.*, 1882, 15, 1695, gives b. p.  $90^{\circ}/50$  mm.).

*Tri-dl- $\beta$ -methylbutylstibine*, obtained from the Grignard reagent made from 76 g. of *dl*- $\beta$ -methylbutyl bromide (yield, 10 g. of purified product), has b. p.  $150^{\circ}/14$  mm.;  $d_4^{25}$  1.242 (Found: Sb, 36.5.  $C_{15}H_{33}Sb$  requires Sb, 36.3%). The synthetic action of the magnesium gave 6 g. of  $\gamma$ -dimethyloctane, b. p.  $159^{\circ}/760$  mm.

The interaction between equivalents of antimony trichloride and magnesium *isoamyl* bromide yielded 10 g. of *triisoamylstibine* (*tri- $\gamma$ -methylbutylstibine*), b. p.  $149^{\circ}/14$  mm.;  $d_4^{25}$  1.227 (Found: Sb, 36.2.  $C_{15}H_{33}Sb$  requires Sb, 36.3%). There were obtained 10 g. of  $\beta$ - $\gamma$ -dimethyloctane, b. p.  $159^{\circ}/760$  mm. When distilled in a stream of carbon dioxide under *atmospheric pressure*, the stibine passed over with considerable decomposition at about  $260^{\circ}$ . All the amyl stibines have a preponderatingly amylic smell. *n*-Amylstibine is colourless, but  $\beta$ - and  $\gamma$ -methylbutylstibines are both yellowish.

*Tri-n-hexylstibine*, prepared (yield 10 g.) from the Grignard reagent made from 83 g. of *n*-hexyl bromide, boils at  $190^{\circ}/10$  mm. with partial decomposition and liberation of antimony. The distillate had  $d_4^{25}$  ca. 1.15. For the purpose of analysis the separated antimony was allowed to settle out of the liquid (Found: Sb, 31.2.  $C_{18}H_{39}Sb$  requires Sb, 32.3%). The smell resembles that of *n*-hexyl alcohol. In this preparation 12 g. of *n*-dodecane, b. p.  $95^{\circ}/12$  mm. (Krafft, *loc. cit.*, gives b. p.  $98^{\circ}/15$  mm.), were obtained.

Investigation of derivatives of the trialkylstibines is being pursued.

## LXIV.—*Syntheses by Means of Magnesium Amyl Halides.*

By WALTER CULE DAVIES, ROBERT SINCLAIR DIXON, and  
WILLIAM JACOB JONES.

ALTHOUGH the magnesium derivatives of *iso*amyl halides have been extensively employed in synthesis, the use of Grignard reagents containing the *n*-amyl radical and, particularly, the  $\beta$ -methylbutyl radical has been rare. Those of the former type have been used by Henry and de Wael (*Rec. trav. chim.*, 1909, **28**, 446), by Pexters (*Bull. Acad. roy. Belg.*, 1906, 796), by Grüttner and Krause (*Ber.*, 1916, **49**, 2666), by Davies, Pearse, and Jones (*J.*, 1929, 1265), and by Dyke, Davies, and Jones (preceding paper); and the Grignard reagent of *dl*- $\beta$ -methylbutyl bromide was used for the first time by Davies, Pearse, and Jones, and later by Dyke, Davies, and Jones, whilst Klages and Sautter (*Ber.*, 1904, **37**, 653) used that prepared from optically active amyl iodide.

The products of the reactions of certain aldehydes and ketones with magnesium *n*-amyl and *dl*- $\beta$ -methylbutyl bromides are now described. In these preparations several types of reaction were encountered, although the conditions were so chosen that the addition reaction yielding carbinol should predominate.

In all cases the decanes were produced as by-products. Under the conditions existing in the present experiments the extent of this synthetic action of metallic magnesium on the amyl bromides was such as to yield about 24 c.c. of decane per 24.3 g. of magnesium. The decane was isolated from the fraction, b. p. 70–100°/50 mm., of the product by shaking with concentrated sulphuric acid, washing with water, drying over sodium, and distillation. In this way were obtained *n*-decane, b. p. 169°/760 mm., and *dl*- $\gamma$ -dimethyloctane, b. p. 79°/50 mm., 159°/760 mm.;  $d_{20}^{25}$  0.7307;  $n_D^{20}$  1.4106;  $[R_L]_D$  48.33 (Calc., 48.38) (Found: C, 84.6; H, 15.3. Calc. for  $C_{10}H_{22}$ : C, 84.5; H, 15.5%) (compare Dupont, *Ann. Chim.*, 1913, **30**, 516).

Enolisation of the reacting ketone by the Grignard compound occurred extensively between acetophenone and magnesium *dl*- $\beta$ -methylbutyl bromide. For instance, purified acetophenone in 52% yield was recovered from the product of reaction, with only 14% yield of the purified tertiary alcohol. In striking contrast thereto was the behaviour of magnesium *n*-amyl bromide with acetophenone, where a 30% yield of purified alcohol was obtained, but no acetophenone was recovered. These results are consonant with the views of Conant and Blatt (*J. Amer. Chem. Soc.*, 1929, **51**, 1236) that the

occurrence of subsidiary reactions, such as enolisation, can be correlated with branching of the alkyl groups involved.

In no case in the present work was reduction met with, but condensation appeared to have occurred in the interaction between methyl *n*-nonyl ketone and magnesium *dl*- $\beta$ -methylbutyl bromide, since an appreciable amount of a substance having a higher b. p. than the carbinol was obtained.

In several cases, details of which are given in the experimental portion, the yield of carbinol was low owing to loss of the elements of water and formation of unsaturated hydrocarbon during the reaction and isolation; and in every case the dehydration was readily effected even on treatment with mild agents.

The preparation of esters of the amylcarbinols, particularly those which contain other higher radicals, is often attended by difficulties. For instance, the acetic ester of *phenylmethyl*-( $\beta$ -methylbutyl)-carbinol was obtained in poor yield, but on being distilled even under reduced pressure it continuously decomposed. Again, in an attempt to prepare the bromide of this carbinol,  $\beta$ -phenyl- $\delta$ -methyl- $\Delta^8$ -hexylene was obtained in good yield. In a similar attempt with *phenyl*-( $\beta$ -methylbutyl)carbinol, the bromide obtained readily parted with hydrogen bromide, yielding *dl*- $\alpha$ -phenyl- $\gamma$ -methyl- $\Delta^4$ -amylene (dibromo-compound, m. p. about 75°), the optically active form of which has been described by Klages and Sautter (*loc. cit.*). In a preparation of the oxalic ester of phenyl-*n*-amylcarbinol, by heating the latter with the anhydrous acid, a considerable amount of unsaturated hydrocarbon was formed, and on distillation the residual oxalate broke down.

The amylcarbinols prepared in the present investigation gave methane with an amyl-ethereal solution of magnesium methyl iodide.

#### EXPERIMENTAL.

*Preparation of Carbinols.*—The aldehyde or ketone in ethereal solution was dropped into the filtered Grignard solution, which was kept at 10°. Equivalent weights of the reactants were used. After the addition was complete the mixture was gently boiled for  $\frac{1}{2}$  hour, poured on ice, and treated with sufficient mineral acid to dissolve the precipitated magnesium salts. The ethereal layer was washed with sodium bicarbonate solution, with the addition, where necessary, of sodium bisulphite solution. The dried ethereal solution was fractionally distilled under 50 mm. pressure. The carbinol fraction was redistilled.

*Preparation of Ketones.*—20 C.c. of the secondary alcohol were gradually added with shaking and cooling to 100 c.c. of a saturated solution of potassium dichromate in 20% aqueous sulphuric acid.

The mixture was then mechanically shaken for 5 hours. The resulting ketone was extracted with ether, isolated by fractional distillation, redistilled, and purified by freezing where possible.

All thermometer readings given have been corrected.

*Phenyl-n-amylcarbinol* was prepared by the addition of 106 g. of benzaldehyde in 100 c.c. of ether to a Grignard solution made from 151 g. of *n*-amyl bromide, 24.3 g. of magnesium, and 500 c.c. of ether. The alcoholic fraction distilled at 167–171°/50 mm., and on redistillation yielded 64 g. of pure alcohol, a thick liquid, b. p. 170°/50 mm.;  $d_4^{25}$  0.9477;  $n_D^{25}$  1.5042;  $[R_L]_D^{25}$  55.65 (Calc. for  $C_{12}H_{18}O$ , 3 $\bar{5}$ , 55.54);  $n_F^{25} - n_C^{25}$  0.0136 (Calc., 0.0122) (Found: C, 81.1; H, 9.9.  $C_{12}H_{18}O$  requires C, 80.9; H, 10.1%). Phenyl *n*-amyl ketone, m. p. 27° (semicarbazone, m. p. 132°) (compare Schroeter, *Ber.*, 1907, 40, 1603), was obtained on oxidation of the alcohol.

From the products of the interaction between anisaldehyde and magnesium *n*-amyl bromide there was obtained a considerable amount of anisaldehyde, identified by b. p., 164°/50 mm. (literature gives 166°/50 mm.), and by conversion into anisic acid, m. p. 184°. The first fractional distillation of the product also gave *p*-methoxyphenyl-*n*-amylcarbinol, b. p. 207–210°/50 mm. On being redistilled at low pressures this carbinol partly decomposed with elimination of water, a behaviour similar to that observed by Stedman and Stedman (*J.*, 1929, 614) in the case of the corresponding methyl carbinol. On this account the carbinol distillate was saturated with hydrogen chloride and then boiled with excess of pyridine, whereby, after treatment with water, there was obtained  $\alpha$ -*p*-methoxyphenyl- $\Delta^2$ -hexylene, b. p. 187–188°/50 mm.;  $d_4^{25}$  0.9594;  $n_D^{25}$  1.5356;  $[R_L]_D^{25}$  61.77 (Calc. for  $C_{13}H_{18}O$ , 4 $\bar{4}$ , 59.81);  $n_F^{25} - n_C^{25}$  0.0213 (Calc., 0.0134) (Found: C, 81.4; H, 9.7.  $C_{13}H_{18}O$  requires C, 82.0; H, 9.5%). This compound readily adds on bromine.

*Methylethyl-n-amylcarbinol* was prepared by adding 72 g. of methyl ethyl ketone in 75 c.c. of ether to the Grignard reagent formed by 151 g. of *n*-amyl bromide, 24.3 g. of magnesium, and 500 c.c. of ether. The alcoholic fraction after several redistillations yielded 35 g. of the purified carbinol, b. p. 97.5°/50 mm.;  $d_4^{25}$  0.8108;  $n_D^{25}$  1.4257;  $[R_L]_D^{25}$  45.52 (Calc., 45.29);  $n_F^{25} - n_C^{25}$  0.0077 (Calc., 0.0074) (Found: C, 75.5; H, 13.8.  $C_9H_{20}O$  requires C, 74.9; H, 14.0%). The carbinol is a mobile liquid, possessing a characteristic, slightly peppermint-like, smell.

*Methyl-n-amyl-n-nonylcarbinol* was obtained from the product of the interaction between 170 g. of methyl *n*-nonyl ketone, dissolved in 100 c.c. of ether, and magnesium *n*-amyl bromide prepared from the equivalent of the amyl bromide. The ketone was obtained by washing oil of rue successively with 20% sulphuric acid, 5% sodium

carbonate, and 5% sodium hydroxide solutions, and fractionally distilling it under reduced pressure, and was finally purified by repeated freezing (Sanderson and Jones, *J. Soc. Chem. Ind.*, 1923, 42, 1). The interaction between the ketone and the Grignard reagent was not vigorous, and, for that reason, the mixture was kept for 12 hours. The usual separation of the magnesium salt-complex was not observed in this case, but the treatment with crushed ice and mineral acid was continued as in the other preparations. The ether having been expelled, the product was repeatedly fractionally distilled under 50 mm. pressure, whereby there were obtained the following main fractions: (1) up to 115°, decane, which on treatment with concentrated sulphuric acid gave 20 c.c. of the hydrocarbon; (2) 143—147°, methyl *n*-nonyl ketone, 50 c.c., identified by its semicarbazone, m. p. 123°; (3) 199—200°, methyl-*n*-amyl-*n*-nonylcarbinol, 80 c.c.;  $d_4^{25}$  0.8316,  $n_D^{25}$  1.4446,  $[R_L]_D$  77.50 (Calc., 77.61),  $n_F^{25} - n_C^{25}$  0.0079 (Calc., 0.0079) (Found: C, 79.7; H, 14.2.  $C_{16}H_{34}O$  requires C, 79.3; H, 14.2%). The large amount of recovered ketone suggests enolisation. It is noteworthy that the only previous application of the Grignard reagent to this ketone was in the preparation of dimethyl-*n*-nonylcarbinol (Houben, *Ber.*, 1902, 35, 3591).

*Phenylmethyl-n-amylcarbinol* has b. p. 169°/50 mm.;  $d_4^{25}$  0.9389;  $n_D^{25}$  1.5028;  $[R_L]_D$  60.47 (Calc. for  $C_{13}H_{20}O, 3$ , 60.16);  $n_F^{25} - n_C^{25}$  0.0131 (Calc., 0.0119) (Found: C, 80.5; H, 9.8.  $C_{13}H_{20}O$  requires C, 81.2; H, 10.5%). It was prepared by the interaction of 120 g. of acetophenone with the magnesium *n*-amyl bromide made from 151 g. of the bromide and 24.3 g. of magnesium. The crude carbinol fraction contained unsaturated hydrocarbon, from which the carbinol was purified by redistillation; yield, 58 g.

Methyl  $\beta$ -methylbutyl ketone has been prepared by Kohler (*Amer. Chem. J.*, 1907, 38, 527) from ethylideneacetone and magnesium ethyl bromide, and by Clarke (*J. Amer. Chem. Soc.*, 1908, 30, 1150) by the hydrolysis of ethyl *sec*-butylacetoacetate. We have now prepared it by treatment of the carbinol fraction, 68—73°/50 mm., obtained from the interaction between acetaldehyde and magnesium *dl*- $\beta$ -methylbutyl bromide, with a saturated solution of potassium dichromate in 20% sulphuric acid. The ketone was purified through its semicarbazone, 62 c.c. of the crude material being mechanically stirred on the water-bath for 2 hours with 38 g. of semicarbazide hydrochloride, 47 g. of sodium acetate trihydrate, 12 c.c. of ethyl alcohol, and 140 c.c. of water. The solid semicarbazone was recrystallised from aqueous alcohol, and gave 27 g. of pure product.

*Methyl  $\beta$ -methylbutyl ketone semicarbazone*, m. p. 120—121°

(Found: N, 24.2.  $C_8H_{17}ON_3$  requires N, 24.5%), was converted by 1 hour's boiling with 15% hydrochloric acid into the ketone, b. p.  $68^\circ/50$  mm.,  $69.5^\circ/57$  mm.;  $d_4^{25}$  0.8085;  $n_D^{25}$  1.4050;  $[R_L]_D$  34.56 (Calc., 34.54);  $n_F^{25} - n_C^{25}$  0.0073 (Calc., 0.0074) (Found: C, 74.0; H, 12.5. Calc. for  $C_7H_{14}O$ : C, 73.7; H, 12.4%).

Klages and Sautter (*loc. cit.*) state that the product of interaction between benzaldehyde and the magnesium derivative of active amyl iodide consists chiefly of active hexenylbenzene, together with some of the carbinol, which they did not isolate. In the present experiments, however, no difficulty was experienced in isolating the inactive carbinol in pure condition and fair yield. Moreover, no elimination of water from the carbinol during reduced-pressure distillation was noticed (contrast Klages and Sautter, *loc. cit.*). *Phenyl-( $\beta$ -methylbutyl)carbinol* (yield, 40 g.), obtained by the addition of 106 g. of benzaldehyde to magnesium *dl*- $\beta$ -methylbutyl bromide prepared from 151 g. of the *dl*-amyl bromide, has b. p.  $163^\circ/50$  mm.;  $d_4^{25}$  0.9523;  $n_D^{25}$  1.5059;  $[R_L]_D$  55.51 (Calc. for  $C_{12}H_{18}O, 3$ ], 55.54);  $n_F^{25} - n_C^{25}$  0.0143 (Calc., 0.0123) (Found: C, 81.0; H, 10.0; OH, 8.3.  $C_{12}H_{18}O$  requires C, 80.9; H, 10.1; OH, 9.5%). On dehydration the carbinol yielded unsaturated hydrocarbon. *Phenyl  $\beta$ -methylbutyl ketone* (Found: C, 81.4; H, 9.0.  $C_{12}H_{16}O$  requires C, 81.8; H, 9.1%) boils at  $163^\circ/50$  mm.;  $d_4^{25}$  0.9640;  $n_D^{25}$  1.5093;  $[R_L]_D$  54.49 (Calc. for  $C_{12}H_{16}O, 3$ ], 54.03);  $n_F^{25} - n_C^{25}$  0.0156 (Calc., 0.0127). The *semicarbazone* (Found: N, 18.3.  $C_{13}H_{19}ON_3$  requires N, 18.0%), m. p.  $160^\circ$ , separates as rods from alcohol.

In an attempt to prepare *p*-methoxyphenyl  $\beta$ -methylbutyl ketone, by oxidising the product obtained from the interaction of magnesium *dl*- $\beta$ -methylbutyl bromide with anisaldehyde, considerable amounts of anisaldehyde and anisic acid were obtained, but no ketone.

*Methylethyl-( $\beta$ -methylbutyl)carbinol*, b. p.  $95-97^\circ/50$  mm.;  $d_4^{25}$  0.8177;  $n_D^{25}$  1.4251;  $[R_L]_D$  45.10 (Calc., 45.29);  $n_F^{25} - n_C^{25}$  0.0076 (Calc., 0.0075) (Found: C, 74.6; H, 13.9.  $C_9H_{20}O$  requires C, 74.9; H, 14.0%), results (in 25 g. yield) from the interaction of 72 g. of methyl ethyl ketone in 100 c.c. of ether with magnesium *dl*- $\beta$ -methylbutyl bromide made from 151 g. of the bromide and 24.3 g. of magnesium. The smell of the carbinol resembles that of the corresponding *n*-amyl carbinol, but is more penetrating.

*Methyl-( $\beta$ -methylbutyl)-*n*-nonylcarbinol* was prepared by treating 170 g. of methyl *n*-nonyl ketone in 100 c.c. of ether with magnesium *dl*- $\beta$ -methylbutyl bromide prepared from the equivalent of the alkyl bromide, and keeping the reaction mixture for 12 hours. Here also, as in the preparation of methyl-*n*-amyl-*n*-nonylcarbinol,

there was no separation of the magnesium salt-complex. After treatment with mineral acid and removal of ether, the resulting oil was repeatedly fractionally distilled at 50 mm. Methyl *n*-nonyl ketone (90 c.c., identified by b. p. and semicarbazone) was recovered. The carbinol fraction (32 c.c.; b. p. 194–202°) was twice redistilled, but yet was not satisfactorily purified. The fraction of b. p. 198–200°/50 mm. (Found: C, 77.4; H, 13.8.  $C_{16}H_{34}O$  requires C, 79.3; H, 14.2%) has  $d_4^{25}$  0.8301;  $n_D^{25}$  1.4438;  $[R_L]_D$  77.50 (Calc., 77.61). The residue, 27 c.c., left after distillation of the carbinol fraction, on being redistilled yielded 11 c.c. of liquid, b. p. 255–265°/50 mm. This substance appears to be  $CH_3 \cdot C(C_5H_{11})(C_9H_{19}) \cdot O \cdot C_5H_{11}$  (Found: C, 81.9; H, 13.7; *M*, 295.  $C_{21}H_{44}O$  requires C, 80.7; H, 14.2%; *M*, 312);  $d_4^{25}$  0.8433;  $n_D^{25}$  1.4582;  $[R_L]_D$  103.5 (Calc., 100.8).

Enolisation was encountered in the interaction between equivalents of acetophenone (120 g.) and magnesium *dl*-β-methylbutyl bromide. Fractionation of the crude product gave (1), b. p. 105–140°/50 mm., 72 g., which on redistillation yielded 62 g. of acetophenone, b. p. 115°/50 mm. (Found: C, 80.1; H, 7.0. Calc.: C, 80.0; H, 6.7%), and (2), b. p. 140–170°/50 mm., 48 g., which on redistillation yielded 27 g. of *phenylmethyl*-(β-methylbutyl)carbinol, b. p. 163.5°/50 mm.;  $d_4^{25}$  0.9388;  $n_D^{25}$  1.5027;  $[R_L]_D$  60.47 (Calc. for  $C_{13}H_{20}O, 3\frac{1}{2}$ , 60.16);  $n_D^{25} - n_D^{20}$  0.0137 (Calc., 0.0119) (Found: C, 81.1; H, 10.2; OH, 8.6.  $C_{13}H_{20}O$  requires C, 81.2; H, 10.5; OH, 8.8%). On dehydration, the carbinol yielded β-phenyl-δ-methyl-Δ<sup>β</sup>-hexylene, b. p. 142°/50 mm.;  $d_4^{25}$  0.8839;  $n_D^{25}$  1.5117;  $[R_L]_D$  59.10 (Calc. for  $C_{13}H_{18}, 4\frac{1}{2}$ , 58.16);  $n_D^{25} - n_D^{20}$  0.0167 (Calc., 0.0132) (Found: C, 89.4; H, 10.3.  $C_{13}H_{18}$  requires C, 89.6; H, 10.4%).

## LXV.—The Reduction of Triphenylhalogenomethanes.

By JAMES CLIFFORD THOMAS, SYDNEY THOMAS BOWDEN, and  
WILLIAM JACOB JONES.

THE utility of certain heavy metals for the reduction of triphenylhalogenomethanes has been demonstrated in the classical investigations of Gomberg (*Ber.*, 1900, **33**, 310) on the preparation of the free radical, triphenylmethyl, and in subsequent work (*Chem. Reviews*, 1924, **1**, 99) on various triarylmethyls. In the case of triphenylchloromethane in benzene solution it was shown that the halogen is quantitatively removed by zinc, and that the reduction is also effected by mercury and silver. Copper, in the form of

Naturkupfer-C, has been employed by Schlenk (*Annalen*, 1909, **372**, 17) for the same purpose, but in this instance the application of heat is usually necessary for the completion of the reaction. The investigation of the action of magnesium on triphenylchloromethane in ethereal solution by Schmidlin (*Ber.*, 1906, **39**, 4183) led to the elaboration of a method for the preparation of triphenylmethyl through the interaction of magnesium triphenylmethyl chloride with triphenylchloromethane (*Ber.*, 1908, **41**, 423).

More recently, Kraus and Kawamura (*J. Amer. Chem. Soc.*, 1923, **45**, 2756) have studied the action of sodium and potassium upon triphenylchloromethane in liquid ammonia, and have found that the primary reduction is followed by the combination of free radical with alkali metal to give the corresponding triphenylmethide. The colour which is produced when liquid ammonia solutions of triphenylmethyl are treated with metallic calcium led these authors to infer the existence of calcium triphenylmethide.

It was observed by Schlenk and Marcus (*Ber.*, 1914, **47**, 1678) that triphenylmethyl in ethereal solution on treatment with sodium is converted into *p*-benzhydryltetraphenylmethane. Sodium triphenylmethide, however, is obtained when an ethereal solution of triphenylchloromethane is treated with sodium amalgam. Grosse (*Ber.*, 1926, **59**, 2652) has shown that lithium, rubidium, and caesium triphenylmethides may be obtained by agitating the aryl chloride in ethereal solution with the corresponding amalgam.

In view of the comparative ease with which triphenyl-chloro- and -bromo-methanes undergo reduction by the heavy metals, it is of interest to note that Blicke (*J. Amer. Chem. Soc.*, 1924, **46**, 1515) was not able to reduce triphenylfluoromethane by means of silver.

No systematic survey of the action of other metals on triphenyl-chloro- and -bromo-methanes has hitherto been undertaken, and we have accordingly carried out a preliminary investigation of the action of a series of representative elements.

The influence of the solvent upon the reaction between triphenyl-halogenomethanes and metals is very marked, and is to be referred primarily to two factors. The first is largely a physical influence, and in view of the heterogeneity of the reaction system, it follows that in those cases where an "active" metallic surface is maintained, as a result of the solution or disintegration of the metallic halide formed on the surface of the metal, an increase will be evident in the rate and extent of reduction. The second is the purely chemical influence, in which the constitutional effect of the solvent is evident in modifying the molecular state of the aryl halide in solution, and in further determining the character of the interfacial phenomena which obtain at the metal-solution interface. These factors are

brought into special prominence in the present investigation by a comparison of the behaviour of acetone and of benzene with that of *n*-hexane. Reduction of triphenylchloromethane in *n*-hexane is effected by only few metals; even with mercury and silver, reaction proceeds much more slowly than in benzene.

Cadmium, thallium, lead, tin, arsenic, antimony, bismuth, selenium, tellurium, and iron were found to react with triphenylchloro- and -bromo-methanes in benzene, toluene, and ethereal solution. The rate of reaction differs considerably in the various cases, the most reactive metal being iron and the least reactive lead. The reduction of triphenylchloromethane by cadmium takes place considerably more slowly than by zinc. Triphenylchloromethane in benzene, toluene, bromobenzene, hexane, or ether is not attacked by cobalt or nickel, and only to a slight extent by manganese and chromium.

In several cases the direct reduction is followed by secondary reactions, which may involve (a) combination of metallic halide with unchanged aryl halide, (b) interaction of the liberated free radical with the metallic halide, (c) combination of the free radical with unchanged element, and (d) interaction of the metallic halide with the solvent. Triphenylbromomethane is rapidly reduced by zinc and tin, the initial reaction being followed by the combination of the metallic bromide with unchanged aryl bromide to give highly coloured addition compounds. The addition of finely divided iron to a benzene solution of triphenylchloromethane immediately produces a yellow coloration, which rapidly increases in intensity until the final colour is greenish-yellow. This solution does not contain free triphenylmethyl, and no triphenylmethyl peroxide is obtained by the prolonged action of oxygen. The evidence would seem to indicate the existence in solution of a stable triphenylmethyl-ferrous chloride complex.

Aluminium, as pure powder, appears to have no action on benzene solutions of triphenylchloromethane at the ordinary temperature, but reaction occurs fairly rapidly with the turnings of the commercial metal. In this reaction, the primary reduction is followed by the formation of an addition compound with aluminium chloride. When, however, the reaction is carried out in acetone, interaction occurs between the aluminium chloride and the solvent, and in some cases the solution sets to a gel in the course of a few days.

The behaviour of cobalt, manganese, and chromium towards triphenylchloromethane in acetone is remarkable, inasmuch as rapid and complete reduction to triphenylmethyl takes place. This reactivity is in direct contrast to the behaviour of these metals towards solutions of the substance in benzene, toluene, bromobenzene,

ether, and hexane. In this connexion, it may be mentioned that tritolylchloromethane in acetone solution has been shown by Norris (*Amer. Chem. J.*, 1907, **38**, 627) to conduct the electric current. In like manner, we find that triphenylchloromethane exhibits a marked conductivity in this solvent, but that in the fused state it is not a conductor.

In several cases anomalous results were obtained with acetone solutions of triphenyl-chloro- and -bromo-methanes, and we have ascertained that this is due to a reaction other than that between metal and the aryl halide. Even at the ordinary temperature, triphenylbromomethane interacts slowly with the enolic form of acetone, the solution assuming a dark brownish colour in the course of a few days. This reaction will be the subject of a further communication.

Both calcium and nickel are entirely non-reactive towards the triphenylhalogenomethanes in all the solvents examined (except possibly acetone), and magnesium is also extremely lethargic except with ethereal solutions. In the latter case, magnesium triphenylmethyl chloride is formed on prolonged agitation at the ordinary temperature and in the absence of external catalyst.

#### EXPERIMENTAL.

In order to avoid the complicating influences of atmospheric oxidation, all the experiments were conducted in the entire absence of air. In general, therefore, the reactions were carried out at the ordinary temperature in sealed tubes. Excess of the element was placed in a suitably constricted tube, and after all the air had been displaced by pure dry carbon dioxide, the tube was almost completely filled with a standard solution of the triphenylhalogenomethane. A small amount of the pure solvent was added in order to remove the film of solution from the constriction, and the tube was then sealed under carbon dioxide. The tubes, together with standard comparison tubes containing silver or mercury, were placed in a shaking machine, and their contents agitated in the dark for specified periods and then examined. Triphenylmethyl was recognised by its characteristic colour, and by its conversion into triphenylmethyl peroxide under the influence of oxygen or into diphenylbisdiphenylene-ethane on irradiation.

In many cases it was necessary to conduct the experiments on a larger scale, and for this purpose the triphenyl-chloro- or -bromo-methane solution and the finely powdered element were placed in a flask, which could be charged with carbon dioxide. After the contents had been agitated for the stipulated period, the solution was drawn under carbon dioxide through a suitable filter into a

partly evacuated vessel, where its nature was examined. The following experiment is representative of the methods employed.

Triphenylchloromethane (5 g.) in acetone (50 c.c.) was agitated under carbon dioxide with excess of metallic cobalt for 3 hours. The resulting greenish-blue solution was filtered in an atmosphere of carbon dioxide, and the filtrate divided into two parts. Air was passed through the first portion, whereupon the solution assumed a blue colour with simultaneous precipitation of finely crystalline triphenylmethyl peroxide, m. p.  $183^{\circ}$ ; yield 60%. The second portion of the filtrate was exposed in a sealed tube to direct sunlight. Photochemical decomposition proceeded more rapidly than with the ordinary yellow solutions of triphenylmethyl in benzene (Bowden and Jones, J., 1928, 1150); the solution became blue, and diphenyl-bisdiphenylene-ethane, m. p. (in a vacuum)  $248-250^{\circ}$ , was precipitated. The presence of cobaltous chloride in the above solutions was demonstrated by the usual tests.

*Interaction of Triphenylbromomethane with Acetone.*—Pure recrystallised triphenylbromomethane (10 g.) was dissolved in dry, acid-free acetone (245 c.c.) in a flask which was then sealed and kept in the dark at the ordinary temperature. The freshly prepared solution was colourless, but after standing for 3 or 4 days, it was brownish-yellow, which changed to a deep dark brown after 12 weeks. At the end of this period the solution was divided into two portions, solution A (205 c.c.) and solution B (40 c.c.), which were examined in the following manner.

*Solution A.* This portion was subjected to careful fractionation through a long Vigreux column, the receiving flask being cooled in a freezing mixture in order to ensure the retention of low-boiling products. Examination of the first portions of the distillate showed the absence of hydrogen bromide and of  $\beta$ -bromopropylene, b. p.  $48^{\circ}$ . After removal of the bulk of acetone, the residual liquid (40 c.c.) was placed in a tightly-stoppered flask and cooled in ice. After some hours, impure triphenylcarbinol (1.2 g.) was deposited. The filtrate was agitated under nitrogen with excess of metallic silver for several hours, after which the solution was filtered in an atmosphere of nitrogen. Dry air was passed through the filtrate in order to effect the complete oxidation of triphenylmethyl formed by the reduction of unchanged triphenylbromomethane. In this manner, crude triphenylmethyl peroxide (0.22 g.), m. p.  $175-178^{\circ}$ , was obtained.

*Solution B.* This solution was agitated under nitrogen with excess of silver for several hours, filtered in a stream of nitrogen, and the clear filtrate oxidised by means of a current of air. The precipitated peroxide (0.18 g.) was practically white; m. p.  $182-183^{\circ}$ .

Preliminary experiments showed that the yield of peroxide obtainable from freshly prepared solutions of triphenylbromomethane was 65%. On this basis, the above results show that 79.2% of the triphenylbromomethane interacted with acetone at the ordinary temperature.

*Addition Compounds of Triphenylbromomethane.*—The following addition compounds of triphenylbromomethane with metallic bromides were prepared during the course of the investigation.

*With aluminium bromide.* Anhydrous aluminium bromide, dissolved in carbon disulphide, was added to a slight excess of triphenylbromomethane in benzene solution. The dark red oil, which separated immediately, was washed rapidly with benzene, and finally with carbon disulphide. After being preserved for some hours in a vacuum, it crystallised in cubes, m. p. 120—123° [Found: C, 37.9; H, 2.6; Br, 53.5; Al, 4.4.  $(C_6H_5)_3CBr, AlBr_3$  requires C, 38.6; H, 2.5; Br, 54.2; Al, 4.6%].

*With zinc bromide.* This compound was precipitated by mixing benzene solutions of triphenylbromomethane and zinc bromide. The dark red oil could not be induced to crystallise [Found: C, 41.0; H, 3.1; Br, 42.9; Zn, 11.6.  $(C_6H_5)_3CBr, ZnBr_2$  requires C, 41.6; H, 2.8; Br, 43.7; Zn, 11.9%].

*With stannic bromide.* This compound, prepared as in the preceding case, was obtained in the crystalline condition, m. p. 171°, after treatment with hexane [Found: C, 29.1; H, 2.1; Br, 52.3; Sn, 15.1.  $(C_6H_5)_3CBr, SnBr_4$  requires C, 29.9; H, 2.0; Br, 52.5; Sn, 15.6%].

## LXVI.—*The Passivity of Metals. Part IV. The Influence of Acids in Passivity and Corrosion.*

By ULICK R. EVANS.

In general, acids dispel passivity and accelerate the corrosion of iron. Occasionally, however, passivity is obtained with acid media, and it has been argued that in such cases the passivity cannot be due to oxide films, which would—it is urged—be dissolved by the acid. One important case, the action of concentrated nitric acid, has been elucidated by Hedges (J., 1928, 969), who finds that, under the conditions where passivity arises, nitric acid has no appreciable solvent power for ferric oxide, which is therefore regarded as the cause of the passivity. Lately Benedicks and Sederholm (*Z. physikal. Chem.*, 1928, 138, 123) have advanced direct evidence that the passivity produced by nitric acid diluted with

alcohol and water is also due to a protective film; here it is considered that the film is ferrous oxide in the inner portions, and hydrated ferric oxide ( $\text{FeO}\cdot\text{OH}$ ) in the outer portions. This seems much more likely than the contention of Fujihara (*Ind. Eng. Chem.*, 1926, 18, 62), that the passivity produced by alcoholic nitric acid is due solely to ferrous hydroxide, which is supposed to cause passivity by maintaining an alkaline reaction; treatment with nitric acid would scarcely leave an alkaline reaction, whilst in any case ferrous hydroxide is unlikely to escape dissolution or further oxidation in such a medium. There seems no reason to doubt that the passivity is due to an oxide film which—at least on the outside—is in the ferric condition.

Two other cases remain to be explained, *viz.*, the passivity produced (1) by immersion in chromic acid and (2) by anodic treatment in dilute sulphuric acid.

*Action of Chromic Acid on Iron.*—There seems to be little information available as to the oxide-solvent powers of chromic acid, or the exact conditions under which it produces passivity. Dunstan, Jowett, and Goulding (J., 1905, 87, 1571) have kept iron bright in chromic acid solution for ten years; but Moody (P., 1903, 19, 158) states that there is a slow dissolution, whilst van Name and Hill (*Amer. J. Sci.*, 1916, 42, 301) have found that mixtures of chromic and sulphuric acids (the latter in excess) cause rapid corrosion. Many samples of "chromic acid" contain sulphuric acid, and it was decided to conduct some new experiments with Kahlbaum's "Chromic Acid, free from Sulphuric Acid." For analyses of the specimens of metal employed, see J., 1929, 93.

It was found that *M*/10-chromic acid did not evolve carbon dioxide from sodium or ammonium carbonate, and failed to dissolve freshly precipitated ferric hydroxide, even on standing over it for several days. The solution had no effect on the colours of heat-tinted iron, even after 24 hours, although *M*/10-sulphuric acid produces an appreciable alteration in a few seconds. Apparently, therefore, chromic acid does not dissolve flaky ferric oxide.

Strips of iron H 28, 2 cm. wide, were abraded with French emery No. 1, degreased, and immersed vertically to a depth of 3.5 cm. in 90 c.c. of chromic acid-sulphuric acid mixtures for 6 hours at 14.0°. The mixtures acted rapidly on the metal, producing ferric and chromic sulphates, and the layer of largely exhausted solution, which had an enhanced specific gravity, sank rapidly down the vertical surface, fresh solution being drawn in at the top. Owing to the partial exhaustion, the numbers given in Table I do not indicate the velocity coefficient, but they show very clearly that (a) at constant concentration of sulphuric acid, chromic acid increases the

attack, evidently acting as a depolariser, since no hydrogen appears when it is present, and (b) at constant concentration of chromic acid, sulphuric acid increases the attack; in the absence of sulphuric acid, chromic acid produced no visible change, but the small loss of weight measured was confirmed by experiments with chromic acid from another source.

TABLE I.

	H <sub>2</sub> SO <sub>4</sub> (mol./l.).	CrO <sub>3</sub> (mol./l.).	Loss of weight, mg.	Mean, mg.

Another series of experiments conducted for 20 hours led to the same conclusions. It was found that immersion in *M*/10-chromic acid for 6 hours rendered the iron passive towards *M*/20-copper nitrate, but not towards copper sulphate, although the latter reagent deposited copper less readily than on the iron merely exposed to air. This was best shown by placing drops of copper sulphate in such a position that only half the drop lay on the area which had been immersed in chromic acid. Copper appeared quickly on the half previously exposed to air, and only slowly on the other half, the line of demarcation being very sharp.

Since chromic acid has powerful oxidising but weak base-dissolving properties, it is easy to understand why it enhances corrosion in the presence of a stronger acid, but produces a protective oxide film when acting alone; the case is completely analogous to that of concentrated nitric acid.

*Passivity produced by Anodic Treatment in Dilute Sulphuric Acid.*—Tronstad (*Z. physikal. Chem.*, 1929, **142**, 272) has proved optically that an oxide film exists on a nickel anode rendered passive in acid solution, but W. J. Müller (*Z. Elektrochem.*, 1928, **34**, 583; *Monatsh.*, 1929, **52**, 463, 474), whilst agreeing that oxide films play an essential part in many types of passivity, considers that iron oxide could not survive in an acid solution, and cannot therefore be the cause of the passivity of an iron anode. This objection has now been examined experimentally.

The fact that sulphuric acid destroys the first-order temper-colours seems to justify the idea that ferric oxide in the form of films is soluble in the acid; the thinning or removal of the films is easily recognisable at *M*/500-concentration after 1 minute's immersion, and becomes very rapid at greater concentrations. *M*/10-

Sulphuric acid, besides rapidly destroying the thin oxide films, also attacks the metal, and the thicker films (above second-order thickness) peel off in flakes, before they are completely destroyed. Now, *when these oxide flakes pass out of electrical contact with the metallic basis, the solvent action practically ceases*; flakes have been preserved in  $M/10$ -acid for long periods without serious change; in one case, they retained their characteristic flake form after standing for 18 days in the acid, although becoming eaten through in places. This suggests that the rapid destruction of the films when in contact with the metal is simply due to the formation, at the various cracks in the film, of the short-circuited cell metal|acid|ferric oxide. The ferric oxide, being the cathode, is rapidly reduced to ferrous oxide, which at once dissolves. Actually, cathodic reduction, conducted with an external source of *E.M.F.*, was employed in earlier work (*Proc. Roy. Soc.*, 1925, *A*, 107, 228) to bring about the uniform thinning of the films.

If this is the true explanation, it should be possible, by using an oxidising agent, to prevent reduction, and thus retard the destruction of the films. A strip of iron, heated at one side so as to give the complete sequence of tints, was partly immersed in a solution containing sulphuric ( $M/100$ ) and chromic acid ( $M/10$ ). After 24 hours, there was not the smallest alteration of any colour. Yet  $M/100$ -sulphuric acid, free from chromic acid, causes appreciable change in 5 seconds, and complete destruction of the earlier colours in 1 minute. Experiments with more concentrated sulphuric acid were complicated by the attack on the metallic basis, but here also the life of the colours was greatly prolonged by the presence of chromic acid.

The rational way to prevent cathodic reduction is to submit the specimen, as a whole, to anodic treatment. A series of experiments was performed in which the anode and cathode were vertical strips 2.0 cm. broad, clamped 3.8 cm. apart, and immersed for a depth of 2.0 cm. The cathode was a plain piece of iron, but the anode, after being ground with French emery No. 1 and degreased, was usually given an appropriate oxidising treatment before the experiment. The liquid was  $M/10$ -sulphuric acid and the *E.M.F.* was 4.0 volts. Except where otherwise stated, the electrodes were connected to the battery *before* introduction into the liquid, so that current commenced to flow from the moment of immersion—a plan previously adopted by Hedges (*J.*, 1926, 2879). The current forced through the cell varied somewhat with the time and pre-treatment, but it always rose to about double its previous value when the iron passed from the passive state into the fully active state. Where the back of the anode was protected by nitrocellulose,

the current was usually about 0.12 amp. (passive) and 0.24 amp. (active).

When the iron anode had been tinted by heating in air on a lead-tin bath, oxygen was evolved from the moment of introduction, and the anode suffered no corrosion and no change of colour. A short interruption of current (a fraction of a second, and sometimes several seconds) did not dispel passivity; in these cases evolution of oxygen recommenced when the circuit was restored, the anode remaining unattacked. But a longer interruption destroyed passivity, and when the circuit was restored, the current jumped to the higher value, the iron began to dissolve, and no further oxygen was produced. With comparatively thick (second-order) films, an interruption of, say, 15 seconds did not destroy the film entirely, but it allowed attack on the iron to commence at certain points, and a series of such interruptions, with intervening periods during which current was allowed to flow, produced complete undermining of the film, which peeled off in characteristic curling flakes; once out of contact with the metal, the oxide film could be kept in the acid for hours without damage. Thinner (first-order) films were completely destroyed by an interruption of a duration which would only cause undermining of the thicker films; the colour vanished, revealing unchanged iron below, and on restoration of the circuit, the iron became etched without any signs of peeling. On the other hand, in experiments when the circuit was restored at the moment when the film had been destroyed at some points, but not everywhere, the thin film peeled off from the parts where it survived; it could then be washed free from acid, and preserved indefinitely.

Although useless for quantitative purposes, this proved a convenient way of preparing oxide films (especially the thicker films) in a state free from secondary hydroxide. The films showed the same behaviour to reagents as those separated by the iodine method, being turned blue by acid ferrocyanide, but not by acid ferricyanide (except, in some cases, at local spots representing inclusions). The film substance is thus ferric oxide with occasional inclusions (metallic iron, or possibly, in some cases, magnetite); the film fragments showed a very feeble response to the magnet, but this has no significance, since ferric oxide can exist in a magnetic form (Welo and Baudisch, *Phil. Mag.*, 1925, 50, 399; 1927, 3, 396).

Unheated specimens simply exposed to air after being ground and degreased showed irregular behaviour when exposed to anodic treatment in *M*/10-sulphuric acid. Occasionally they were active from the moment of immersion; in other cases, after identical treatment, they were passive from the moment of immersion, and after oxygen had passed for a minute, the current could be inter-

rupted for a limited period without loss of passivity. The interruption which could be tolerated without causing activity varied somewhat from one specimen to another, and seemed to depend on the time during which current had been passing, but the following observation appeared to provide the explanation. After the current had been interrupted, small oxygen bubbles continued to be evolved for some seconds, slackening as the supercharge of oxygen became exhausted. If the circuit was restored *before* this evolution of "residual" oxygen ceased, the iron remained passive and a lively production of oxygen set in again as soon as the current began to flow; but if the interruption was prolonged until the slow evolution of "residual" oxygen had completely ceased, the iron became active, and began to dissolve, without oxygen evolution, when the circuit was restored; evidently a considerable supercharge of oxygen is needed to prevent the reduction of the film during the interruption. On some specimens, after a few seconds' interruption, small oxygen bubbles continued to stream from certain points after they had ceased to come off from the specimen as a whole; if, at this stage, the circuit was restored, small bubbles continued to rise from the points in question, although elsewhere the electrode became rapidly attacked. In such cases the strength of current passing was intermediate between the ordinary active and passive values.

The irregular behaviour of the air-exposed electrodes provided another example of the variable character of the film produced by the action of air at low temperatures; on some specimens, a weak point would chance to be included in the electrode area, whilst on others there would be no spots sufficiently faulty to cause breakdown under the prevailing conditions. Specimens exposed to *M*/10-potassium chromate for five days evidently possessed a more uniform skin; without exception, these behaved as "passive" electrodes, provided that the circuit was completed before the specimen was introduced into the acid. Immersion in *M*/10-chromic acid for the same period afforded even better protection; here it was possible to place the specimen in the acid for short periods before the current was turned on, and yet to obtain oxygen evolution immediately the circuit was completed. In four experiments in which the current was started respectively 1, 1, 2, and 4 seconds after immersion, passivity was obtained; but in a fifth experiment, where a period of 5 seconds was attempted, the electrode had become active.

The objections raised to the "film theory" of anodic passivity in acid solutions can thus be answered as follows.

- (1) The statement that the oxide film on iron is rapidly destroyed

by acid is true of ordinary conditions, but not of anodic conditions. Under suitable anodic conditions, these films are unaffected by the acid (best observed if the films are thick enough to produce interference tints).

(2) The statement that the nature of the film does not affect the time which elapses before passivity appears is only true of experiments in which the film is dissolved away before the current is turned on. If the circuit is completed before introduction of the specimen, the nature of the film may make all the difference between immediate passivity and serious corrosion.

(3) The statement that iron rendered passive by anodic treatment behaves differently from iron rendered passive, *e.g.*, by simple immersion in a chromic acid solution is perfectly true; the reason is clearly found in the fact that the anodically polarised iron possesses a supercharge of oxygen, which serves to keep the oxide film repaired and in the fully oxidised condition.

Experiments conducted at higher current densities, which permitted the electrode to revert to the passive state after once it had become active, confirmed several of the observations of W. J. Müller (*Z. Elektrochem.*, 1927, 33, 401; 1928, 34, 572; 1929, 35, 656) and of Hedges (*J.*, 1926, 2878; 1927, 2710; 1928, 969). A visible brown coat often appeared on the electrode prior to the arrival of oxygen bubbles; if, for any reason, this brown coat appeared first at one particular region, bubbles were subsequently observed first at that region; in general, the evolution of bubbles started first at the bottom, and spread upwards, producing the U-shaped area described by Hedges. W. J. Müller is undoubtedly right in thinking that saturation of the liquid with ferrous sulphate must be attained before passivity can set in; the difficulty of obtaining passivity with vertical electrodes is explained by the fact that heavy ferrous sulphate solution—clearly distinguishable by reason of its different refractive index—sinks continuously down from the anode, and this circulation hinders the attainment of saturation.

*Principles governing Anodic Passivity in Acid Solution.*—When a metal is subjected to anodic treatment, its surface layers are converted *in situ* into a compound with the principal anion of the liquid. If this compound is freely soluble, it will dissolve, exposing a fresh surface of metal to attack; but if sparingly soluble, it will remain *in situ*, protecting the underlying metal. Thus, lead in a sulphate solution, silver in a chloride solution, and iron in a hydroxide solution escape attack almost from the first; the protective layer, being in optical contact with the metal, is frequently invisible. But ferrous sulphate is readily soluble, and a film-free iron anode in a sulphuric acid solution will dissolve freely at first. If, however, the layer of liquid

next to the metal should become saturated with ferrous sulphate, the behaviour of iron will be analogous to that of lead, and if now the surface portions are converted into sulphate, this will no longer dissolve and will temporarily protect the metal. This *protective* sulphate is probably invisible; it is fairly certain that the visible deposit is not the protective layer, but the result of spontaneous crystallisation of hydrated sulphate from the liquid which is locally supersaturated with respect to that salt; its importance lies in furnishing a sure sign that saturation has been reached. When once the whole anode surface is converted into sulphate, any further discharge of  $\text{SO}_4^{--}$  ions cannot cause further attack on the iron, and must (as on a platinum anode) lead to evolution of oxygen. The bubbles of oxygen, however, will soon stir up the liquid, and the visible layer will gradually dissolve or flake off (a phenomenon observed by Hedges and by W. J. Müller). Meanwhile, however, the metal will have become supercharged with oxygen, and, at high current densities, this may be sufficient to produce and maintain an oxide film on the surface which (as shown) will *not* be dissolved by the acid under anodic conditions; in that case passivity will persist indefinitely, and the current will be expended on the production of oxygen. At lower current densities, the oxide film may not be maintained, and the electrode may revert to the freely dissolving condition; if so, periodicity may be set up. At still lower current densities, a state of saturation in the anodic layers will never be reached and the electrode will remain active indefinitely; this is most likely to occur if the conditions are favourable to convection.

A theory that the anodic passivity of iron in a sulphate solution may be initiated by a protective layer of *ferric* sulphate has been put forward by McCulloch (*Trans. Amer. Electrochem. Soc.*, 1929, 56, 325). He points out that ferric sulphate dissolves only slowly in water, and that such a film might persist even in unsaturated solution. McCulloch is undoubtedly right in thinking that salts, as well as oxides, may constitute protective films. Moreover, it is not impossible that the slow dissolution of ferric sulphate by water may itself be the cause of the slow dissolution of ferric oxide film by dilute sulphuric acid; but it is not easy to explain the facts set forth above on the hypothesis that the protection is due solely to a film of ferric sulphate.

*Function of Carbon Dioxide in Corrosion by Condensed Moisture.*—Many early workers and one recent writer (Fujihara, *Chem. Met. Eng.*, 1925, 32, 810) have ascribed to carbon dioxide a special rôle in rusting; this idea may have arisen from the serious damage produced by the combustion products of coal, now commonly attributed to oxides of sulphur. The researches of Dunstan, Jowett,

and Goulding (J., 1905, **87**, 1548), Tilden (J., 1908, **93**, 1356), and Hicks (*J. Physical Chem.*, 1929, **33**, 781) have definitely proved that the presence of carbon dioxide or other acidic substance is not necessary for rusting; but the measurements of Hicks indicate that moist oxygen does produce rust more quickly if carbon dioxide also is present.

Apart from the scientific, historical, and economic interest of the matter, the question whether carbon dioxide—in amounts normally present in air—constitutes a serious cause of corrosion is important to experimenters, since the detailed observation needed for detection of vital microscopic occurrences becomes almost impossible if the work has to be conducted exclusively in closed vessels. Some experiments have, therefore, been performed to elucidate this point.

Specimens, 5.5 cm. square, were degreased with carbon tetrachloride and then alternately ground and degreased three times. Into each of a series of beakers, 8.5 cm. high and 4 cm. in diameter, a small quantity of water (2 c.c. in the main series) was placed, and one of the specimens was cemented over the mouth of each beaker with nitrocellulose. After the seal had set, the bottoms of the beakers were placed in warm water (50°), and a metal dish containing ice was placed on the upper side of the specimen. Water then distilled without ebullition, condensing on the lower side of the specimen in droplets, fairly large in the centre and microscopic around the edges. In other parallel experiments saturated carbon dioxide solution or *N*/100-sodium hydroxide solution was used instead of water; four different materials were employed, *viz.*, steel H 28, electrolytic iron E 28, commercial zinc containing lead, and electrolytic zinc; abrasion with four different grades of emery, and also scraping with a knife, was studied in different series.

The fact that the presence of carbon dioxide may affect results is clearly shown by the experiments on zinc: the distillate from dilute alkali produced, in practically every drop, a microscopic circle or sphere of membranous zinc hydroxide surrounding a tiny dark point representing the seat of corrosion; in the presence of carbon dioxide, however, the white hydroxide did not appear, but there was general darkening of the metal.

On iron and steel, the result was identical whether distillation was conducted from *N*/100-sodium hydroxide, distilled water, or carbon dioxide solution; in every case, some of the drops developed rust, whilst others remained perfectly clear. On many specimens, the frequency of rust-developing droplets varied from one part to another in a manner not depending on the drop size. Thus no accurate count could be made of the proportion of drops developing

rust, but this appeared to be highest in the coarsely abraded specimens. There was no evidence that the presence of carbon dioxide increased the probability of rust formation in a drop, although, where rust appeared at all, it seemed to be developed more quickly if carbon dioxide was present, thus confirming Hicks's results. After time had been allowed for the development of rust in those drops which were able to produce it, the specimen could be taken off the beaker and exposed to a stream of carbon dioxide (or to carbon dioxide and air alternately) without causing any rust in the clear droplets; indeed the specimen could conveniently be dried in a stream of carbon dioxide without fear of increasing the number of rust spots. Apparently the presence of carbon dioxide is incapable of causing rusting in places which have escaped rusting in its absence. On the other hand, exposure to the vapour of hydrochloric acid for only 15 seconds caused rapid rusting, in the places which had previously escaped. There seems no doubt that the corrosive qualities of the air of many laboratories—frequently attributed to carbonic acid—are really due to other acids.

The observations are explained by the fact that iron specimens are covered with an invisible film of ferric oxide with irregularly distributed weak spots (Evans, J., 1929, 117). The chance of rust formation will depend on the "probability" that the drop area includes a place on the skin sufficiently "weak" to admit the most penetrating anion present. In pure water this will be the hydroxyl ion, and the ferrous hydroxide formed as the anodic product will interact with dissolved oxygen at a distance to form the less soluble ferric hydroxide ("rust"). The presence of carbon dioxide will certainly not increase the probability of initiation of rusting, since it is unlikely to dissolve the film of ferric oxide, whilst it will decrease the hydroxyl-ion concentration; the penetrating power of the  $\text{HCO}_3^-$  or  $\text{CO}_3^{--}$  ions can probably be neglected. But if it be assumed that the weak spot *does* exist under a droplet, the carbon dioxide may accelerate the electrochemical action, by enhancing the conductivity and hydrogen-ion concentration.

In some of the early experiments, a small proportion of the previously rust-free droplets developed rust after the vessels were opened; this may have been due to traces of acid fumes, but was probably due to the bending that accompanied opening. It was found that if a specimen was cut with small shears when the droplets were in position, the drops near the shear-lines, although quite untouched by the shears, quickly developed rust, clearly because the cutting stresses fractured the protective film.

Droplets produced by distillation from ammonia caused no true rust, evidently owing to the presence of sufficient alkali to depress

the solubility of ferrous hydroxide; some attack did occur, however, since, after the drops had been removed by evaporation, interference tints were noticed.

It was observed (before the opening of the vessels) that droplets which developed rust tended to "dry up"—partially or completely—and that the clear drops situated close to a drop which had developed rust frequently disappeared altogether; on the other hand, in regions where no rust appeared, the drops showed no signs of evaporation. This confirms the early view of Crum Brown (*J. Iron Steel Inst.*, 1888, ii, 129) that rust is essentially hygroscopic—a matter recently discussed by Hudson and others (*Trans. Faraday Soc.*, 1929, 25, 207, 485, 487, 493).

*Corrosion of Iron immersed in a Carbonic Acid Solution.*—Some confusion exists regarding the effect of carbon dioxide in "immersed corrosion." In *hard, natural* waters containing calcium bicarbonate, it is unquestionable that excess of carbonic acid increases the corrosive character; in the absence of free carbonic acid such waters, when they act on iron, necessarily deposit calcium carbonate on the cathodic areas, and the deposit obstructs diffusion of oxygen, bringing the action to a standstill (Tillmans and Klarmann, *Z. angew. Chem.*, 1923, 36, 94, 103, 111, 113; Baylis, *Ind. Eng. Chem.*, 1927, 19, 177; Evans, *J. Soc. Chem. Ind.*, 1928, 47, 57T); in the presence of excess of carbonic acid, this deposition does not occur, and the corrosion continues. The indirect action of "aggressive" carbon dioxide may be serious even with metals where its direct action is undoubtedly inhibitive; thus the corrosion of lead by distilled water is retarded by the presence of carbon dioxide, but waters containing sufficient calcium bicarbonate to have no permanent action on lead become distinctly plumbosolvent if much excess carbon dioxide is present.

The action of dissolved carbonic acid *in the absence of calcium compounds* is quite different. The normal product is soluble ferrous bicarbonate, as indicated by Crum Brown (*loc. cit.*); the bicarbonate is formed very quickly if the carbon dioxide is under 50 atm. pressure (E. Müller and Henecka, *Z. anorg. Chem.*, 1929, 181, 159), but at ordinary pressures the action is much slower, quite small quantities of iron rendering the liquid supersaturated with respect to ferrous carbonate (Tillmans and Klarmann, *loc. cit.*). If oxygen is present, the iron is likely to be precipitated as ferric hydroxide (rust) in a form which will hinder diffusion; indeed Bauer's tests (*Stahl u. Eisen*, 1921, 41, 37, 76) indicate that distilled water containing carbon dioxide may produce less corrosion than distilled water free from carbon dioxide, owing to the obstructive character of the rust produced.

To elucidate this matter further, new experiments have been performed. A number of strips of iron H 28, 2 cm. wide, were cut, abraded, degreased, and immersed vertically to a depth of 4 cm. for 15.5 hours at 14° in 65 c.c. of liquid in beakers 8.5 cm. high and of 4 cm. diameter. The loss of weight produced by different liquids is shown in Table II; it will be noticed that within this time saturated carbon dioxide has produced more corrosion than distilled water but much less than *M*/20-sulphuric acid; the water "condensed on silica" was a sample prepared by L. C. Bannister and S. C. Britton for work on electrode potentials, the special object being to exclude traces of metals.

TABLE II.

Liquid.	Loss of weight, mg.			Mean, mg.
<i>M</i> /20- $K_2SO_4$ .....	2.9,	3.3,	3.5	3.2
<i>M</i> /20- $H_2SO_4$ .....	20.1,	20.5,	20.6	20.4
Saturated $CO_2$ solution .....	5.9,	7.0,	7.0	6.6
Laboratory distilled water .....		1.5,	1.7	1.6
Laboratory distilled water, redistilled and condensed on silica .....		1.0,	1.3	1.1

A series of qualitative experiments, interrupted at different stages, showed the action of carbonic acid solution to be as follows. Freshly immersed specimens are attacked by carbonic acid just as by any dilute acid, hydrogen being evolved slowly; the bubbles appear mainly at the edges and a few favoured spots on the faces (evidently points of low over-potential); but the actual attack commences at quite different points (evidently weak spots on the skin). For a time the liquid remains clear, though containing a considerable quantity of iron dissolved as ferrous bicarbonate; after about 2 hours, rust (ferric hydroxide) begins to appear along the water-line, and gas evolution gradually ceases, as the  $p_H$  value rises from about 4.0, where hydrogen production is appreciable, to a range (5.0—6.0) where direct hydrogen evolution is almost negligible. Meanwhile the oxygen absorption type of attack is increasingly hindered by the formation of rust over the water-line zone. The conditions thus become less favourable for corrosion than in a neutral sulphate or chloride solution, where the corrosion is of the differential aeration type from the first moment, and where the cathodic zone near the water-line remains comparatively free from rust, so that oxygen can continue to reach the place where it is required for corrosion. It is to be expected, therefore, that over long tests carbonic acid would produce a smaller amount of corrosion than a salt solution; and it was found in a 39-day test by the author (*J. Soc. Chem. Ind.*, 1928, 47, 77r) that actually the corrosion by saturated carbonic acid was less than that produced by *M*/20-

sodium sulphate or chloride. Probably Bauer's results, mentioned above, can be explained in the same way. In effect, carbonic acid solution is not a serious corroding agent.

It would appear that, with carbonic acid, the "hydrogen-evolution type" of corrosion lasts just long enough to produce rust at a point unfavourable to subsequent attack of the "oxygen-absorption type." The apparent exhaustion of hydrogen ions occurs long before the quantity of iron dissolved is stoichiometrically equivalent to the carbonic acid present; some experiments conducted with sulphuric acid showed that here the attack persists rapidly even when most of the acid has been used up. The difference between the action of sulphuric and carbonic acids is easily understood by considering the movement of  $p_H$  during titration of these acids with alkalis; with sulphuric acid, the  $p_H$  value remains very low (below 3.0) until the end-point is approached, whereupon it suddenly rises; with the weak carbonic acid, the  $p_H$  value is higher at the first (about 4.0) and commences to rise even with the first addition of alkali. The  $p_H$  value alters in much the same way when the acid is used up on the corrosion of iron; thus sulphuric acid continues to evolve hydrogen almost to the last, whilst with carbonic acid, the evolution of hydrogen—weak even from the first—soon dies away.

The rapid exhaustion of carbonic acid stands in contrast to the view of Crum Brown (*loc. cit.*) that a limited quantity of carbonic acid "can carry on the process indefinitely," being regenerated in full when the ferrous bicarbonate is oxidised to ferric hydroxide. Actually the conception of "regeneration in full" is inadmissible, since the precipitation of ferric hydroxide is inconsistent with concentrations of hydrogen ions such as are present in pure water saturated with carbon dioxide at normal pressure. Only if the concentration of carbon dioxide is kept low, can ferric hydroxide be produced. Since, however, the oxidation of ferrous bicarbonate to the ferric condition occurs at the water-line, the dissociation of any ferric carbonate that may temporarily be formed is quite to be expected, the carbon dioxide passing out into the gas phase (where the partial pressure of carbon dioxide is usually low) as quickly as oxygen is taken in. This accounts for the fact that, in 24-hours experiments, practically no carbonate was found in the "rust," which was mainly hydroxide, and practically no free carbon dioxide was found in the liquid, although this still contained much ferrous iron in solution. The facts do not support Crum Brown's idea of the cyclic regeneration of carbonic acid.

Recently, theories based on liberation of acid by hydrolysis of ferric salts have been suggested for other types of corrosion.

McCulloch (*Trans. Amer. Electrochem. Soc.*, 1929, 55, 268) considers that, in corrosion by chloride solution, the ferrous chloride first produced "may be oxidized to ferric chloride by absorption of oxygen, and ferric chloride may hydrolyze to give hydrochloric acid. This hydrochloric acid may attack the steel." It seems difficult to understand how any considerable increase of acidity can be produced by the action of oxygen on ferrous chloride, since in addition to ferric chloride, this oxidation itself must produce ferric hydroxide or basic ferric chloride. Whilst the hydrolysis of ferric salts undoubtedly is responsible for the formation of rust in the final stages of the action of acids on metals, it is doubtful whether regeneration of acid plays any serious part in prolonging the attack.

### *Summary.*

Chromic acid has strong oxidising and weak base-dissolving properties; it produces passivity when present alone, but stimulates corrosion if sulphuric acid also is present.

The ferric oxide film usually present on iron is rapidly destroyed by dilute sulphuric acid owing to the formation of the circuit iron|acid|oxide; the ferric oxide suffers cathodic reduction to ferrous oxide, which is rapidly dissolved by the acid. If the reduction is prevented by the presence of excess of chromic acid, or by anodic treatment of the specimen as a whole, the film can remain in contact with  $M/10$ -sulphuric acid for hours without change. This explains why iron can remain passive in acid solution during anodic treatment.

The explanation of anodic passivity in acid solution is as follows. When lead is anodically treated in sulphuric acid, the conversion of the metallic surface into sulphate will protect the metal below, but with an iron anode this will only occur when the liquid has locally become saturated with ferrous sulphate. At that stage, any further current must be expended on the production of oxygen, and although the bubbles stir the liquid, dispelling the saturated layer, the metallic surface may in the meanwhile have been converted into ferric oxide, which will protect the metal so long as the current continues to flow. Indeed, a short interruption of current can also be tolerated without resumption of activity, and this seems to depend on the presence of an oxygen supercharge, which prevents reduction to the rapidly soluble lower oxide.

The corrosive qualities of carbon dioxide have been exaggerated in the past, and probably the damage attributed to carbon dioxide has really been due to sulphur dioxide or hydrogen chloride. If water is allowed to condense in droplets on iron, some of them develop rust, whilst others (which do not happen to rest on a weak point) remain clear; this is true whether carbon dioxide is present

or absent, and the clear drops may be dried up in a current of carbon dioxide without developing rust; hydrogen chloride vapours quickly produce rusting. A solution of carbonic acid causes at first slight corrosion of the hydrogen-evolution type, but the  $p_H$  rapidly rises and the formation of hydrogen ceases; the ferrous bicarbonate produced yields ferric hydroxide at the water-line, and this obstructs diffusion of oxygen and prevents attack of the oxygen-absorption type. In effect, therefore, a solution of carbonic acid is not dangerously corrosive; but it must be remembered that the presence of excessive free carbonic acid in a hard natural water may prevent the deposition of calcium compounds which would otherwise bring the action to a standstill.

UNIVERSITY CHEMICAL LABORATORY,  
CAMBRIDGE.

## LXVII.—N-Acylpyrazolones as Acylating Agents.

By JOTI SARUP AGGARWAL and JNANENDRA NATH RAY.

ETHYL acetoacetate reacts with benzoylhydrazine at  $100^\circ$ , s-di-benzoylhydrazine and 3-methyl-5-pyrazolone being formed. Their production may be explained by the fact that 1-benzoyl-3-methyl-5-pyrazolone, which can be isolated when the above condensation is carried out at  $10-16^\circ$ , reacts readily with compounds containing an amino-group, 3-methyl-5-pyrazolone and the benzoyl derivative of the amine being formed.

Under the same conditions, benzoylhydrazine does not benzoylate a primary amine.

Similar results are obtained when phenylacetylhydrazine is substituted for benzoylhydrazine in the above reactions.

Bongert (*Compt. rend.*, 1901, **132**, 973) has obtained 3-methyl-5-pyrazolone and butyrylhydrazine by the interaction of methyl  $\beta$ -butyryloxyacrylate and hydrazine.

### EXPERIMENTAL.

*Interaction of Phenylacetylhydrazine and Ethyl Acetoacetate. Formation of s-Diphenylacetylhydrazine and 3-Methyl-5-pyrazolone.*—Phenylacetylhydrazine (7.5 g.), ethyl acetoacetate (6.5 g.), absolute alcohol (1.3 c.c.), and 3 or 4 drops of piperidine were heated together

on the steam-bath for 3 hours. The solid product was extracted with hot water, and the residue crystallised from absolute alcohol, colourless needles of *s*-diphenylacetylhydrazine (4.0 g.), m. p. 232—233°, being obtained; Pinner and Gobel (*Ber.*, 1897, **30**, 1889) give m. p. 231° (Found: N, 10.65. Calc. for  $C_{16}H_{16}O_2N_2$ : N, 10.4%). The aqueous extract on concentration gave 3-methyl-5-pyrazolone, m. p. (after recrystallisation) and mixed m. p. with an authentic specimen, 215°.

*s*-Dibenzoylhydrazine.—A mixture of benzoylhydrazine (7 g.), ethyl acetoacetate (6 g.), alcohol (2 c.c.), and piperidine (3 or 4 drops) was heated on the steam-bath as in the preceding case. The product, isolated in a similar way and recrystallised from alcohol, gave colourless plates (3.5 g.), m. p. 235°, of *s*-dibenzoylhydrazine (Struve, *J. pr. Chem.*, 1894, **50**, 299, gives m. p. 233°) (Found: N, 11.8. Calc. for  $C_{14}H_{12}O_2N_2$ : N, 11.7%).

1-Phenylacetyl-3-methyl-5-pyrazolone.—A mixture of phenylacetylhydrazine (7.5 g.), ethyl acetoacetate (6.5 g.), and piperidine (3 or 4 drops) was kept at the ordinary temperature for 12 hours. The solid product crystallised from hot xylene in pale brownish needles, m. p. 134—136° (Found: N, 13.3.  $C_{12}H_{12}O_2N_2$  requires N, 13.0%). A small quantity of a substance, m. p. 228—230°, insoluble in hot xylene was not investigated.

1-Phenylacetyl-3-methyl-5-pyrazolone (0.8 g.) was heated with an equivalent quantity of aniline at 130—140° for an hour or at 100° for 3 hours. Phenylacetanilide, m. p. 116° after recrystallisation, was isolated from the reaction mixture, and 3-methyl-5-pyrazolone from the acid extract (see below).

Phenylacetanilide.—A mixture of phenylacetylhydrazine (5 g.), ethyl acetoacetate (4.3 g.), and a few drops of piperidine was kept over-night, aniline (3 g.) added, and the mixture heated at 130—140° for an hour. The cooled mass was ground with dilute hydrochloric acid, the liquid filtered, and the residue extracted with tepid alcohol. The alcoholic extract on concentration and dilution with water furnished phenylacetanilide (1.9 g.) which, after recrystallisation from hot dilute alcohol, melted, alone or mixed with an authentic specimen, at 116°; a further quantity (0.9 g.) was isolated, by fractional crystallisation, from the residue from the alcohol extraction.

A mixture of phenylacetylhydrazine (3 g.) and aniline (2 g.), heated at 130° for 1 hour, gave no phenylacetanilide.

LXVIII.—*The Vapour Density of Zirconium Tetrachloride.*

By JOHN ALBERT NEWTON FRIEND, ALBERT THOMAS WILLIAM COLLEY, and RICHARD SIDNEY HAYES.

THE only published data on the vapour density of zirconium tetrachloride appear to be those of Deville and Troost (*Compt. rend.*, 1857, 45, 821), who, using Dumas's method at the boiling point of sulphur, obtained the values 8.10 and 8.21 (Calc. : 8.09; air = 1). These results were of particular interest at the time, since they indicated that zirconium was quadrivalent, in opposition to the general belief in its trivalency. The second value for the density is somewhat greater than the theoretical. Apart from error of observation, this might be accounted for by the presence of hafnium, although the possibility of association of the tetrachloride deserves consideration.

During experiments on the volatilisation of pure zirconium tetrachloride in a current of chlorine, it had frequently been observed by one of us that brown fumes were formed characteristic of zirconium trichloride (Ruff and Wallstein, *Z. anorg. Chem.*, 1923, 128, 96). It seemed of interest, therefore, (i) to determine if association could be detected in the vapour at temperatures only slightly above that at which volatilisation begins, and (ii) to follow up the observed dissociation into trichloride at higher temperatures with vapour-density measurements.

## EXPERIMENTAL.

*Purification of Materials.*—Elimination of hafnium was effected by a method based on the observation that zirconium is more readily precipitated from solution by citric acid than is hafnium (Drophy and Davey, *Physical Rev.*, 1925, 25, 882). A sample of "pure" zirconia was converted into sulphate by heating with concentrated sulphuric acid, and the solution diluted and filtered. The hydrated oxide was precipitated with ammonia from the boiling solution, washed, and dissolved in pure nitric acid; the clear solution was evaporated to dryness, the residue dissolved in water and filtered, and citric acid added in sufficient amount to precipitate about half the zirconium as citrate, any hafnium together with the remainder of the zirconium being retained in solution. The precipitate was filtered off, washed, ignited to oxide, and the process repeated. A very pure sample of zirconia was thus obtained.

*Test for cerium.* The following test for traces of ceria in zirconia was found useful. Cerium colours a borax bead yellowish-green

when heated in the oxidising flame. A borax bead weighing 0.056 g. was perceptibly coloured (in daylight) by 0.0015 g. of zirconia containing 4% of ceria.

*Purity of the zirconia.* Several attempts were made to follow the elimination of hafnia from zirconia by density measurements (Hevesy, J., 1924, 125, 2372). The results, however, were not sufficiently concordant to be of service, possibly owing to the mechanical loss of oxide during ignition, which it is extraordinarily difficult to avoid (see Venable and Bell, *J. Amer. Chem. Soc.*, 1917, 39, 1599). The equivalent of the zirconium was therefore determined chemically from the ratio  $\text{Zr}(\text{SO}_4)_2 : \text{ZrO}_2$ . A weighed quantity of the purified zirconia was heated with concentrated sulphuric acid for at least an hour. The rate of solution of the oxide was found to depend upon its previous history, frequent ignition rendering it very refractory. In none of our experiments were we able to effect complete solution of the sample taken. After cooling, the mixture was poured into excess water, and heated to boiling, any undissolved zirconia being filtered off, ignited, and weighed.

The solution of zirconium sulphate was evaporated to dryness in a platinum dish, the heating being carefully controlled towards the close of the experiment in order to drive off the excess of acid without decomposing the sulphate. When a constant weight had been obtained, the temperature was raised and the sulphate ignited to oxide. In every case the weight of oxide thus obtained was slightly less than that originally dissolved, presumably owing to mechanical loss. For instance, in two experiments, the initial weights of zirconia were 0.4051 and 0.2707 g. and the final weights 0.3926 and 0.2687 g. respectively. As calculated from the initial weights, the values obtained for the equivalent weight of zirconium were 22.04, 22.00, mean 22.02; the accepted value for 1929 being  $91.2/4 = 22.8$ . Our value is somewhat low in common with early atomic-weight determinations by this method [compare Weibull (*Lund. Årsskrift*, 1881—1882, vol. xviii), who obtained the mean value of  $89.54/4 = 22.39$ ], probably owing to the difficulty of completely expelling the acid without simultaneously decomposing the sulphate. The results, however, indicate the absence of appreciable quantities of hafnium.

*Preparation of Zirconium Tetrachloride.*—This was effected by Demarçay's method (*Compt. rend.*, 1887, 104, 1136), viz., by passing chlorine, laden with carbon tetrachloride vapour and dried by phosphoric oxide, over heated zirconia as described by Venable and Bell (*loc. cit.*). The chloride was collected in a long tube and transferred by shaking into a bottle. It invariably contained traces of zirconia

carried over mechanically. To obtain the pure chloride, the first batch was returned to the apparatus and re-sublimed in a very slow current of chlorine—about 2 bubbles per second, as recommended by Lely and Hamburger (*Z. anorg. Chem.*, 1914, 87, 223). Since the tetrachloride is very susceptible to moisture, it was condensed on tube A (see fig.), which easily slid over the water-cooled tube BC. When sufficient had collected, BC was withdrawn and A rapidly slid into a slightly wider tube, which thus enclosed the tetrachloride. After being weighed, this double tube was used as the dropping bottle in the Victor Meyer apparatus. It was ascertained that no condensation of carbon tetrachloride took place along with the zirconium salt under our experimental conditions.

Venable and Bell state that formation of chloride in their experiments began a little above  $300^{\circ}$  and was rapid at  $450$ – $500^{\circ}$ , though Lely and Hamburger found it necessary to employ a temperature of  $800^{\circ}$  to obtain the chloride in bulk. We attempted to determine the lowest temperature by passing chlorine and carbon tetrachloride vapour over zirconia in a tube supported vertically in a metal-bath, the temperature of which was slowly raised, and noting the first appearance of sublimate. This occurred at  $355^{\circ}$ , but the whole of the oxide was not converted into chloride even at  $500^{\circ}$ . The temperature necessary evidently varies with the physical condition of the oxide.

*Determination of Vapour Density.*—A modification of Victor Meyer's apparatus was used, the heated portion consisting of a silica vaporising tube of 350 c.c. capacity, supported vertically in an electric furnace. The upper part of the apparatus was of glass and fitted into the silica tube with a ground joint lubricated with phosphoric acid. The whole was thoroughly dried, and the vertical portion filled with dried chlorine. Traces of moisture were rigidly excluded, as they reduced the vapour density enormously. In all the experiments at  $700^{\circ}$  the sublimate in the tube at the close of the tests was tinged with brown.

The results are given below, the vapour density being referred to that of air as unity.

		At $400^{\circ}$ .		At $445^{\circ}$ .

*Conclusions.*—Consideration of the results shows that (1) there is no evidence of association at 400° or above. The four high results at 500° and the one at 700° are believed to be due to decomposition as indicated below. (2) The vapour density of zirconium tetrachloride in chlorine falls with rise of temperature, and appears to fall slightly with dilution. Presumably the vapour first dissociates into the trichloride and free chlorine,  $2\text{ZrCl}_4 \rightleftharpoons 2\text{ZrCl}_3 + \text{Cl}_2$ . The decomposition can hardly end there, however, since according to Ruff and Wallstein (*loc. cit.*) the trichloride also dissociates above 330°, thus:  $2\text{ZrCl}_3 \rightleftharpoons \text{ZrCl}_4 + \text{ZrCl}_2$ ; moreover, above 600° the dichloride deposits zirconium,  $2\text{ZrCl}_2 = \text{ZrCl}_4 + \text{Zr}$ . The reactions in the vaporising tube may thus be very complex and it is not regarded as possible that a complete equilibrium could be obtained in the brief course of an experiment.

THE TECHNICAL COLLEGE,  
BIRMINGHAM.

[Received, November 28th, 1929.]

## LXIX.—3-Halogeno-6-nitro- and -6-amino-dimethylanilines.

By HERBERT HENRY HODGSON and ARNOLD KERSHAW.

THE 2:4-dihalogenonitrobenzenes have been found to react readily with an alcoholic solution of dimethylamine in the absence of a catalyst, and in every case it is the 2-halogeno-substituent that is easily and exclusively replaced by the dimethylamino-group, this being in accordance with the well-known promotion of mobility of halogens by an adjacent nitro-group. Further, the ease of replacement of one halogen only, indicates considerable satisfaction of the electronic demands of the nitro-group by one dimethylamino-group (compare the ease with which sodium methoxide replaces both halogens in a 2:4-dihalogenonitrobenzene, a further illustration of the fact that  $\text{NMe}_2 > \text{OMe}$  as a potential electron-source). It is noteworthy also that in 4-chloro-2-iodonitrobenzene the iodine only is replaced by dimethylamine under the same conditions, a fact which indicates that the 2-carbon atom is more positive than the

4-carbon atom, notwithstanding the greater positivity produced by chlorine as compared with iodine, and therefore that the general effect of the nitro-group (Allan, Oxford, Robinson, and Smith, J., 1926, 401) is much greater on the 2-carbon than on the 4-carbon atom.

Most unsubstituted 2-nitrodialkylanilines are liquids at the ordinary temperature, but the derivatives now under consideration are solids of low m. p., and since the *p*-nitrodialkylanilines have high m. p.'s (*e.g.*, 4-nitrodimethylaniline has m. p. 168°), it is probable that the low m. p.'s of the *o*-compounds are due to co-ordination of a similar type (I) to that described by Bennett and Willis (J., 1929, 256).

The 3-halogeno-6-nitrodialkylanilines are not sufficiently basic to form salts except with strong acids, and these are immediately hydrolysed by water. In non-dissociating solvents such as light petroleum and naphthalene, 1% solutions are yellow, and the molecular weight of 3-chloro-6-nitrodialkylaniline in naphthalene is about 10% above that of the single molecule (compare the discussion of similar cases by Sidgwick, "Electronic Theory of Valency," 1927, p. 149 *et seq.*, who considers that such cryoscopic evidence of association must be interpreted with caution). Very deep red 1% solutions are formed in phenol, the product being unimolecular, which might reasonably indicate a change of structure produced by co-ordination of solvent (II). Anisole does not give this colour change.

The picrates of the 3-halogeno-6-nitrodialkylanilines are stable, with m. p.'s below those of the 3-halogeno-6-aminodimethylanilines: these are true salts soluble in water, so the diminution of melting point may be due to chelation (III)—a point of view which is supported by the fact that the more salt-like is the picrate of a 3-halogeno-6-nitrodialkylaniline the higher is its m. p.; *e.g.*, iodo- (104°), bromo- (85°), and chloro- (70°), a series conforming with the well-known order of the general effects of the halogens, Cl > Br > I.

The 3-halogeno-6-aminodimethylanilines are all liquids at the ordinary temperature, owing doubtless to chelate union (IV) (compare Sidgwick and Callow, J., 1924, **125**, 527), which should be stronger than in the case of *o*-phenylenediamine (m. p. 102°), since the dimethylamino-nitrogen is more negative than the amino-nitrogen atom. Moreover, the free bases, including *o*-aminodimethylaniline itself, are much more stable in air than *p*-aminodimethylaniline and much less soluble in water: this is further evidence of the great stability associated with 5-membered chelate rings.

All the above substances form stable monohydrochlorides; but only the halogeno-compounds give dihydrochlorides, which diminish in stability from the chloro- to the iodo-compound. It would appear that salt formation produces in the monohydrochloride of *o*-aminodimethylaniline a 5-membered chelate ring, by the sharing of a hydrogen ion between the amino-groups (V) (compare Sidgwick's discussion on hydrofluoric acid, *op. cit.*, p. 72), which is sufficiently stable to prevent further salt-formation at the amino-nitrogen atom; but that when the 3-halogeno-atom is introduced, its general (inductive) effect on the chelating electrons of the *p*-amino-nitrogen atom is a weakening of their union to such an extent that, under the influence of the powerful kationoid reagent (a second molecule of hydrochloric acid), the dimethylamino-group captures the hydrogen atom and thus enables further salt formation to take place at the released amino-group. This salt formation is facilitated by the alternating (tautomeric) effect of the halogen substituent, now rendered available (compare the greater positivity of the 3-carbon atom in comparison with the 4-carbon atom in activated 1-chloro-3:4-dinitrobenzene, due to the alternating effect of the chlorine atom). Since the order of the general effect of the halogens is  $\text{Cl} > \text{Br} > \text{I}$ , it follows that 3-chloro-6-aminodimethylaniline dihydrochloride will be the most easily formed and, in consequence, be the most stable of the analogues.

Only the free bases mentioned above give violet colours with ferric chloride; the salts, however, do so with stronger oxidising agents (*e.g.*, chromic acid).

3-Chloro-6-aminodimethylaniline was recovered unchanged after repeated treatment with Caro's acid under widely varying conditions: this resistance to oxidation is probably due to chelation both in the free base and in the salt (compare the ready oxidation of *o*-anisidine and *o*-nitroaniline to the corresponding nitroso-derivatives, and the instantaneous destruction of *p*-aminodimethylaniline under the same conditions).

## EXPERIMENTAL.

*Action of Dimethylamine on the 2:4-Dihalogenonitrobenzenes.*—The 2:4-dihalogenonitrobenzene (10 g.) was boiled under reflux with 10% more than the theoretical quantity of a solution of dimethylamine (1 g.-mol.) in ordinary alcohol (400 c.c.) to which an equal volume of the solvent had been added. The chloro- and bromo-compounds were refluxed for 10 hours and the iodo-analogue for 15 hours, the alcohol then being removed by steam; the oily reaction product solidified on cooling [compare Weissenberger (*Monatsh.*, 1912, **33**, 821), who in a similar reaction with *o*-chloronitrobenzene used absolute alcohol and copper powder, both of which have now been found unnecessary].

*3-Chloro-6-nitrodimethylaniline* crystallises from light petroleum in short, stout, dull yellow prisms, often almost cubes, m. p. 49° (Found: Cl, 17.5; *M*, cryoscopic in phenol, 185.9, 187.8; *M*, cryoscopic in naphthalene, 199.5, 210.5.  $C_8H_9O_2N_2Cl$  requires Cl, 17.7%; *M*, 188.5), which are fairly readily volatile in steam. The constitution of this compound was confirmed by its preparation (as above) from 4-chloro-2-bromo- and also from 4-chloro-2-iodonitrobenzene. The *picrate*, prepared from the compound (0.6 g.) and picric acid (0.7 g.) in boiling alcohol (7 c.c.), is deposited, on cooling, in bright yellow, flat prisms, m. p. 70° (Found: Cl, 8.1.  $C_8H_9O_2N_2Cl \cdot C_6H_3O_7N_3$  requires Cl, 8.3%).

*3-Bromo-6-nitrodimethylaniline* separates from light petroleum in crystals, m. p. 58.5°, resembling those of the chloro-analogue (Found: Br, 32.4.  $C_8H_9O_2N_2Br$  requires Br, 32.6%). The *picrate* melts at 85° (Found: Br, 16.6.  $C_8H_9O_2N_2Br \cdot C_6H_3O_7N_3$  requires Br, 16.9%). Their constitutions follow from their identity (mixed m. p., etc.) with the compound and its *picrate* made from 2-chloro-4-bromonitrobenzene by the general process above. The 2-chloro-4-bromonitrobenzene was obtained from 3-chloro-4-nitroaniline by means of the Sandmeyer reaction.

*3-Iodo-6-nitrodimethylaniline* crystallises from light petroleum in long orange prisms, m. p. 52° (Found: I, 43.7.  $C_8H_9O_2N_2I$  requires I, 43.5%). It was also obtained from 2-chloro-4-iodonitrobenzene, prepared from 3-chloro-4-nitroaniline by the usual iodination process. The *picrate* melts at 104° (Found: I, 24.2.  $C_8H_9O_2N_2I \cdot C_6H_3O_7N_3$  requires I, 24.4%). All the 3-halogeno-6-nitrodimethylanilines are precipitated on dilution of their colourless solutions in concentrated sulphuric acid. *o-Nitrodimethylaniline picrate* crystallises from alcohol in long yellow prisms, m. p. 103° (Found: N, 18.0.  $C_8H_{10}O_2N_2 \cdot C_6H_3O_7N_3$  requires N, 17.7%).

*Reduction of the 3-Halogeno-6-nitro- to the 3-Halogeno-6-amino-dimethylanilines.*—Each of the above nitro-compounds is readily

reduced by iron powder and 50% aqueous acetic acid to the corresponding amine, which is then removed by steam distillation from the reaction mixture, made alkaline. The amines are colourless viscous oils of a not unpleasant odour and are volatile in steam. The chloro- and bromo-compounds are conveniently isolated from the steam distillates directly as hydrochlorides, but the iodo-compound, on account of its ready decomposition when boiled with hydrochloric acid, is extracted with ether prior to its conversion into the hydrochloride.

**3-Chloro-6-aminodimethylaniline** (Found: Cl, 20.6.  $C_8H_{11}N_2Cl$  requires Cl, 20.8%) forms a *monohydrochloride*, which crystallises from water in long needles (Found: Cl, 34.1.  $C_8H_{11}N_2Cl.HCl$  requires Cl, 34.3%). The *dihydrochloride* separates from concentrated hydrochloric acid solution in colourless prisms (Found: ionisable Cl, 29.1; total Cl, 43.5.  $C_8H_{11}N_2Cl.2HCl$  requires ionisable Cl, 29.1; total Cl, 43.7%). The *picrate* separates from a hot alcoholic solution of equimolecular quantities of the amine and picric acid in bright yellow prisms, m. p.  $151^\circ$  (to a brown-red liquid) (Found: Cl, 8.7.  $C_8H_{11}N_2Cl.C_6H_3O_7N_3$  requires Cl, 8.9%).

**3-Bromo-6-aminodimethylaniline** (Found: Br, 37.0.  $C_8H_{11}N_2Br$  requires Br, 37.2%) forms a *monohydrochloride* (Found: Cl, 14.1.  $C_8H_{11}N_2Br.HCl$  requires Cl, 14.1%) and a *dihydrochloride* (Found: Cl, 24.6.  $C_8H_{11}N_2Br.2HCl$  requires Cl, 24.6%). The *picrate* crystallises from alcohol in bright yellow prisms, m. p.  $137^\circ$  (Found: Br, 17.9.  $C_8H_{11}N_2Br.C_6H_3O_7N_3$  requires Br, 18.0%).

**3-Iodo-6-aminodimethylaniline** (Found: I, 48.2.  $C_8H_{11}N_2I$  requires I, 48.5%) forms a *monohydrochloride* (Found: Cl, 11.8.  $C_8H_{11}N_2I.HCl$  requires Cl, 11.9%) and a *dihydrochloride* (Found: Cl, 20.0.  $C_8H_{11}N_2I.2HCl$  requires Cl, 21.2%). The latter analysis indicates the presence of monohydrochloride (compare the theoretical discussion). The *picrate* crystallises in thin, bright yellow plates, m. p.  $167^\circ$  (Found: I, 25.6.  $C_8H_{11}N_2I.C_6H_3O_7N_3$  requires I, 25.9%).

**o-Aminodimethylaniline** is prepared as above by reduction of o-nitrodimethylaniline and has b. p.  $212^\circ$  (Found: N, 20.7.  $C_8H_{12}N_2$  requires N, 20.6%). Its *monohydrochloride* separates from concentrated hydrochloric acid in long colourless prisms (Found: Cl, 20.9.  $C_8H_{12}N_2.HCl$  requires Cl, 20.6%). The *picrate* crystallises in bright yellow prisms, m. p.  $136^\circ$  (Found: N, 19.3.  $C_8H_{12}N_2.C_6H_3O_7N_3$  requires N, 19.2%).

The authors desire to thank the British Dyestuffs Corporation for generous gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [Received, December 23rd, 1929.]

# LXX.— $\gamma$ -Phenyl- $\alpha$ -methylpropyldimethylarsine, $\beta$ -Benzylbutyldimethylarsine, and Some Related Compounds.

By ALBERT BREWIN and EUSTACE EBENEZER TURNER.

BEFORE the appearance of the paper by Mills, Parkin, and Ward (J., 1927, 2613), we were attempting to prepare certain derivatives of dihydroarsindole and of tetrahydroarsinoline in which *cis-trans* isomerism should be exhibited. For one reason or another, no suitable ring arsines were obtained, but the results now recorded may be of value to future workers.

We have endeavoured to carry out a number of syntheses of the type :

$\beta$ -Benzylbutyl bromide (I; R = Et, R' = H) readily formed a Grignard reagent, but this reacted with dimethyliodoarsine to give only a poor yield of  $\beta$ -benzylbutyldimethylarsine (as III).

Neither  $\alpha\gamma$ -diphenylpropyl bromide (I; R = H, R' = Ph) nor  $\gamma$ -phenyl- $\alpha$ -m-chlorophenylpropyl bromide (I; R = H, R' = *m*-C<sub>6</sub>H<sub>4</sub>Cl) could be caused to combine with magnesium. On the other hand,  $\gamma$ -bromobutylbenzene readily formed a Grignard reagent, which reacted with dimethyliodoarsine to give  $\gamma$ -phenyl- $\alpha$ -methylpropyldimethylarsine, CH<sub>2</sub>Ph·CH<sub>2</sub>·CHMe·AsMe<sub>2</sub>. The dichloride (as IV) of this substance, however, underwent the expected loss of methyl chloride (on heating) only to the extent of a few units %, the major portion decomposing to give  $\gamma$ -chlorobutylbenzene and dimethylchloroarsine.

## EXPERIMENTAL.

$\beta$ -Benzylbutyl bromide, b. p. 135°/20 mm. (yield, 73%) (Found: Br, 34.9. C<sub>11</sub>H<sub>15</sub>Br requires Br, 35.2%), was prepared from  $\beta$ -benzylbutyl alcohol by means of phosphorus tribromide, the alcohol (b. p. 128—132°/11 mm.) being obtained in 73% yield by reducing ethyl  $\alpha$ -benzylbutyrate (b. p. 133—136°/15 mm.; 145—150°/20 mm.; 155—160°/30 mm.) with sodium and absolute alcohol. The most convenient synthesis of the ester proved to be the following: Benzylidenemalonic acid was prepared (43% yield) and reduced (yield, almost quantitative) by the methods of Claisen and

Crismer (*Annalen*, 1883, **218**, 135). Esterification of the benzylmalonic acid with alcohol and concentrated sulphuric acid proceeded to the extent of 75%, and the resulting ester (b. p.  $170^{\circ}/13$  mm.) gave rise by normal procedure to a 90% yield of ethyl benzylethylmalonate. This was converted by Mohr's method (*J. pr. Chem.*, 1905, **71**, 331) into  $\alpha$ -benzylbutyric acid, b. p.  $175$ — $177^{\circ}/20$  mm. (yield, 77%).

$\beta$ -Benzylbutyldimethylarsine.—A solution of  $\beta$ -benzylbutyl bromide in three times its weight of ether was added gradually to slightly less than one atomic proportion of magnesium turnings, covered with ether, initial interaction being promoted by the use of iodine. Dimethyliodoarsine (1 mol.), dissolved in twice its volume of benzene, was slowly added to the formed Grignard reagent and the whole was gently boiled for an hour. Water and dilute hydrochloric acid were then added and the ether-benzene layer was worked up in the usual manner. The arsine, distilled in a current of hydrogen, was a colourless, strongly smelling oil, b. p.  $150^{\circ}/20$  mm. (yield, 30%).

$\alpha\gamma$ -Diphenylpropyl bromide, b. p.  $185$ — $190^{\circ}/30$  mm. (Found: Br, 29.0.  $C_{15}H_{15}Br$  requires Br, 29.1%), was prepared by the action of phosphorus tribromide on the corresponding alcohol, which was obtained (80 g.) from benzaldehyde and the Grignard reagent from 100 g. of  $\beta$ -phenylethyl bromide.

$\gamma$ -Bromobutylbenzene.— $\beta$ -Phenylethyl bromide (170 g.) was converted into a Grignard reagent, and the latter was treated with 120% of the calculated quantity of acetaldehyde, dissolved in ether. An 85% yield of  $\beta$ -phenylethylmethylcarbinol, b. p.  $124$ — $126^{\circ}/15$  mm., or  $128$ — $130^{\circ}/20$  mm., was obtained, together with a small quantity of  $\alpha\delta$ -diphenylbutane. From 80 g. of the carbinol, by means of phosphorus tribromide, 90 g. of  $\gamma$ -bromobutylbenzene, b. p.  $118$ — $119^{\circ}/14$  mm.,  $129$ — $130^{\circ}/20$  mm., or  $137$ — $138^{\circ}/34$  mm., were obtained (Found: Br, 36.9.  $C_{10}H_{13}Br$  requires Br, 37.5%).

$\gamma$ -Phenyl- $\alpha$ -methylpropyldimethylarsine was obtained in 56% yield from the interaction of dimethyliodoarsine and a Grignard reagent from  $\gamma$ -bromobutylbenzene. It is a colourless, highly refractive oil, b. p.  $143$ — $145^{\circ}/20$  mm., or  $163^{\circ}/50$  mm. The methiodide was readily produced, and formed globular crystals, m. p.  $156^{\circ}$  (softening at  $153^{\circ}$ ) (Found: I, 33.3.  $C_{13}H_{22}IA$ s requires I, 33.5%).

$\gamma$ -Phenyl- $\alpha$ -m-chlorophenylpropyl alcohol was obtained in 64% yield from *m*-chlorobenzaldehyde and magnesium  $\beta$ -phenylethyl bromide in ethereal solution. It boiled at  $210$ — $215^{\circ}/25$  mm. (Found: Cl, 14.65.  $C_{15}H_{15}OCl$  requires Cl, 14.45%).

$\gamma$ -Phenyl- $\alpha$ -m-chlorophenylpropyl bromide was obtained from the alcohol in 43% yield, and boiled at  $200$ — $205^{\circ}/30$  mm. (0.2258 g.

gave 0.2457 g. of  $\text{AgCl} + \text{AgBr}$ .  $\text{C}_{15}\text{H}_{14}\text{ClBr}$  requires 0.2435 g. of  $\text{AgCl} + \text{AgBr}$ .

One of us (A. B.) is indebted to the Department of Scientific and Industrial Research for a maintenance grant held while this investigation was in progress.

## LXXI.—*The Reactivity of Halogen Atoms in Compounds of the Pyridine Series. Part I. The Halides of 2-Stilbazole.*

By JOHN WALTER BLOOD and BRIAN DUNCAN SHAW.

BAURATH (*Ber.*, 1887, **20**, 2719; 1888, **21**, 818) found that 2-stilbazole (2-styrylpyridine) dibromide reacted with alcoholic potassium hydroxide, but was unable to isolate an acetylenic base analogous to tolane. Ladenburg (*Ber.*, 1903, **36**, 119), who reinvestigated the reaction at higher temperatures, described his product as deoxybenzazoin. Five years ago, one of us observed that the action of pyridine upon the dibromide regenerated 2-stilbazole. This evidence of the presence of a "positive" bromine atom led us to study the reaction of a variety of other reagents. Pyridine, phenol, aqueous-alcoholic potassium hydroxide, potassium iodide, and hydriodic acid yield 2-stilbazole even when the quantity of reagent is equivalent only to one bromine atom; indicating that after replacement of one bromine atom with hydrogen, loss of hydrogen bromide occurs spontaneously. This agrees with the known inability of 2-stilbazole to combine additively with hydrogen bromide at the ethylenic linking (compare Rath, *Ber.*, 1924, **57**, 841). On the other hand, with piperidine or sodium ethoxide a *monobromostilbazole* results, and alcoholic potassium hydroxide containing very little water yields a mixture of stilbazole and bromostilbazole. The position of the bromine atom in the latter compound, which is singularly unreactive, has not yet been determined; but as one of us has been obliged to abandon the work, the results so far obtained are now given. Similar results were obtained with 2-stilbazole *dichloride*. When stilbazole was the product, a small quantity of oil usually accompanied the solid base. This oil gradually yielded the solid base and treatment with bromine gave stilbazole dibromide. Similar oils accompanied the solid chloro- and bromo-stilbazoles; these also solidified on long standing. The investigation is being extended to the isomeric stilbazoles and their substitution products.

## EXPERIMENTAL.

*The 2-Stilbazole Chlorides.*—A solution of chlorine (7.1 g.; 1 mol.) in carbon tetrachloride (50 c.c.) was added gradually to a solution of 2-stilbazole (18.1 g.; 1 mol.) in the same solvent. The mixture boiled, and was cooled in water; a gummy solid then separated. The clear solution deposited colourless needles of 2-stilbazole dichloride, m. p. 153—154° after recrystallisation from alcohol. The dichloride was readily soluble in acetone and sparingly soluble in cold alcohol, chloroform, or carbon tetrachloride (Found: Cl, 28.3.  $C_{13}H_{11}NCl_2$  requires Cl, 28.2%). A little unchanged stilbazole was recovered from the mother-liquor.

The gummy solid was dissolved in hot alcohol; on cooling, small plates of 2-stilbazole tetrachloride were deposited, m. p. 180—181° after recrystallisation from alcohol (Found: Cl, 43.6.  $C_{13}H_{11}NCl_4$  requires Cl, 43.96%). On treatment with cold aqueous sodium carbonate solution the compound readily gave the dichloride, indicating that half the chlorine was united to the nitrogen atom.

*The 2-Stilbazole Bromides.*—In the preparation of the dibromide by Baurath's method (*loc. cit.*) it was found better to employ less than the theoretical amount of bromine, as otherwise the product was contaminated with a yellow insoluble substance which appeared to be 2-stilbazole tetrabromide. The compound decomposed on being heated. Consistent analytical results could not be obtained, as it gradually lost bromine on exposure to the atmosphere, yielding the dibromide. The latter, crystallised from alcohol, had m. p. 172° (Baurath gives 166—167°).

*Action of Reagents upon the Stilbazole Dihalides.*—Except where otherwise stated, the results with the dichloride were exactly similar to those given for the dibromide.

*Alcoholic potassium hydroxide.* 2-Stilbazole dibromide (6.8 g.; 1 mol.) was boiled with a solution of potassium hydroxide (2.28 g.; 2 mols.) in 95% alcohol (50 c.c.). The solution rapidly became red, but was still alkaline after 6 hours. The alcohol was removed, water added to the residue, and the brown oil extracted with benzene. After removal of the solvent the oil was treated with successive small quantities of light petroleum (b. p. 50—60°). The first fractions deposited long, pale yellow prisms of monobromostilbazole, which were obtained colourless by recrystallisation from alcohol; m. p. 74—75° (Found: C, 60.15; H, 4.0; Br, 30.5.  $C_{13}H_{10}NBr$  requires C, 60.2; H, 3.9; Br, 30.8%).

The later light petroleum fractions were coloured, and left a thick brown oil on removal of the solvent. The residue was distilled with steam; a colourless oil, which distilled very slowly, was separated with benzene. After removal of the solvent the pale

brown oil partly crystallised. The solid, after crystallisation from light petroleum, had m. p.  $91^{\circ}$  alone or mixed with 2-stilbazole. A portion of the residual oil gave, with bromine, 2-stilbazole dibromide, m. p.  $172^{\circ}$ . The remainder, on exposure to the air, yielded the solid base. Yields: bromostilbazole 1.5 g., 2-stilbazole 2.1 g.; 30% and 60% of the theoretical respectively. Increase in the percentage of water raised the proportion of 2-stilbazole.

In a repetition experiment the mixture was not heated, but kept at room temperature for 2 days. Yields: bromostilbazole 2.5 g., 2-stilbazole 0.32 g.; 50% and 9% of the theoretical respectively. The residual oil slowly deposited more of the solid bromostilbazole.

*Sodium ethoxide.* Preparation of monobromostilbazole. A solution of sodium (0.35 g.; 1 atom) in anhydrous alcohol (7.0 c.c.) was added to stilbazole dibromide (5.1 g.; 1 mol.). A reaction commenced on warming and was complete after 5 minutes' boiling. Water (50 c.c.) precipitated an oil which solidified when rubbed; yield, 3.8 g. (85% of the theoretical). Crystallisation from light petroleum gave long colourless prisms, m. p.  $75^{\circ}$ . The mother-liquor, after evaporation, left an oil which gave solid monobromostilbazole on long standing. The length of the crystals obtained by slow crystallisation from light petroleum appears to be limited only by the size of the vessel. From alcohol, on the other hand, large compact prisms are obtained.

*Pyridine.* 2-Stilbazole dibromide (3.4 g.) was boiled with pyridine (6 g.) for 1 hour. The dark solution was poured into water, and the solid crystallised from alcohol; m. p.  $90-91^{\circ}$ , mixed m. p. (with 2-stilbazole)  $90-91^{\circ}$ . Yield, 1.35 g. (75% of the theoretical).

*Piperidine.* 2-Stilbazole dibromide (6.8 g.) was heated on the water-bath with piperidine (5 g.) during 10 minutes. The semi-solid product was treated with water (30 c.c.) and extracted with benzene. The solvent was removed and the residual oil crystallised from light petroleum; m. p.  $74-75^{\circ}$ ; yield, 3.3 g. of monobromostilbazole (63% of the theoretical). A small quantity of oil was not examined.

*Potassium iodide.* 2-Stilbazole dibromide (0.2049 g.) was boiled with potassium iodide (4 g.) in alcoholic solution (100 c.c.). The reaction was followed by titration of aliquot portions of the liquid, largely diluted with water, with *N*/10-sodium thiosulphate solution. After 3 hours, the rate of liberation of iodine slackened and became constant; total, 0.1820 g.  $I_2$ . In a parallel experiment from which the dibromide was omitted, 0.025 g.  $I_2$  was liberated; difference 0.1570 g. Theoretical, calculated from the equation  $C_5NH_4 \cdot CHBr \cdot CHBrPh + 2KI = C_5NH_4 \cdot CH \cdot CHPh + 2KBr + I_2$ , 0.1527 g.

*Hydriodic acid.* 2-Stilbazole dibromide (0.110 g.) was heated on the

water-bath with potassium iodide (0.10 g.) in acetic acid (10 g.). The iodine liberated was titrated with *N*/10-sodium thiosulphate solution. Found, 0.080 g. The equation  $C_5NH_4 \cdot CHBr \cdot CHBrPh + 2HI = C_5NH_4 \cdot CH \cdot CHPh + 2HBr + I_2$  requires 0.0804 g.

A mixture of 2-stilbazole dibromide (3.4 g.; 1 mol.), acetic acid (10 c.c.), and potassium iodide (3.34 g.; 2 mols.) was heated to boiling and rapidly cooled to 15°. The brown crystalline mass which separated was removed, pressed, and treated with sulphurous acid to remove iodine. The yellow needles obtained softened at 96°, melted at 100°, resolidified at 116–120°, and again melted at 179–180°. A portion crystallised from hot water and dried at 100° had m. p. 182–184°, and mixed m. p. (with an authentic specimen of 2-stilbazole hydriodide) 182–184° (Found: *I*, 36.6; *M*, by titration with *N*/10-NaOH, 341. Calc. for  $C_{13}H_{11}N, HI, 2H_2O$ : *I*, 36.8%; *M*, 345). A portion gave with sodium carbonate solution a white solid, m. p. 90–91°; mixed m. p. (with 2-stilbazole) 90–91°.

*Phenol.* 2-Stilbazole dibromide (2.5 g.) was heated with phenol (0.50 g.; excess) at the melting point of the mixture during 2 hours. The solid product was dissolved in hot alcohol; needles of hydrated 2-stilbazole hydrobromide, m. p. 187–189°, separated on cooling. Treatment with sodium carbonate gave 2-stilbazole, m. p. 90–91°. The alcoholic mother-liquor was poured into water; the red solid obtained, crystallised from hot water, had m. p. 94–95°, and mixed m. p. (with tribromophenol) 94–95°.

An authentic specimen of 2-stilbazole hydrobromide was prepared from the pure base in needles, readily soluble in hot water and sparingly soluble in alcohol; m. p. (anhydrous) 188–189° (Found: *M*, 280.5.  $C_{13}H_{11}N, HBr, H_2O$  requires *M*, 280).

The experiment was repeated, sufficient phenol being used to remove only half the bromine as tribromophenol; the result was as before.

*Action of Sodium Ethoxide upon 2-Stilbazole Dichloride.*—To a solution of sodium (0.50 g.) in anhydrous alcohol (10 c.c.), 2-stilbazole dichloride (3 g.) was added, and the solution boiled during 10 minutes. The alcohol was removed, the residue treated with water and extracted with benzene, the solvent removed, and the oil dissolved in light petroleum; colourless prisms of monochlorostilbazole, m. p. 63°, readily soluble in alcohol and sparingly soluble in light petroleum, were obtained (Found: *Cl*, 16.5.  $C_{13}H_{10}NCl$  requires *Cl*, 16.4%).

The authors are indebted to Professor F. S. Kipping, F.R.S., for his interest in this work, and to the South Metropolitan Gas Company for a supply of pyridine bases.

LXXII.—*Digoxin, a New Digitalis Glucoside.*

By SYDNEY SMITH.

IN recent years it has been shown that the leaves of *Digitalis lanata* have a greater physiological activity than those of *Digitalis purpurea*, the species used in medicine; e.g., Wokes (*Quart. J. Pharm. Pharmacol.*, 1929, 2, 292) found the potency of a specimen of *Digitalis lanata* to be 3.5—4 times that of the international standard leaf.

The total glucosides of the leaves of this species were therefore isolated and fractionated in order to separate the glucosides and compare them with those from the official species. This part of the work is not yet completed, but during the fractionation a glucoside was obtained in small amount differing from those hitherto known. This new glucoside, which has been named *digoxin*, resembles gitoxin in its sparing solubility in chloroform, but is readily distinguished from it by giving an olive-brown colour completely free from red when dissolved in acetic acid containing a trace of ferric chloride and treated with sulphuric acid (Keller reaction). In the latter respect it is similar to pure digitoxin. Digoxin is optically active. It is very easily hydrolysed and gives a crystalline genin and only one sugar, digitoxose. The results of combustion and the molecular-weight determinations of the genin suggest the empirical formulæ  $C_{41}H_{64}O_{14}$  and  $C_{23}H_{34}O_5$  for digoxin and *digoxigenin* respectively and the yields of the hydrolytic products are in agreement with the equation  $C_{41}H_{64}O_{14} + 3H_2O = C_{23}H_{34}O_5 + 3C_6H_{12}O_4$ .

Dr. J. W. Trevan, of the Wellcome Physiological Research Laboratories, has kindly estimated the activity of the glucoside and its genin by the Trevan and Boock frog method with the following results: 1 mg. of digoxin is equivalent to 0.28 mg. of standard ouabain and 1 mg. of digoxigenin is equivalent to 0.026 mg. of standard ouabain.

## EXPERIMENTAL.

The total glucosides were dissolved in acetone and kept for some time until a mixture of the less soluble glucosides (fraction A) separated. The mother-liquor was diluted with water and allowed to stand. The precipitate (fraction B) was separated, and the filtrate saturated with sodium chloride (fraction C). Each of these three precipitates contained digoxin. The acetone crop (A) may be worked up by dissolving it in 80% alcohol and concentrating the solution under diminished pressure until solid separates; after filtering, the solution is concentrated and one or two further crops are obtained. By boiling each fraction with chloroform or ethyl acetate,

a sparingly soluble portion is obtained which is purified by solution in 80% alcohol and concentration as before. The purification is continued in this way until the specific rotation remains unchanged and the Keller reaction gives an olive-brown colour completely free from any trace of red. Fractions B and C may be worked up by dissolving them in alcohol and gradually diluting the solutions with water. The less soluble fractions are then purified by the process described for fraction A.

*Digoxin* crystallises from dilute alcohol or from pyridine and water in colourless, four- or five-sided plates free from solvent (Found in material dried at 100° in a vacuum: C, 63.1, 63.1, 63.0; H, 8.2, 8.3, 8.2.  $C_{41}H_{64}O_{14}$  requires C, 63.0; H, 8.3%). The m. p. varies with the rate of heating, but when placed in a bath at 260° and slowly heated, the substance melts and decomposes at about 265° (corr.). It is almost insoluble in chloroform, ethyl acetate, and acetone, but dissolves in a mixture of chloroform and alcohol or in pyridine or dilute alcohol. It is more soluble in hot 80% alcohol than gitoxin. In pyridine solution the specific rotation  $[\alpha]_{5461}^{20} = +13.3^\circ$  ( $c = 1.5$ ). Like digitoxin and gitoxin, digoxin gives on heating an oily distillate which readily crystallises.

*Hydrolysis of digoxin.* Digoxin (2.903 g. dried at 100° in a vacuum) was boiled under reflux with a mixture of alcohol (290 c.c.) and water (290 c.c.) containing 2.25 c.c. of hydrochloric acid ( $d$  1.16) for  $\frac{1}{2}$  hour. The solution was neutralised with sodium hydroxide and concentrated under reduced pressure. The genin separated in well-defined prisms and after drying at 80° in a vacuum weighed 1.387 g. (47.8%). The filtrate and washings were diluted to 200 c.c. and after addition of 0.4 c.c. of concentrated hydrochloric acid the mixture was heated on a water-bath for 20 minutes. After cooling, the liquid was extracted with chloroform, which removed a trace of sticky material (0.037 g.; 1.3%). The aqueous liquid was neutralised with sodium hydroxide and evaporated to dryness under diminished pressure, the residue was thoroughly dried over sulphuric acid in a vacuum desiccator and extracted with dry acetone, and the extract was evaporated to dryness. The residual sugar rapidly crystallised and after drying at 80° in a vacuum weighed 1.541 g. (53.1%).

*Digoxigenin.* The anhydrous genin without purification had  $[\alpha]_{5461}^{20} = +25.8^\circ$  ( $c$  in methyl alcohol, 1.04). After one crystallisation from ethyl acetate it had  $[\alpha]_{5461}^{20} + 27.0^\circ$  ( $c$  in methyl alcohol, 1.77), and this value was not altered by further crystallisation. *Digoxigenin* separates from ethyl acetate in stout colourless prisms free from solvent, m. p. 222° (corr.). It crystallises from dilute alcohol in prismatic rods containing water of crystallisation. When dissolved

in glacial acetic acid containing a trace of ferric chloride and treated with sulphuric acid, it gives a greenish-yellow ring (Found for the air-dried crystals: C, 64.5; H, 8.8; loss at 80° in a vacuum, 8.6.  $C_{23}H_{34}O_5 \cdot 2H_2O$  requires C, 64.7; H, 9.0;  $H_2O$ , 8.5%. Found for the substance dried in a vacuum at 80°: C, 70.7, 70.5, 70.7, 70.4; H, 8.6, 8.6, 8.7, 8.7; *M*, in camphor, 394, 366, 372.  $C_{23}H_{34}O_5$  requires C, 70.7; H, 8.8%; *M*, 390.3).

*Digitoxose*. The sugar (1.541 g.) without purification had  $[\alpha]_{5461}^{20} + 55.5^\circ$  (*c* in water, 1.6). After crystallisation from ethyl acetate it had  $[\alpha]_{5461}^{20} + 55.6^\circ$  and melted at 104°. Yield of successive crops, 1.134 g., 0.145 g., and 0.084 g. (total, 88.5%). By recrystallisation the *m. p.* was raised to 112°. Cloetta (*Arch. Exp. Path. Pharm.*, 1926, 112, 276) recorded 110°. The sugar gave the Keller reaction characteristic of digitoxose (Found: C, 48.9, 48.6; H, 8.2, 8.2. Calc. for  $C_6H_{12}O_4$ : C, 48.6; H, 8.2%).

The author is indebted to Dr. Hill, Director of the Royal Botanic Gardens, Kew, for the botanical verification of the material used and to Mr. A. Bennett for the micro-analyses.

[Received, February 8th, 1930.]

### LXXIII.—*Properties of Conjugated Compounds. Part VIII. Addition of Bromine to $\alpha\delta$ -, $\alpha\gamma$ -, and $\beta\gamma$ -Dimethylbutadienes.*

By ERNEST HAROLD FARMER, CYRIL DUNN LAWRENCE, and WILLIAM DALLAS SCOTT.

THE experiments here described are a continuation of the investigation on the influence of substitution in the butadiene chain on (1) the tendency towards the initial formation of adjacent and terminal dibromides and (2) the related structural mobility of the dibromides themselves. As in previous papers, all methods of determining the constitutions of the bromination products which involve the formation and decomposition of cyclic oxides, interactions with sodiomalonic esters, amines, etc., have been rejected; reliance has been placed on the detailed examination of the action of permanganate and of ozone, and densities and refractive indices have frequently been determined as an aid in detecting isomerisation. The conclusions reached for each hydrocarbon are based on the observations made over a large number of bromination and oxidation experiments.

*$\alpha\delta$ -Dimethylbutadiene.*—The addition of bromine to  $\alpha\delta$ -dimethylbutadiene has been examined by Duden and Lemme (*Ber.*, 1902, **35**, 1338), who obtained their hydrocarbon by the removal of hydrogen bromide from  $\beta\epsilon$ -dibromohexane with quinoline. The boiling point of their specimen was somewhat high ( $87$ – $89^\circ$ ),\* but evidence was brought forward which showed that the major portion of the (distilled) dibromide obtained therefrom was the terminal dibromide.

Our experiments have shown that the dibromide produced is a stable compound having no recognisable tendency towards isomerisation at room temperature or on heating. The densities and refractive indices of freshly prepared, distilled, and aged specimens are identical, and the evidence of oxidation processes indicates the absence therefrom of any proportion of an isomeride. Consequently the formation of a homogeneous terminal dibromide from this hydrocarbon appears to be more complete than in any instance yet investigated. In order to show this directly, attempts have been made to convert the dibromide quantitatively into its dihydroxy-derivative,  $\text{CHMeBr}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CHMeBr}$ , a solid form of which (see p. 516) is readily produced during oxidation with permanganate. Invariably, however, two dibromoglycols are formed—the solid already mentioned (representing about 60% of the dibromide which suffers oxidation) and a liquid which loses hydrogen bromide during distillation. The former resists the further action of cold permanganate, but the latter is so readily attacked that its degradation proceeds side by side with the preliminary hydroxylation of the hydrocarbon dibromide. Consequently the liquid dibromoglycol is always accompanied by considerable quantities of  $\alpha$ -bromopropionic, lactic, and pyruvic acids: presumably these are its own degradation products, but since it is obtainable only in small yield, a direct demonstration of its oxidisability to these substances has not been possible.

*$\alpha\gamma$ -Dimethylbutadiene.*—The hydrocarbon was obtained by dehydration of  $\beta$ -methylpentane- $\beta\delta$ -diol,  $\text{OH}\cdot\text{CMe}_2\cdot\text{CH}_2\cdot\text{CHMe}\cdot\text{OH}$ , the reduction product of diacetone alcohol. Our early experiments on the oxidation of the derived dibromide at once showed that the constitution of  $\alpha\alpha$ -dimethylbutadiene assigned to the hydrocarbon by Kyriakides (*J. Amer. Chem. Soc.*, 1914, **36**, 994) was incorrect.

\* The homogeneity of conjugated hydrocarbons prepared by recorded methods has been concurrently investigated by one of us with Dr. F. L. Warren. The results of this investigation will shortly be published together with the physical properties of the seven mono- and di-methylbutadienes. For this reason, physical data (other than boiling points) relating to hydrocarbons are here omitted. For convenience in this and subsequent papers, the Geneva names for the hydrocarbons are restricted to the experimental portion.

but details of the establishment of the alternative constitution are here omitted because Diels and Alder (*Annalen*, 1929, 470, 98) have shown that this and several other methods believed to give the  $\alpha\alpha$ -hydrocarbon yield in fact the  $\alpha\gamma$ -isomeride. The intermediate dehydration product, represented as  $\text{CMe}_2\cdot\text{CH}\cdot\text{CHMe}\cdot\text{OH}$  by Kyriakides, is probably an isomeric methylpentenol, since we could not isolate acetone from its oxidation products.

The oily dibromide obtained from  $\alpha\gamma$ -dimethylbutadiene is unstable, suffering partial degradation to a monobromide on heating or (slowly) on standing. Since at *each* successive distillation a considerable portion of the dibromide is broken down, leaving a residue which is to all appearances homogeneous and without tendency towards isomeric change, there is nothing to suggest that a preferential degradation of one component in a mixture of  $\alpha\beta$ - (or  $\gamma\delta$ -) and  $\alpha\delta$ -dibromides is taking place. The densities of freshly prepared undistilled and distilled samples do indeed differ slightly (1.586 and 1.603 respectively), probably owing to the formation of a trace of monobromide during the isolation of the former. Permanganate oxidation experiments with distilled and undistilled specimens of the dibromide show that *at least* it consists largely of the terminally dibrominated compound  $\text{CHMeBr}\cdot\text{CH}\cdot\text{CMe}\cdot\text{CH}_2\text{Br}$ , and both permanganate and ozone oxidations fail to furnish any vestige of positive evidence pointing to the initial occurrence of a proportion of an  $\alpha\beta$ - or  $\gamma\delta$ -isomeride. Although ozonolysis might be expected to reveal the presence of any appreciable proportion of either of these forms, the difficulties attending the examination of the products of permanganate oxidation and of ozonolysis are such that small quantities of their degradation products could remain undetected. Permanganate oxidation follows a course similar to that outlined in the preceding section, and therefore quantitative conversion into stereoisomeric dibromoglycols is not possible.

*$\beta\gamma$ -Dimethylbutadiene.*—The bromination of  $\beta\gamma$ -dimethylbutadiene has been extensively investigated (Mariuza, *J. Russ. Phys. Chem. Soc.*, 1889, 21, 434; Couturier, *Ann. Chim.*, 1892, 26, 480; Kondakov, *J. pr. Chem.*, 1900, 62, 166; Courtot, *Bull. Soc. chim.*, 1906, 35, 969). The completion of our study of this process synchronised with the publication of further work on the subject by Macallum and Whitby (*Trans. Roy. Soc. Canada*, 1928, III, 22, 33), to whom we are indebted for an early copy of their memoir.

*$\beta\gamma$ -Dimethylbutadiene*, when brominated at a low temperature, readily yields a mixture of dibromides. The main constituent is a solid terminal dibromide,  $\text{CH}_2\text{Br}\cdot\text{CMe}\cdot\text{CMe}\cdot\text{CH}_2\text{Br}$ , m. p.  $47^\circ$  (Kondakov, *loc. cit.*; Macallum and Whitby, *loc. cit.*; p. 520 below), but the nature of the residual liquid product has not been determined.

Assuming that the liquid, like the solid, is an  $\alpha\delta$ -compound, Macallum and Whitby attempted to determine which is the *cis*- and which the *trans*-form by causing reaction with diethylamine. The results were anomalous and the authors state that the explanation may be that the liquid dibromide is a mixture rather than a chemical individual.

The liquid dibromide cannot be freed from the dissolved solid form by repeated freezing and filtration (with or without a solvent); the freezing point of the residual liquid, however, rises considerably and the density diminishes. A close estimate of the composition of the dibromide mixture has consequently not been possible. The solid form is certainly produced originally to the extent of more than 80% of the total yield, and it gives, on heating at 100°, a liquid which is *in no respect distinguishable* (this applies to general properties and behaviour on oxidation and distillation) from that obtained by direct bromination. This liquid, after being freed as far as possible from the solid form, represents about 18% of the bromide taken. The reverse change, liquid  $\rightarrow$  solid, can be brought about by heating for a short time at 100°; we have not thus succeeded in obtaining so high a yield as 80% of the solid form, but estimation has been difficult with the comparatively small quantities of purified material available. The use of quinoline perbromide as a brominating agent causes a considerable diminution in the proportion of solid bromide separable from the product but offers practical difficulties in large-scale preparations.

Macallum and Whitby state that both liquid and solid dibromides distil at 105–110°/18.5 mm. We have found, by repeated tests with the "frozen out" liquid, that distillation begins at 101° and continues to 105° at 15 mm. (the solid distils at 103–105° with some change to the liquid form); the character of the fractions collected over 1° ranges indicates that the solid form (already present or formed during distillation) progressively volatilises in the vapour of the liquid form. Nevertheless, the difference in boiling point of the two substances is much smaller than that of the corresponding butadiene derivatives.

Long-continued degradation experiments have failed to demonstrate that the liquid form is the  $\alpha\beta$ -dibromide. In all our oxidations, as was to be expected, degradation products from the solid dibromide appeared. Otherwise the products from the two dibromides differed considerably. Ozonolysis of  $\alpha\beta$ -hydrocarbon dibromides has rarely been satisfactory in our hands; gross decomposition, involving loss of hydrogen bromide, usually occurs during hydrolysis of the ozonide, and, in this instance, although the presence of formaldehyde and of a bromo-ketone other than bromoacetone could be detected amongst the non-resinous products, the expected

ketone  $\text{CH}_3\text{CO}\cdot\text{CMeBr}\cdot\text{CH}_2\text{Br}$  (or its debromination product, methyl isopropenyl ketone) could not be recognised. Nevertheless, in view of the fact that ozonolysis of the solid dibromide readily gives bromoacetone in more than 80% of the theoretical yield, the difference in behaviour of the two isomerides on oxidation is hardly to be reconciled with a differentiation of merely *cis-trans*-nature. There remains for consideration the possibility that the liquid portion of the bromination product is a mixture of two liquid dibromides, namely, the  $\alpha\beta$ - and the *cis*- $\alpha\delta$ -compound. No adequate ground for considering this to be the case has been encountered, yet statements or suggestions to the effect that the *cis*- $\alpha\delta$ -dibromide is the principal constituent of the bromination product are exceedingly difficult to prove or disprove: it is very doubtful if any constitutional significance is to be attached to the double decomposition reactions (Braun, *Ber.*, 1922, 55, 3536; Macallum and Whitby, *loc. cit.*) of substances so mobile as those under consideration.

In this series of papers, the addition of bromine to hexatriene, butadiene, cyclopentadiene, cyclohexadiene, and three of the five dimethylbutadienes has been discussed. Amongst these instances the isomerising capacity of dibromide forms is widespread: yet with fair certainty in the case of  $\alpha\delta$ -dimethylbutadiene and with a high degree of probability in the case of  $\alpha\gamma$ -dimethylbutadiene it has been shown that the bromination product is entirely non-mobile; moreover, in neither of the latter instances has it been possible in a large number of experiments (free bromine being the addendum) to alter recognisably the composition of the bromination mixture. It seems unlikely, therefore, that experimental conditions leading to the production of only  $\alpha\beta$ - ( $\gamma\delta$ -) forms could be obtained in these instances, and, that being so, the *general* possibility in this direction disappears. Of the hydrocarbons mentioned above, only cyclohexadiene (J., 1929, 172) has been considered to suffer complete  $\alpha\beta$ -dibromination, and in determining the orientation of its dibromides importance has been attached to the great contrast between the oxidisability and extent of degradation of the dibromoglycols from original and from derived forms. It is now clear that there is quite a considerable, although less marked, difference in oxidisability of the isomeric dibromoglycols from  $\alpha\delta$ -forms (the carbon atoms carrying bromine are not here, however, oxidised to carboxyl) and to this extent the evidence formerly relied on is weakened. An attempt is being made to improve the oxidative technique employed in the degradation of dibromoglycols, and it is hoped later to supplement the evidence already brought forward in connexion with the constitution of the cyclohexadiene addition products.

## EXPERIMENTAL.

$\alpha\delta$ -Dimethylbutadiene ( $\Delta^{88}$ -hexadiene) was prepared by the catalytic dehydration of ethylpropenylcarbinol (Kyriakides, *J. Amer. Chem. Soc.*, 1914, **36**, 994). The hydrocarbon, after being thoroughly washed and dried, was fractionated over sodium, the portion of b. p.  $80-82^\circ$  being used. This preparation gave a quantitative yield of 3 : 6-dimethyl- $\Delta^4$ -tetrahydropthalic anhydride, m. p.  $92^\circ$ , with maleic anhydride (Found: C, 66.7; H, 6.65. Calc. for  $C_{10}H_{12}O_3$ : C, 66.7; H, 6.7%). Diels and Alder (*loc. cit.*, p. 102) give the m. p. as  $95-96^\circ$ .

*Bromination.* This was carried out under conditions similar to those previously described (Farmer and Scott, J., 1929, 172). The dibromination product, after removal of the solvent (both hexane and chloroform were used), was an almost colourless oil (Found: Br, 65.8.  $C_6H_{10}Br_2$  requires Br, 66.1%). It had  $d_4^{20}$  1.621 and  $n_D^{20}$  1.536 immediately after isolation, and almost the same values after it had been (a) slowly distilled or (b) kept at room temperature for several days. On distillation the crude dibromide in the different preparations yielded only insignificant quantities of low-boiling material. The distillate was always a colourless oil (b. p.  $85^\circ/11$  mm.,  $d_4^{20}$  1.622,  $n_D^{20}$  1.534. Found: Br, 66.2%) which appeared to be homogeneous (Duden and Lemme, *loc. cit.*, also give b. p.  $85^\circ/11$  mm.). Distilled and undistilled specimens of the substance were repeatedly submitted to oxidation with permanganate and with ozone (see below) in order to detect admixed isomeric dibromides, if such were present. The failure to find even small amounts of the degradation products of the latter, and the complete absence of any detectable tendency to partial isomerisation as revealed by changing physical constants, point to the fact that the addition product is pure  $\beta\epsilon$ -dibromo- $\Delta^7$ -hexene.

Unless the bromination was carried out in very dilute solution, there was a tendency towards the production of tetrabromides.

*Oxidation of  $\beta\epsilon$ -Dibromo- $\Delta^7$ -hexene.*—The oxidation with neutral permanganate at  $0^\circ$  was carried out essentially as previously described (Farmer and Scott, J., 1929, 172). Since no difference could be detected between the oxidation products of distilled and of undistilled specimens of the dibromide, only typical experiments are here included. In these, 20 g. portions of the dibromide, dissolved in acetone, were supplied with (a) 1 atom and (b) 4 atoms of oxygen per molecule.

(a) On removal of the acetone from the filtered oxidation liquor in a current of air, a semi-solid mixture separated containing unchanged dibromide. This was combined with a small residue from the acetone washings of the manganese mud. The solid

portion of the mixture was removed, and the filtrate thoroughly extracted with water; the residue was unchanged dibromide. The aqueous liquor, together with the cold aqueous extract of the manganese mud, yielded, on extraction with pure ether, a syrup from which crystals of the solid material separated. This solid, which crystallised from petroleum in colourless prisms, m. p.  $95^{\circ}$ , was  $\beta$ -dibromohexane- $\gamma$ -diol and was doubtless identical with the dibromohexanediol of Duden and Lemme, for which no m. p. is recorded (Found: Br, 58.0.  $C_6H_{12}O_2Br_2$  requires Br, 58.0%). On further oxidation with permanganate it was converted into  $\alpha$ -bromopropionic acid, mixed with some lactic acid, and finally into pyruvic acid (phenylhydrazone, m. p.  $191^{\circ}$ ; mixed m. p. with authentic specimen,  $191^{\circ}$ ); with aqueous chromic acid it gave a 75% yield of crystalline  $\alpha$ -bromopropionic acid (Found: Br, 52.4; equiv., 153. Calc.: Br, 52.3%; equiv., 153).

The water-soluble syrup accompanying the solid dibromohexanediol, when freed as thoroughly as possible from the latter, amounted to 5–10% of the total oxidation products isolated. Although it differed considerably from the solid dibromoglycol in its greatly inferior stability towards permanganate and towards heat, it appeared to be a stereoisomeride (or mixture of stereoisomerides) of  $\beta$ -dibromohexane- $\gamma$ -diol (Found: Br, 58.4%). When it was heated under reduced pressure, decomposition took place, giving dehydrobromination products which appeared to be partly of cyclic-oxide and partly of ethylenic type (the main portion, b. p.  $115$ – $125^{\circ}/1$  mm., corresponded closely in bromine content to the formula  $C_6H_{11}O_2Br$ ); the highest fraction (about  $1/3$  of the whole), however, consisted of the solid dibromoglycol, which appeared to have been formed by isomerisation during heating. The liquid dibromoglycol was obtained in reasonably pure condition only at a late stage in the experiments and the amount of material accumulated was insufficient for making trustworthy observations as to its oxidation products. The aqueous liquors, when acidified and extracted with ether, yielded a small quantity of acidic liquid. This was fractionated and consisted mainly of  $\alpha$ -bromopropionic acid; pyruvic acid was present in the very small, low-boiling fraction.

(b) In effecting more complete oxidation of distilled and of undistilled specimens of the dibromide it was desired to search for  $\alpha\beta$ -dibromobutyric and  $\alpha$ -bromocrotonic acids, the acidic fission products of an  $\alpha\beta$ -dibromide (acetic acid, the complementary fission product, if detected, could have arisen from the acetone used as solvent). The acid product, when carefully fractionated, was found to consist mainly of  $\alpha$ -bromopropionic acid, mixed with lactic acid

and a little pyruvic acid—this mixture gave excellent yields of pyruvic acid on further oxidation—but  $\alpha\beta$ -dibromobutyric or  $\alpha$ -bromocrotonic acid could not be found.

The absence of any significant quantity of an  $\alpha\beta$ -dibromide followed, however, more convincingly from the result of parallel ozonisation experiments. In all these experiments the decomposition of the ozonide by water was carried out at the lowest effective temperature while carbon dioxide was passed through the apparatus to sweep out any acetaldehyde or other volatile product that might have been formed. Immediately the decomposition was complete the cold aqueous reaction product was treated with 30% hydrogen peroxide and kept for 12 hours (isolation of the brominated products as aldehydes was not possible owing to their facile polymerisation). In no experiment could a trace of acetaldehyde, or indeed any highly volatile product, be detected; similarly, none of the degradation products to be expected from an  $\alpha\beta$ -dibromide could be separated or derived from the acidic reaction product.

*$\alpha\gamma$ -Dimethylbutadiene* (*8-Methyl- $\Delta^{8,9}$ -pentadiene*).—The hydrocarbon (see p. 511), after being thoroughly washed with water and fractionated over sodium, boiled at 75.8–76.0°. It gave a quantitative yield of the maleic anhydride addition compound.

*Bromination.* Both hexane and chloroform were used as solvents during bromine addition, but no difference could be detected in the products. The undistilled dibromide,  $d_4^{20.5}$  1.624, was an almost colourless oil (Found: Br, 66.1.  $C_6H_{10}Br_2$  requires Br, 66.1%).

On distillation the dibromide decomposed to an extent which varied in different experiments. Fractions were collected, as shown below, some carbonised residue always remaining in the flask.

B. p. at 22 mm.	Proportion (%).	Bromine content (%).
70—86°	3—7	52.8
86—96	6—11	61.2
96—104	50—80	66.0
104—115	10—15	—

The bromine content showed that, although more than half the distilled material consisted of dibromide, a considerable portion had lost hydrogen bromide. At each subsequent redistillation of the dibromide fraction (b. p. 101–103°/22 mm.) a partly carbonised residue and a low-boiling fraction (below 80°/22 mm.) were again obtained, the yield of the latter depending to some extent on the rate of distillation. Redistillation of the low-boiling portions yielded a colourless oil, b. p. 60–62°/22 mm., which was apparently an almost pure bromo- $\alpha\delta$ -dimethylbutadiene (Found: Br, 51.1.

$C_6H_9Br$  requires Br, 49.6%). As a result of the observations here recorded, the original dibromination product is regarded as pure or only slightly impure  $\beta\epsilon$ -dibromo- $\delta$ -methyl- $\Delta^8$ -pentene.

*Oxidation of  $\beta\epsilon$ -Dibromo- $\delta$ -methyl- $\Delta^8$ -pentene.*—Here also, repeated experiments disclosed no constitutional difference between freshly prepared, undistilled specimens, and the dibromide fraction of b. p. 101–103°/22 mm.; accordingly, in the following account of oxidation by (a) ozone and (b) neutral permanganate, the nature of the specimen is not indicated.

(a) The dibromide, dissolved in chloroform, was submitted to ozonisation for 24 hours. The crude ozonide obtained on removal of the chloroform was decomposed by gentle warming with water and the decomposition products were extracted with pure ether. The extract was washed with sodium bicarbonate solution, and the ether removed. The residue on distillation yielded the fractions (i) b. p. 50–60°, (ii) b. p. 60–95°, and (iii) b. p. 95–115° at 22 mm. Of these, the first consisted almost wholly of bromoacetone (Found : Br, 56.2. Calc. for  $C_3H_5OBr$  : Br, 58.4%. Semicarbazone, m. p. 143°; mixed m. p. with authentic specimen, 143°) and the last consisted partly of unchanged dibromide. As  $\alpha$ -bromopropionaldehyde, the fission product complementary to bromoacetone, is destroyed by distillation, it was necessary to isolate it as the corresponding acid. Accordingly in another experiment the aqueous liquor containing the decomposed ozonide was allowed to stand with hydrogen peroxide. The product, after the neutral material had been removed in ether, was acidified and thoroughly extracted. The dried extract yielded an acidic liquid, from which fractions of b. p. 90–105°/757 mm. (40–100°/22 mm.) and 100–120°/22 mm. were obtained; the former satisfied no test for formic acid or acetic acid, and the latter, consisting of somewhat impure bromopropionic acid, was readily converted successively into sodium lactate and pyruvic acid (phenylhydrazone, m. p. 191°; mixed m. p. with an authentic specimen, 191°). It was thus established that both fission products of an  $\alpha\delta$ -dibromide were produced in considerable amounts; it remained to search for fission products of an  $\alpha\beta$ - and of a  $\gamma\delta$ -dibromide. Since little success attended the manipulation or attempted isolation of the non-volatile brominated aldehydes and the acids derived therefrom by gentle oxidation, effort was especially directed to the recognition of even traces of formaldehyde (from an  $\alpha\beta$ -dibromide) or of acetaldehyde (from a  $\gamma\delta$ -dibromide). The vapours generated during the hydrolysis of ozonide specimens were therefore swept by a stream of carbon dioxide into water and into an alcoholic solution of  $\beta$ -naphthol. In the many experiments carried out, the formation of neither formaldehyde nor acetaldehyde

could be detected by odour, by the formation of a  $\beta$ -naphthol derivative, or by other tests.

(b) The oxidation of the dibromide by neutral permanganate at  $0^\circ$  (1 atom of oxygen per molecule of dibromide) was carried out in acetone solution in the usual way. After removal of the manganese mud and acetone, the aqueous oxidation liquid deposited a solid and an oily liquid. The former was a solid dibromoglycol, which crystallised from petroleum in colourless prisms, m. p.  $94-95^\circ$  (Found: Br, 58.0.  $C_6H_{12}O_2Br_2$  requires Br, 58.0%); the latter contained bromoacetone (semicarbazone, m. p.  $143^\circ$ ) and unchanged dibromide, both of which were readily separated, but the remaining brominated material decomposed on attempted distillation at 1 mm. pressure. The solid dibromoglycol was  $\beta$ -dibromo- $\delta$ -methylpentane- $\gamma$ -diol. When gently oxidised with aqueous chromic acid, it yielded an oil, the neutral portion of which was bromoacetone and the acidic portion was converted into pyruvic acid by hydrolysis and subsequent oxidation with permanganate. Since the solid dibromoglycol was obtained in much smaller yield than the corresponding compound from  $\alpha$ -dimethylbutadiene, attempts were made to isolate a second isomeric compound. The oxidation products, however, proved too intractable for success in this direction, and attempts to demonstrate by permanganate oxidation anything beyond the fact that a considerable proportion of the dibromide suffered decomposition into the appropriate products proved unprofitable.

*$\beta$ -Dimethylbutadiene.*—The hydrocarbon was prepared from pinacol by the method of Kyriakides (*J. Amer. Chem. Soc.*, 1914, **36**, 987). It was very thoroughly washed, dried, and fractionated; after a final distillation over sodium, it boiled at  $69.5-70^\circ/765$  mm. Yield, 60%.

*Bromination.* The addition of bromine was carried out in chloroform, carbon disulphide, purified petroleum, ether, and hexane, at  $-15^\circ$ . Removal of the solvent under reduced pressure yielded a pale yellow semi-solid mass, from which liquid and solid components were separated by mixing it with light petroleum and freezing out the solid: this was so excessively soluble in the liquid bromide that after six freezings and filtrations only an indifferently good separation was effected. Working without a solvent, or with other solvents, gave even less satisfactory results. The total yield of solid separated was slightly more than 80% of the bromination product. All operations with the bromides were carried out in front of a powerful suction fan on account of their lachrymatory nature.

*The solid portion of the bromination product.* This consisted entirely of the  $\alpha$ -dibromo- $\beta$ -dimethyl- $\Delta^2$ -butene (colourless needles, m. p.  $47^\circ$ . Found: Br, 66.5. Calc.: Br, 66.4%) described

by Kondakov (*loc. cit.*). Concerning its easy and very extensive degradation to bromoacetone by permanganate oxidation and by ozonolysis, our results agreed entirely with those of Kondakov and of Macallum and Whitby (*loc. cit.*).

When heated at  $100^{\circ}$  for 1 hour, the solid dibromide suffered partial conversion into a liquid. This liquid, freed as thoroughly as possible from unchanged solid, amounted to about 18% of the total—a proportion that could not be increased by prolonging the period of heating (decomposition became serious on long heating). It had invariably the correct bromine content and showed no appreciable difference from the directly obtained liquid dibromide when submitted to most of the operations and reactions employed in the examination of the latter. The change produced by heating took place to some extent during distillation, causing the pure substance to boil over a range ( $103\text{--}105^{\circ}/15\text{ mm.}$ ); the distillate yielded a small proportion of oily dibromide.

*The liquid portion of the bromination product.* When strongly cooled, the liquid product solidified to a hard crystalline mass; this rapidly liquefied when the temperature rose, leaving crystals of the solid form temporarily undissolved. It distilled completely between  $101^{\circ}$  and  $105^{\circ}$  at 15 mm., the fractions collected at  $1^{\circ}$  intervals freezing with different degrees of ease. Attempts were made, by distilling a considerable quantity of the liquid dibromide, to isolate a pure compound, but none of the fractions appeared to be free from the solid dibromide: indeed, distillation gave no better separation than filtration and resulted in considerable loss of liquid material by isomerisation. Such isomerisation was readily effected by heating the liquid compound at  $100^{\circ}$  for a few minutes; after dilution and cooling, the solid compound could be filtered off.

*Ozonolysis of the Liquid Bromination Product.*—The liquid, dissolved in chloroform and cooled in an ice-salt mixture, was ozonised for 8 hours. The ozonide decomposed very slowly when gently heated with water, giving a large quantity of resinous material. The aqueous liquor, in which formaldehyde could be detected, was submitted to steam distillation; the volatile degradation products were extracted with ether and fractionated. The distillate comprised (i) bromoacetone, b. p.  $45\text{--}50^{\circ}/16\text{ mm.}$  (semicarbazone, m. p.  $143^{\circ}$ ; Found: Br, 58.6. Calc.: Br, 58.4%); (ii) a bromine-containing mobile liquid, b. p.  $50\text{--}55^{\circ}/16\text{ mm.}$ , which yielded a crystalline precipitate with semicarbazide, the precipitate being halogen-free and giving a red colour with ferric chloride; (iii) a small amount of a mobile bromine-containing liquid, b. p.  $55\text{--}90^{\circ}/16\text{ mm.}$ ; and (iv) a viscous high-boiling fraction which contained some unchanged dibromide but consisted mainly of polymerised material.

The liquid produced by heating the solid dibromide gave exactly similar products, but in neither case was it possible to isolate pure substances directly or indirectly from the distillate.

*Permanganate Oxidation of the Liquid Bromination Product.*—The bromine, in 15–20 g. portions, was suspended in water (or dissolved in acetone) and oxidised with neutral permanganate at 0° (1 atom of oxygen per molecule). The product, worked up in the usual way and freed from traces of acidic matter, was a liquid which yielded on distillation the fractions: (i) bromoacetone, b. p. 45–50°/15 mm.; (ii) and (iii) mobile bromine-containing liquids (partly at least ketonic) similar to the corresponding fractions of the ozonolysis product; (iv) a mobile liquid, b. p. 93°/16 mm., obtained in considerable yield and evidently derived from a dibromoglycol by loss of hydrogen bromide (Found: C, 35.5; H, 5.8; Br, 40.4.  $C_6H_{11}O_2Br$  requires C, 36.9; H, 5.6; Br, 41.0%); (v) a viscous liquid, b. p. 120°/16 mm., apparently derived from a dibromoglycol by loss of hydrogen bromide (Found: C, 33.2; H, 4.9; Br, 45.4%); (vi) a small quantity of a solid dibromoglycol, b. p. 148°/16 mm., which crystallised from petroleum in colourless prisms, m. p. 93° (Found: Br, 57.5.  $C_6H_{12}O_2Br_2$  requires Br, 57.2%). Since this was further oxidisable to bromoacetone, it was *αδ-dibromo-βγ-dihydroxy-βγ-dimethylbutane*. The liquid obtained by heating the solid dibromide yielded similar oxidation products.

For comparison, the solid dibromide was likewise oxidised with permanganate, only 1 atom of oxygen per molecule being used. There were obtained: (i) bromoacetone; (ii) a small amount of viscous liquid, b. p. about 120°/15 mm., which from its nature and composition appeared to be somewhat impure dibromoglycol; (iii) a large amount of the solid dibromoglycol, m. p. 93°, described above. Thus, whereas the solid dibromide yielded two dibromoglycols and some bromoacetone, the liquid yielded (in addition to a minor proportion of the same products) a very considerable proportion of other products, including dihydroxylated compounds which had lost hydrogen bromide. The difference between the oxidation products of the two dibromides was maintained from experiment to experiment; but since permanganate oxidation appeared quite unlikely to furnish conclusive evidence of the constitution of the liquid dibromide, experiments were discontinued.

The authors desire to express to the Chemical Society their thanks for a grant (to W. D. S.) which has defrayed a portion of the cost of the investigation.

LXXIV.—*Properties of Conjugated Compounds. Part IX. The Formation of Bimolecular Reduction Products of Butadiene Acids.*

By CHARLES MILLS CAWLEY, JOHN TREVOR EVANS, and ERNEST HAROLD FARMER.

EVANS and FARMER (J., 1928, 1644) have shown that the addition of hydrogen to conjugated carbon compounds is not invariably terminal, thus taking the first step towards bringing hydrogen into line with other common addenda. It has now been found that the presence of alkyl groups at different positions in the butadiene chain of  $\beta$ -vinylacrylic acid seems to affect the relative extents to which  $\alpha\beta$ - and  $\alpha\delta$ -dihydrogen derivatives are produced: the crudeness of the method of estimating the proportion of the  $\alpha\beta$ -acid\* (Evans and Farmer, *loc. cit.*), however, prevents any confident application of the results to quantitative discrimination between alkylation effects. It has also been found in experiments with different types of butadiene compound, hydrogenated by the action of different metals, media, etc., that the formation of hydrogenated bimolecular compounds is so common that it must be considered a normal feature of reduction. Since the bimolecular compounds are frequently formed side by side with the simple dihydrogen derivatives, their theoretical significance cannot be neglected in a consideration of the mechanism of hydrogen addition.

It has been shown that linkage of monohydrogenated molecules may occur at the  $\beta$ -carbon atom of the butadiene chain. Corresponding linkage of reactant molecules might be expected also to be possible at the  $\delta$ - or the  $\zeta$ -carbon atom and the principle entailed would merely represent an extension of that underlying the formation of pinacols and the bimolecular reduction products of mesityl oxide, ethyl  $\alpha$ -cyano- $\beta\beta$ -dimethylacrylate, etc.

Crotylideneacetone and ethyl crotylidenemalonate were the first instances discovered in which there was a definite departure from the rule respecting terminal hydrogen addition. The reduction products from the former of these have already been described, but the constitutions attributed at the same time to those from the

\* The method presents two unsatisfactory features: (1) The acid mixture must be fractionated so thoroughly that no unreduced acid is left behind. It is well-nigh impossible to do this without sacrificing a portion of the distillate and so running the risk of changing the proportion of the isomerides. (2) In addition to the expected acids the permanganate oxidation product yields syrupy residues which survive re-oxidation processes. These are persistently obtained from the alkylsorbic acids.

latter proved so difficult of establishment that an account of the reduction is only now possible.

The unimolecular hydrogenation products from ethyl crotylidene-malonate appear in quite insignificant quantity when aluminium amalgam is the reducing agent; almost the entire product consists of a mixture of two isomeric bimolecular *esters*, one of which is a solid. It was expected that each of these substances would be correctly represented by one or other of the formulæ (I) and (II).

Although the composition of the substances corresponded with this expectation, it soon became obvious that both representations were incorrect. In the first place, both substances were so saturated that they were quite unaffected by permanganate at 20° or by ozone; in the second place, both substances took up two, and *only two*, atoms of hydrogen in the presence of palladium, the hydrogenation being effected with difficulty. The first of these properties could conceivably be the result of steric hindrance, but the two in combination suggested at once the dicyclic constitution (III) for the original compounds (alternatively, but improbably, IV, for one or both) and the monocyclic constitution (V) for their fully reduced derivatives. It was remarkable that with one exception all the

numerous derivatives prepared from the bimolecular compounds were liquids.

In the detailed examination chief attention was paid to the solid compound. This substance absorbed 4 atoms of bromine per molecule to yield a *tribromide* and 6 atoms of bromine (the limit of absorption) to yield a *tetrabromide*. The bromination process was obviously one of combined substitution and addition so that the results corresponded with the formation of (VI) and (VII) from (III). The corresponding fully reduced ester absorbed, in accordance with formula (V), only 4 atoms of bromine per molecule to yield a *di-bromide* representable by (VIII). Attempts were made to oxidise

to carboxyl the bromomalonic groups in the compounds to which formulæ (VII) and (VIII) apply, but oxidation always proceeded irregularly and failed to yield homogeneous products.

The solid bimolecular ester, when hydrolysed with alkali, yielded a mixture of unsaturated tetrabasic acids—liquid and solid: these appeared from their behaviour with permanganate to be representable by (IX) and (X) respectively. The sodium salts of this acid

mixture, when reduced catalytically, yielded a somewhat impure tetrabasic acid, and this, by decarboxylation, a crude dibasic acid the ethyl ester of which agreed in composition with formula (XI). An apparently identical dibasic acid was obtained by hydrolysing and decarboxylating the fully reduced ester (V). If the bimolecular esters were representable by formula (I) or (II), the corresponding saturated dibasic acid would be dipropyladipic or dimethylsuberic acid—acids almost certainly of highly crystalline character.

Although the general behaviour of the solid bimolecular ester corresponded with the constitution (III), it was desired to gain direct evidence of the existence of an intermolecular bridge-bond at the  $\delta$ -carbon atoms of the original butadiene chains. Since regulated oxidation was out of the question, various drastic oxidising agents were tried. With only one of these, hot chromic acid, was there success. This reagent broke down the solid ester to volatile acids and carbon dioxide to the extent of about 96%, but yielded a small quantity of *s*-dimethylsuccinic acid. This acid always appeared if the conditions of oxidation were not greatly changed, but the yield could not be increased.

Most of the experiments carried out with the solid bimolecular ester were also repeated with the isomeric liquid ester. No essential difference in structure between the two compounds (such, for instance, as that holding between III and IV) is adjudged to exist. Probably the two substances are geometrical isomerides, but con-

ditions for oxidising the liquid isomeride to dimethylsuccinic acid were not discovered: under moderately drastic conditions of operation, complete degradation to volatile products ensued.

In the formation of a "para"-bridged cyclohexane derivative from ethyl crotylidenemalonate, the important features from the point of view of additive mechanism are doubtless the attachment of hydrogen at the  $\alpha$ -carbon atoms and the union of the radicals so formed at the  $\beta$ -carbon atoms. The subsequent establishment of bonds between  $\gamma$ - and  $\delta$ -carbon atoms respectively may be regarded as involving an intramolecular variation of the truxillic acid condensation. Therefore, so far as these examples are concerned, true attachment of hydrogenated radicals at the  $\delta$ -carbon atoms remains to be sought.

Ethyl crotylidenecyanoacetate (two forms) has also been reduced: the product consisted mainly of a bimolecular substance very similar in general properties to that from ethyl crotylidenemalonate. Owing to its high boiling point, however, adequate fractionation could not be carried out and detailed examination was abandoned.

The simple butadiene acids which have been reduced— $\beta$ -vinylacrylic, sorbic,  $\alpha$ -methylsorbic, and  $\beta\gamma$ -dimethylsorbic acids—all give considerable yields of high-boiling products which are undoubtedly bimolecular compounds; cinnamylideneacetic acid also gives an intractable acid mixture very different from the dihydrogenated product obtainable with sodium amalgam. It is hoped later to report in detail on some of these substances.

It might be supposed that constitutive influences in the conjugated compound would determine or seriously affect the formation of bimolecular reduction products as well as that of simple  $\alpha\beta$ - and  $\alpha\delta$ -dihydrogen derivatives. Actually, however, the character of the metal and medium employed in reduction appears to exercise a more important influence. Evans and Farmer looked for a difference in the proportion of  $\alpha\beta$ - and  $\alpha\delta$ -dihydrogen derivatives of sorbic and  $\beta$ -vinylacrylic acids to be obtained by using different metals, and media of different acidity (alkalinity), but since the experimental figure for the  $\alpha\beta$ -acid in each case could only be regarded as a lower limit of production, no definite conclusion was possible. Shortly afterwards, however, the appearance of Willstätter, Seitz, and Bumm's paper on the reduction of terephthalic,  $\Delta^{1:3}$ -dihydroterephthalic and  $\Delta^2$ -tetrahydroterephthalic acids (*Ber.*, 1928, **61**, 871) made plain that the character of the reduction product from the first of these is determined by the hydrogen-ion concentration of the medium and that with pure sodium amalgam, under carefully controlled conditions of alkalinity, the last of these may be reduced *more readily* than the corresponding  $\Delta^1$ -acid. Burton and

Ingold (J., 1928, 904) have now recorded figures representing the comparative extents to which the  $\alpha\beta$ -dihydrogen derivatives of sorbic and vinylacrylic acids are formed by sodium in a weakly alkaline and in a weakly acidic medium, but the effect of different metals remains undetermined. From such comparative experiments as have been made by the authors, aluminium amalgam in an aqueous medium appears specially prone to yield bimolecular compounds and all the compounds referred to above can be obtained through its agency. Since a similar state of affairs holds in the reduction of ethylenic acids and ketones by metals, the attribution of reductive polymerisation to a primarily constitutive cause would appear to be ruled out, and consequently the  $\alpha\beta$ ,  $\beta\gamma$ -ratio of simple dihydrogenated molecules (primarily dependent on constitution so far as experiments have yet shown) would seem in all probability to be unaffected by the concurrent formation of bimolecular compounds.

The hydrogenation mechanism suggested by Ingold in discussing the results of Evans and Farmer (*Chem. and Ind.*, 1928, 47, 268) would allow for this probability, but the theoretical basis of the hydrogenation hypothesis subsequently developed (Burton and Ingold, J., 1928, 904; 1929, 2022) appears insufficiently broad to cover Willstätter, Seitz, and Bumm's result with  $\Delta^2$ -tetrahydro-terephthalic acid. (It should be stated, however, that attempts by one of the authors to reduce in similar fashion  $\Delta^8$ -dihydromuconic acid have so far been unsuccessful.)

#### EXPERIMENTAL.

*Reduction of Ethyl Crotylidenemalonate.*—A moist ethereal solution of the ester (prepared by the method of Meerwein, *Annalen*, 1908, 358, 82) was allowed to react with amalgamated aluminium foil for 36 hours. The reduction product was an oil which partly solidified when strongly cooled. The solid portion crystallised from petroleum in stout prisms, m. p.  $61.5^\circ$  (Found: C, 61.8; H, 8.1.  $C_{22}H_{34}O_8$  requires C, 62.0; H, 8.0%), and the liquid distilled as a colourless oil, b. p.  $235\text{--}240^\circ/14$  mm. (Found: C, 61.5; H, 7.8%). These two substances, considered to be isomeric forms of ethyl 1:2-dimethylbicyclohexane-4:5-dimalonate (ethyl butane-2:<sup>3</sup>II:2-cyclobutane-3:4-dimalonate) (III), represented the whole of the reduction product save a very small proportion of low-boiling material. The yield of the solid product was always about 15%.

*Investigation of the Low-boiling Reduction Product.*—This material, accumulated from a series of reductions, was not homogeneous. After several distillations a few grams of liquid, b. p.  $133\text{--}140^\circ/18$  mm., were separated, the first fraction being rejected. Specimens of this substance were oxidised with neutral permanganate in order

to find if simple  $\alpha\beta$ - and  $\alpha\delta$ -dihydrogen derivatives of ethyl crotylidenemalonate were present. Some of the material appeared to be saturated, since considerably less than the calculated quantity of permanganate was reduced. The product, which contained no recognisable trace of succinic acid, consisted of a volatile acid and a little oxalic acid. The former, treated with *p*-bromophenacyl bromide, yielded a solid derivative, which was fractionally crystallised. The *p*-bromophenacyl derivative of acetic acid, m. p. 82—83°, was thus isolated, but the corresponding derivative of propionic acid, which appeared also to be present, could not be separated in pure form. Ozonisation experiments yielded no further information.

*Unsaturation of the Main Reduction Products.*—Both the solid and the liquid substance which constituted the main reduction product remained inappreciably attacked when vigorously shaken with aqueous permanganate at room temperature or when kept in acetone solution in contact with permanganate for several days. Both substances appeared to be little changed by prolonged treatment with ozone, and, even when boiled with permanganate in acetone solution, suffered change extremely slowly. Regulated oxidation was therefore impossible.

Nevertheless, both esters became further hydrogenated when dissolved in alcohol and shaken with hydrogen in the presence of colloidal palladium. Absorption of hydrogen was at first moderately rapid, but the rate decreased until it was barely 1 c.c. per hour. The hydrogen pressure was increased to 2 atmospheres, but still the rate of absorption was very slow. When absorption finally ceased, both esters had taken up the equivalent of two atoms of hydrogen per molecule. Both products, when isolated in the usual way, were colourless oils: that from the solid ester distilled at 225—230°/7 mm. and corresponded in composition with *ethyl 1:2-dimethylcyclohexane-4:5-dimalonate* (V) (Found: C, 61.8; H, 8.6.  $C_{22}H_{36}O_8$  requires C, 61.7; H, 8.5%); that from the liquid ester distilled at 217—223°/13 mm. and was isomeric with the first (Found: C, 61.8; H, 8.2%).

*The Dicyclic Reduction Products.*—(1) *Hydrolysis.* The solid compound (1 mol.) was warmed with alcoholic caustic soda derived from the calculated quantity of sodium (4 atoms). The sodium salt immediately deposited was collected and dissolved in a little water, and the solution evaporated to dryness. The residue, acidified with the calculated quantity of hydrochloric acid and diluted with an equal volume of water, yielded crystals of an acid. These were filtered off and the mother-liquor was thoroughly extracted with ether. The ethereal extract yielded a syrupy acid. Some decarboxylation accompanied hydrolysis.

The solid acid (35% yield), when reprecipitated from ethereal solution by addition of petroleum, formed a crystalline powder, m. p.  $175^{\circ}$  with evolution of carbon dioxide. It was an unsaturated tetrabasic acid, which at  $0^{\circ}$  rapidly decolorised an amount of permanganate equivalent to 3 atoms of oxygen per molecule (more could be reduced slowly). The oxidation product was an enolic syrupy acid of doubtful homogeneity which could not be purified or successfully broken down to known compounds. The solid acid is probably to be represented as 1:2-dimethyl- $\Delta^5$ -cyclohexene-4:5-dimalonic acid (X) (Found: C, 53.5; H, 6.0.  $C_{14}H_{18}O_8$  requires C, 53.5; H, 5.7%).

The liquid acid did not consist entirely of a tetrabasic substance. It readily lost carbon dioxide on heating, rapidly reduced cold permanganate (3 atoms of oxygen per molecule), and yielded an oxidation product somewhat similar to that derived from the solid acid, except that a proportion of oxalic acid was also formed. It probably represented a mixture of partly decarboxylated dimethylcyclohexene- and dimethylcyclohexylidene-dimalonic acids.

The liquid ester also yielded a bulky sodium salt when warmed with alcoholic caustic soda. The acid derived therefrom was wholly syrupy and could not be purified. On oxidation with permanganate the latter yielded some oxalic acid and a large proportion of syrupy acid. Numerous attempts were made to obtain solid or homogeneous liquid acids (a) by the decarboxylation of the tetrabasic acids described above and (b) by the decarboxylation of their oxidation products. All the products, however, were liquid acids of doubtful homogeneity.

(2) *Bromination*. The solid ester (chloroform solution), when treated with the equivalent of 4 atoms of bromine per molecule, yielded an oily tribromo-derivative (Found: Br, 36.6.  $C_{22}H_{33}O_8Br_3$  requires Br, 36.1%), which solidified after long standing; when treated with the equivalent of 6 atoms of bromine, an oily tetrabromide was obtained which would absorb no more bromine (Found: Br, 42.6.  $C_{22}H_{32}O_8Br_4$  requires Br, 43.0%). It was attempted to oxidise the bromomalononic groups of the tetrabromide to carboxyl by gradually adding finely powdered permanganate to an acetone solution of the bromide containing some free caustic alkali. Oxidation proceeded, but the product consisted of some oxalic acid and a large amount of a viscous acid which would not crystallise.

(3) *Degradation*. Since oxidising agents were almost without action on them, the dicyclic esters were subjected to vigorous oxidation with chromic acid. To the solid ester (10 g.), dissolved in glacial acetic acid (160 c.c.), a solution of chromic acid (50 g.) in 50% acetic acid (80 c.c.) was slowly added in small portions, the

mixture being continuously shaken and finally heated on a steam-bath for 1 hour. The product, from which acetic acid was removed by steam distillation, was saturated with sulphur dioxide and kept over-night; the excess of sulphur dioxide was then boiled off and the solution was made alkaline with concentrated aqueous ammonia and filtered. The filtrate, combined with several aqueous extracts of the chromium oxide, was evaporated to small bulk, acidified, and finally evaporated to dryness. The residue, when extracted with ether, gave a small yield of a slightly syrupy, solid acid. This, when drained and recrystallised from ether, formed colourless prisms, m. p.  $192-193^{\circ}$ , which were identified as *trans*-dimethylsuccinic acid (Found: C, 49.5; H, 6.9. Calc.: C, 49.3; H, 6.8%. Mixed m. p. with an authentic specimen,  $192-193^{\circ}$ ).

Similar experiments were carried out with the liquid dicyclic ester, but the conditions for getting even a small yield of a solid degradation product were not found.

*The Monocyclic Products of Complete Reduction.*—(1) *Hydrolysis and decarboxylation.* In attempting to derive 1:2-dimethylcyclohexane-4:5-diacetic acid from the solid dicyclic ester, two methods were employed: (a) the catalytically reduced ester was hydrolysed with the theoretical quantity of alcoholic caustic soda, the derived acid being decarboxylated by heating at  $180^{\circ}$ , and (b) the dicyclic ester was hydrolysed with alcoholic caustic soda, the sodium salt catalytically reduced, and the derived acid decarboxylated by heating to  $180^{\circ}$ . (Re-submission of the decarboxylated acid to hydrogenation resulted in no further absorption of hydrogen.) The crude reduced tetrabasic and dibasic acids obtained in both processes were liquids which showed no tendency to crystallise. No difference was observed between corresponding products and since the second process was the more economical, a considerable quantity of the dibasic acid was thereby prepared. This was esterified with alcohol and hydrogen chloride, and the product distilled. The distillate was a colourless oil, b. p.  $179^{\circ}/9$  mm., which is considered to be *ethyl 1:2-dimethylcyclohexane-4:5-diacetate* (Found: C, 67.45; H, 10.1.  $C_{16}H_{28}O_4$  requires C, 67.55; H, 9.9%). A portion of this ester was re-hydrolysed with alcoholic caustic soda. The free acid was a colourless oil which still showed no tendency to crystallise. Since it could not be distilled, it contained traces of impurity (Found: *M*, dibasic, 237.  $C_{12}H_{20}O_4$  requires *M*, 228).

(2) *Bromination and oxidation.* The fully reduced derivative of the solid dicyclic ester, dissolved in carbon disulphide, absorbed 4 atoms of bromine per molecule (with evolution of hydrogen bromide). The product, *ethyl 1:2-dimethylcyclohexane-4:5-di-*

*bromodimalonate* (VIII), when well washed and freed from solvent, was obtained as a yellow oil (Found: Br, 26.3.  $C_{22}H_{34}O_8Br_2$  requires Br, 27.3%). This was used without further purification in an attempt to oxidise the bromomalononic groups (bromine first being replaced by hydroxyl through the action of cold caustic potash) to carboxyl. Permanganate, dissolved in acetone, was the reagent employed, but oxidation did not proceed smoothly to yield the desired dimethylcyclohexanedicarboxylic acid. As expected, oxalic acid was formed, but the accompanying gummy acid when esterified yielded an ester which was far from homogeneous.

*Ethyl Crotylidenecyanoacetate*.—Crotonaldehyde and ethyl cyanoacetate, mixed in molecular proportion, were cooled to  $-15^\circ$  and a little piperidine was added. The mixture was allowed to attain room temperature and was then kept at  $30^\circ$  for 24 hours. There were two products: (1) a solid which crystallised from petroleum in colourless prisms, m. p.  $57-58^\circ$  (Found: C, 65.6; H, 6.7.  $C_9H_{11}O_2N$  requires C, 65.4; H, 6.7%), and (2) an isomeric liquid, b. p.  $122^\circ/9$  mm. (Found: C, 65.8; H, 6.5%).

The authors desire to express their thanks to the Chemical Society for grants (to C. M. C. and J. T. E.) which have defrayed a considerable portion of the cost of the investigation.

## LXXV.—*The Electrical Conductivities of Solutions of Tetraethylammonium Iodide in Benzonitrile.*

By AUSTIN RAYMOND MARTIN.

WALDEN has shown that the mobility of the tetraethylammonium ion is inversely proportional to the viscosity of the solvent. On the basis of this relationship and a knowledge of the equivalent conductivity at infinite dilution ( $\Lambda_0$ ) of tetraethylammonium iodide in benzonitrile, certain ionic mobilities in this solvent may be determined from the conductivity measurements previously recorded (Martin, J., 1928, 3270). Walden's early measurements of the conductivities of solutions of tetraethylammonium iodide in benzonitrile (*Z. physikal. Chem.*, 1906, 54, 189; 55, 710; see also "Elektrochemie nichtwässeriger Lösungen," 1924, p. 135) are too erratic to give an unequivocal value of  $\Lambda_0$ . Hence the present investigation was undertaken. The degree of dissociation of tetraethylammonium iodide in benzonitrile is also of interest.

## EXPERIMENTAL.

The apparatus and method used were the same as those described previously (Martin, *loc. cit.*).

*Tetraethylammonium Iodide.*—Kahlbaum's product was recrystallised three times from redistilled absolute alcohol, powdered in an agate mortar, and dried by being heated electrically in a vacuum at 100° over phosphoric oxide, the drying agent remaining at room temperature (Found: I, 49.30. Calc.: I, 49.36%). The molecular weight of tetraethylammonium iodide has been taken as 257.13.

*Solvent Correction.*—In series *a* the specific conductivity of the pure solvent at 25° was  $0.99 \times 10^{-7}$  mho, and in series *b*  $0.38 \times 10^{-7}$  mho. The conductivity of the solvent was in all cases subtracted from the observed conductivity in order to obtain the conductivity due to the dissolved salt. In series *a* the largest correction was 1.8% and in series *b* 0.5%.

## Results.

The results of the conductivity measurements are given in Table I. The dilution, in litres, is denoted by *v*, and  $\Delta$  is the difference between the observed value of the equivalent conductivity ( $\Lambda$ ) and the straight line obtained by plotting  $\Lambda$  against the square root of the concentration ( $\sqrt{c}$ ), a positive sign before  $\Delta$  indicating that the observed point is above the straight line.

1000	29.47	46.22	64.88	80.65					

*Extrapolation to  $\Lambda_0$ .* The square-root law was used to extrapolate to  $\Lambda_0$ . Ferguson and Vogel's method (*Phil. Mag.*, 1925, 1, 971) gave values of the index  $n$  in the formula,  $\Lambda_0 = \Lambda + ac^n$ , which were so close to 0.5 (namely, 0.507, 0.502, 0.491, 0.500) that this equation led to practically the same values of  $\Lambda_0$  as the square-root law. The values of  $\Lambda_0$  are:

Temp. ....	0°	25°	50°	70°
$\Lambda_0$ .....	33.71	53.13	75.47	94.12

#### Discussion.

*Values of  $\Lambda_0$ .*—The values of the product of  $\Lambda_0$  and the viscosity of the solvent ( $\eta$ ) at the same temperature are given below. The constancy of this product shows the exactness to which  $\Lambda_0$  is proportional to the fluidity of the solvent as the temperature is varied. The values of the viscosity of benzonitrile used were those determined previously (Martin, *loc. cit.*).

Temp. ....	0°	25°	50°	70°
$\Lambda_0\eta$ .....	0.65	0.66	0.66	0.63

In Table III are the ratios of the values of  $\Lambda_0$  of tetraethylammonium iodide in benzonitrile to the values at the same temperatures in acetone, acetonitrile, and ethylene chloride, the only solvents for which modern data are available. The ratios of the fluidities of the solvents are also given. The data for acetone are those of Walden, Ulich, and Busch (*Z. physikal. Chem.*, 1926, 123, 429), for acetonitrile those of Walden and Birr (*ibid.*, 1929, A, 144, 269), and for ethylene chloride those of Walden and Busch (*ibid.*, 140, 89). Extrapolation to  $\Lambda_0$  was in all cases carried out by the square-root law.

TABLE III.

50	0.295	0.292				

*Ionic Mobilities in Benzonitrile.*—On the assumption that the mobility of the tetraethylammonium ion is given by the relation (Walden and Birr, *Z. physikal. Chem.*, 1929, A, 144, 308),

$$\text{Mobility} \times \text{Viscosity of solvent} = 0.296,$$

its mobility in benzonitrile has been calculated, and from Kohlrausch's law of the independent migration of ions and the data recorded previously, the ionic mobilities given in Table IV were obtained. In calculating the mobilities of the silver and nitrate ions, Koch's value, 0.475 (determined from *E.M.F.* measurements; J., 1928, 524), was used for the transport number of the silver ion in silver nitrate. In the rows designated *l* are the ionic mobilities, and in those designated *r'* are the apparent values of the ionic radii calculated from these mobilities on the assumptions (i) that the only resistance to the motion of the ions at infinite dilution is the viscous drag of the solvent, and (ii) that the magnitude of this drag is given by Stokes's law. In the rows *r* are the ionic radii obtained from crystal data by Goldschmidt (*Trans. Faraday Soc.*, 1929, 25, 253); both *r* and *r'* are expressed in Ångström units.

The differences between *r* and *r'* cannot be used to calculate the degree of chemical solvation of the ions, since Born has shown (*Z. Physik*, 1920, 1, 220) that on physical grounds a difference is to be expected, owing to the fact that the dipolar solvent molecules take a finite time to orient themselves in the ionic field as the ion moves through the solvent. However, the physical theory is not sufficiently developed to be used for the quantitative interpretation of the present results.

*Dissociation of Tetraethylammonium Iodide in Benzonitrile.*—The observed slopes of the  $\Lambda - \sqrt{c}$  straight lines are given below, together with those calculated from the Debye-Hückel-Onsager equation

$$\Lambda = \Lambda_0 - \left[ \frac{5.78 \times 10^5}{(DT)^{3/2}} \Lambda_0 + \frac{58.0}{(DT)^{1/2} \eta} \right] \sqrt{2c}$$

where *D* = the dielectric constant of the solvent,  $\eta$  = the viscosity of the solvent, and *T* = the absolute temperature.

The author is indebted to Dr. A. O. Ball for the values of  $D$ .

Temp. ....	0°	25°	50°	70°
$D$ .....	27.58	25.22	23.31	21.98
Slope, obs. ....	133.6	217.6	332.1	423.3
Slope, calc. ....	90.9	147.3	202.4	259.4

The values of the degrees of dissociation,  $\alpha$ , and of the corresponding dissociation constants,  $K$  (corrected for activity), calculated by the method given previously (Martin, *loc. cit.*), are set out in Table V. The Debye-Hückel equations used for calculating the ionic activity coefficients ( $\gamma$ ) were (after insertion of numerical values):  $-\log_{10} \gamma = 2.78\sqrt{c'} - 9.66c'$  at 0°;  $= 2.78\sqrt{c'} - 9.69c'$  at 25°;  $= 2.78\sqrt{c'} - 9.66c'$  at 50°;  $= 2.77\sqrt{c'} - 9.63c'$  at 70°;  $c'$  being the ionic concentration.

It is not unlikely that at a dilution of 100 litres the Debye-Hückel-Onsager equation gives too large a value for the diminution in conductivity resulting from the interionic Coulomb forces, perhaps owing to the neglect of higher terms. For  $K$  increases at this dilution; and completely dissociated salts such as potassium and sodium chlorides in aqueous and methyl-alcoholic solutions at dilutions less than 100 and 300 litres, respectively, have values of  $\Lambda$  greater than those calculated from this equation (Onsager, *Trans. Faraday Soc.*, 1927, 23, 341). These deviations from the predicted values are, however, much smaller than those in the opposite direction in the cases of thallium chloride and silver nitrate resulting from incomplete dissociation.

If the foregoing mean values of the dissociation constants be compared with those of the iodides of lithium, sodium, and potassium, lithium bromide, and silver nitrate (Martin, *Phil. Mag.*, 1929, 8, 547), it is seen that in benzonitrile tetraethylammonium iodide is a stronger electrolyte than any of these salts, although it is apparently only slightly stronger than sodium iodide.

Calculation by means of the van 't Hoff isochore from the variation

of the dissociation constant with temperature indicates that the heat change in the dissociation of tetraethylammonium iodide in benzonitrile is an evolution of approximately 1 kg.-cal. per mol.

*Summary.*

1. The electrical conductivities of solutions of tetraethylammonium iodide in benzonitrile have been measured at 0°, 25°, 50°, and 70° over the range of dilution 100 to 10,000 litres.

2. By utilising the fact that the mobility of the tetraethylammonium ion is inversely proportional to the viscosity of the solvent, together with data previously recorded, certain ionic mobilities in benzonitrile have been determined.

3. The electrolytic dissociation of tetraethylammonium iodide in benzonitrile has been investigated.

The author wishes to thank Professor J. C. Philip, F.R.S., for very kindly placing at his disposal facilities for carrying out this work.

LXXVI.—*Investigations on the Bivalency of Carbon.*  
*Part III. Some Experiments on Xanthhydrol,*  
*Dixanthhydril Ether, and Xanthhydril Chloride.*

By FREDERIC GORONWY KNY-JONES and  
ALLAN MILES WARD.

XANTHHYDROL and benzhydrol being very similar in their properties, an attempt was made to study quantitatively the rate of displacement of chlorine from xanthhydril chloride as in the case of diphenylchloromethane (Ward, J., 1927, 2285). In lime-dried ethyl alcohol at room temperature, however, the chloride lost its halogen immediately and completely as hydrogen chloride, the reactivity appearing to be exactly comparable with that of triphenylmethyl chloride.

Xanthhydril chloride reacted readily with water at room temperature, giving xanthone and xanthen in approximately equal quantities, together with some xanthhydrol. As was to be expected in view of this result, xanthhydrol was readily decomposed by hydrochloric acid, being changed completely to equal quantities of xanthone and xanthen after 5 minutes' boiling with *N*/100-acid: it was, however, not attacked by boiling *N*/10-sodium hydroxide. Dibenzhydril ether (Ward, *loc. cit.*) was formed from benzhydrol

by boiling with dilute acids, but it was stable to boiling *N*/100-acid : such acid converted dioxanthhydryl ether into xanthone and xanthen (equal quantities) in  $\frac{1}{2}$  hour.

The reactions with alcohol are analogous. Xanthhydryl chloride and ethyl alcohol yielded xanthen as the main product, and some xanthone. (The alcoholic solution restored the colour to Schiff's reagent, but responded to no other test for acetaldehyde : compare Fosse, *Compt. rend.*, 1901, **133**, 880; *Bull. Soc. chim.*, 1906, **35**, 1005.) Xanthhydrol also was completely converted into xanthen (main product) and xanthone on being boiled with *N*/20-ethyl-alcoholic hydrogen chloride for 1 hour. The change was incomplete after shorter times of heating. Xanthhydrol, therefore, is much more stable in the presence of alcoholic than of aqueous hydrogen chloride. Dioxanthhydryl ether, which is insoluble in ethyl alcohol, dissolved readily on being boiled with ethyl-alcoholic hydrogen chloride (*N*/20) for a few minutes : the solution remained homogeneous when cooled to room temperature and the product was xanthhydrol (yield, at least 89% of the theoretical).

Xanthhydrol, dioxanthhydryl ether, and xanthhydryl chloride, therefore, are far more reactive than benzhydrol, dibenzhydryl ether, and diphenylchloromethane. Although, however, diphenylmethane and benzophenone are not produced from the last three compounds under the conditions under which xanthen and xanthone are produced from the first three, they can be obtained by reactions at higher temperatures (see, *e.g.*, Nef, *Annalen*, 1897, **298**, 234; also in the thio-series, Schönberg, Schütz, Bruckner, and Peter, *Ber.*, 1929, **62**, 2550). In connexion with the preceding transformations in ethyl alcohol, the observations of Bacon (*Amer. Chem. J.*, 1905, **33**, 92), Goldthwaite (*ibid.*, 1903, **30**, 461), and Norris and Young (*J. Amer. Chem. Soc.*, 1924, **46**, 2580) on the pyrogenic decomposition of arylalkyl alkyl ethers are of interest. Kauffmann and Pannwitz (*Ber.*, 1912, **45**, 766) have shown that triarylcarbinols in general are reduced to the corresponding triarylmethanes by alcoholic hydrogen chloride or by formic acid, and triphenylmethyl chloride in pure ethereal solution in the presence of zinc chloride (Gomberg, *J. Amer. Chem. Soc.*, 1913, **35**, 204) or aluminium chloride (Norris and Young, *loc. cit.*) decomposes into triphenylmethane and acetaldehyde, doubtless by a similar mechanism (see also Hardy, *J.*, 1929, 1000). The scheme which has been used to explain these decompositions would in the case of dioxanthhydryl ether be as follows :

The instability of dixanthhydryl ether in the presence of acids finds a parallel in the decomposition of bistriphenylmethyl ether (Gomberg, *loc. cit.*); the acids he used were, however, more concentrated and the product was triphenylcarbinol. The reaction between xanthhydryl chloride and ethyl alcohol may be assumed to proceed *via* the ethyl ether, which, however, has not been isolated :

It appears highly probable, therefore, that the displacement mechanisms for systems  $\text{CHR}_1\text{R}_2\text{X}$  and  $\text{CR}_1\text{R}_2\text{R}_3\text{X}$  are closely allied. The displacements of halogen which have been studied for some systems  $\text{CHR}_1\text{R}_2\text{Cl}$  may be interpreted as proceeding through a phase  $\text{R}_1\text{R}_2\text{C}^<$ , but an hypothesis involving the ion  $\text{CR}_1\text{R}_2\text{H}^+$  will also provide an explanation (Ward, *loc. cit.*, p. 2287). The bivalent-carbon hypothesis is impossible for systems of the triphenylmethane type, and a larger range of reactions can be interpreted on the ionisation theory. Certain reactions which have been regarded as evidence of the formation of ions in the triphenylmethane series were observed in the xanthhydryl experiments. Conant and Evans (*J. Amer. Chem. Soc.*, 1929, **51**, 1934), for example, consider that the presence of free radicals is indicated by the precipitation of Prussian blue when a chloroform solution of the material under investigation is shaken with an aqueous solution of potassium ferricyanide and ferric chloride. Dixanthhydryl ether readily brings about this reaction. Further, Boyd and Hardy (*J.*, 1928, 632) attribute to ionisation the red colour developed when triphenylcarbinol is dissolved in a mixture of sulphuric and acetic acids:  $\text{Ph}_3\text{C}\cdot\text{O}\cdot\text{SO}_3\text{H} \rightleftharpoons \text{Ph}_3\text{C}^+ + \text{SO}_4\text{H}^-$ . The colour may be due to a quinonoid tautomeride of this ion (see Gomberg and Sullivan, *J. Amer. Chem. Soc.*, 1922, **44**, 1810; Gomberg and Blicke, *ibid.*, 1923, **45**, 1765). The development and subsequent disappearance of a yellow-green colour in all the experiments in hydrochloric acid here described may therefore be evidence of the presence of the ion  $\text{O} \begin{array}{c} \text{C}_6\text{H}_4 \\ \diagup \quad \diagdown \\ \text{C}_6\text{H}_4 \end{array} \text{CH}^+$ . Conant and Sloan (*ibid.*, 1923, **45**, 2468) consider that they have obtained the free xanthyl radical in an impure state.

The accumulated evidence supports the ionisation theory rather than the theory of bivalent carbon. As applied to the problem of the Walden inversion (Ward, *J.*, 1927, 445), the latter theory is now recognised to be untenable (see also the criticism of Ashworth and Burkhardt, *J.*, 1928, 1795): three groups, and not two, must be

momentarily attached to the asymmetric carbon atom during the transformations, and evidence has been obtained that optical activity can persist under such conditions (McKenzie, Roger, and Wills, J., 1926, 779).

#### EXPERIMENTAL.

*Preparation of Dixanthhydrl Ether.*—When xanthhydrol was heated with petroleum for several days (Meyer and Saul, *Ber.*, 1893, 26, 1276), the conversion into dixanthhydrl ether was incomplete. The preparation was therefore carried out by heating moist xanthhydrol, prepared from xanthone (25 g.), at 150–155°, and finally at 175° for 1½ hours. The product was cooled, powdered, and extracted three times with methylated spirit. The residue (19.1 g.), m. p. 193–209°, was crystallised from 200 c.c. of xylene, washed with the same substance and with ether, and air-dried (yield, 17.8 g.); m. p. 205–211°. A sample of the dixanthhydrl ether, twice recrystallised from xylene, well washed with ether, and dried in a desiccator over paraffin wax, melted at 219° (Meyer and Saul, *loc. cit.*, give m. p. about 200°) (Found: C, 82.4; H, 5.0. Calc.: C, 82.5; H, 4.8%).

*Preparation of Xanthhydrl Chloride.*—(1) Thionyl chloride (2 c.c.), dissolved in 50 c.c. of light petroleum (b. p. 40–60°), reacted readily with dixanthhydrl ether (5 g.) suspended in the solution; as, however, needle-shaped crystals soon began to separate, the mixture was gently refluxed for 15 minutes until only a small amount of brown solid remained in suspension. The colourless solution was cooled in ether-solid carbon dioxide, and the crystals thus produced were collected and recrystallised repeatedly from 100 c.c. of the same solvent, long colourless needles being obtained. The solvent was removed as completely as possible in an atmosphere of nitrogen and the crystals were dried in a stream of the warmed gas (yield, 3–3.5 g.). The crystals became discoloured on drying and decomposition doubtless took place, but they could be kept unchanged for days in contact with light petroleum (Found, by titration of the hydrogen chloride liberated in alcoholic solution: Cl, 14.8, 15.0, 16.1, 13.8. Calc.: Cl, 16.4%).

The product melted at 60–65° after softening at 50°: selected crystals melted above 70°, e.g., 71–73°, 72–74.5° (Gomberg and Cone, *Annalen*, 1910, 376, 188, give m. p. 73–75° after sintering at 71°). Colourless crystals when removed from the mother-liquor became yellow on drying in the air and then colourless again; they were unmelted at 100° and kept their needle shape.

(2) The same results were obtained by the interaction of xanthhydrol and thionyl chloride in boiling light petroleum.

*Reaction between Xanthhydrol and Hydrochloric Acid.*—(a) Xanthhydrol, prepared from xanthone (5 g.), was washed with water and refluxed for 1 hour with 75 c.c. of *N*/100-hydrochloric acid. The solid melted and needle-shaped crystals then separated. They were removed from the cooled solution, washed with water, and immediately heated to boiling with 30 c.c. of methylated spirit. The solution was cooled to room temperature, filtered from the crop of crystals, added to an equal bulk of glacial acetic acid containing 5 c.c. of a concentrated aqueous solution of urea, and poured after 2 hours into excess of water. The precipitate then formed was collected, washed with water, and added to the crop of crystals above. The whole was dried over calcium chloride (yield, 5.15 g.) and extracted four times with 40–50 c.c. of boiling light petroleum (b. p. 40–60°). The extracts were well cooled and filtered, and the combined filtrates evaporated to dryness, leaving 2.42 g. of colourless solid, m. p. 94–96°, mixed m. p. with xanthen (m. p. 100–101°) 96–97.5°. Two further similar extractions of the undissolved solid gave 0.09 g., m. p. 97–135°, and a seventh extraction gave 0.05 g., m. p. 142–158°. The remaining undissolved solid (2.46 g.) melted alone at 163–168°, and at 167–170° when mixed with xanthone (m. p. 174°).

This method of separating xanthen from xanthone, although not quantitative, since xanthone was slightly soluble in the light petroleum used, was the one that gave the best results. The steam-distillation method used by Heller and Kostanecki (*Ber.*, 1908, 41, 1325) is unsatisfactory because xanthone is slightly volatile in steam.

(b) Xanthhydrol (0.5 g.) was boiled with *N*/100-hydrochloric acid (7.5 c.c.) for 5 minutes; the subsequent procedure was as described under (a). The alcoholic filtrate, after being added to the urea-glacial acetic acid, was still clear after 7 hours, whereas a portion of the same preparation of xanthhydrol, when dissolved in methylated spirit and added to the urea-acetic acid solution, was converted into a stiff paste after a few minutes.

(c) Similar experiments were carried out with hydrochloric acid, the strength being gradually increased to 5*N*; xanthen and xanthone were the only products isolated.

*Xanthhydrol and Aqueous Sodium Hydroxide.*—Xanthhydrol (0.5 g.) was boiled with 7.5 c.c. of *N*/10-aqueous sodium hydroxide for 1 hour. No yellow-green colour appeared and the xanthhydrol did not melt as in the hydrochloric acid reactions. The solid dissolved completely in about 10 c.c. of cold methylated spirit and the addition of this solution to the urea reagent gave a precipitate comparable in amount with that obtained on testing the xanthhydrol in (b).

*Reaction between Dixanthhydryl Ether and Hydrochloric Acid.*—(d) Dixanthhydryl ether (5 g.) was boiled with *N*/2-hydrochloric acid (75 c.c.) for 1 hour. The products were examined and separated as in (a); xanthhydrol was not present. The product (2.16 g.) obtained from the first four extractions melted at 97–98°, and at 98–99° when mixed with xanthen; the seventh extract (0.02 g.) had m. p. 163–166°. The remaining portion (2.35 g.), insoluble in the light petroleum, melted at 165–169°, and at 169–172° when mixed with xanthone.

(e) Finely powdered dixanthhydryl ether (0.5 g.) was boiled with *N*/100-hydrochloric acid (7.5 c.c.) for 15 minutes. The solution was cooled, and the product, which contained needle-shaped crystals, was collected, washed with water, and boiled with alcohol (15 c.c.). A part, doubtless unchanged ether, did not dissolve. The alcoholic solution did not give the urea reaction for xanthhydrol, but yielded a copious white precipitate on being poured into water.

(f) This experiment was carried out as in (e), but the mixture was boiled for  $\frac{1}{2}$  hour. The product dissolved completely in 5 c.c. of hot ethyl alcohol; the solution thus formed gave a crop of colourless needles on cooling, and the filtrate did not contain any xanthhydrol.

*Reaction between Xanthhydryl Chloride and Water.*—Xanthhydryl chloride (2 g.; Cl, 14.8%) was triturated with 30 c.c. of water at room temperature for  $\frac{1}{2}$  hour. The chloride, initially yellow-brown, rapidly became almost colourless. The products, collected and washed with water, were extracted with 30–40 c.c. of methylated spirit and the alcoholic solution was added to the urea reagent: a precipitate separated. Two more extractions of the residue were made and the precipitates were collected after some hours, washed with methylated spirit, and dried (total yield, 0.43 g., corresponding to 0.41 g. of xanthhydrol). The solutions and the remaining residue were worked up as in (a), the following yields being obtained: (i) 0.56 g., m. p. 94–96°, (ii) 0.05 g., m. p. 165–167°, (iii) 0.53 g., m. p. 168–170°.

*Reaction between Xanthhydrol and Ethyl-alcoholic Hydrogen Chloride.*—(g) Xanthhydrol (0.2 g.), dried over stick sodium hydroxide, was dissolved in ethyl-alcoholic hydrogen chloride (*N*/10 approx., prepared by passing hydrogen chloride into lime-dried ethyl alcohol) and boiled for 5 minutes. The cooled solution was tested for xanthhydrol and gave a copious precipitate. When the reaction mixture was boiled for 15 or for 30 minutes, there was also a positive test, but the amount of condensation product which separated in the latter case was small. Heating for 1 hour brought about complete decomposition of the xanthhydrol.

(h) Xanthhydrol (2.5 g.) was boiled with 20 c.c. of *N*/20-ethyl-alcoholic hydrogen chloride for 1 hour. The solvent was then distilled: it restored the colour to Schiff's reagent, but only slightly reduced ammoniacal silver nitrate. The solid residue was dried over calcium chloride (yield, 2.4 g.) and examined in the usual way. It gave: (i) 1.36 g., m. p. 93—95°, mixed m. p. with xanthen, 94—96°; (ii) 0.09 g., m. p. 142—164°; (iii) 0.80 g., m. p. 163—166°, mixed m. p. with xanthone, 168—171°.

*Reaction between Dixanthhydryl Ether and Ethyl-alcoholic Hydrogen Chloride.*—Dixanthhydryl ether (2 g.), when boiled with *N*/20-ethyl-alcoholic hydrogen chloride (20 c.c.), dissolved after 4 minutes, and solid did not separate when the solution was cooled. An equal volume of the urea reagent was added; a copious white precipitate, which separated after a few minutes, was collected after 14 hours and washed repeatedly with methylated spirit until the washings gave only a small precipitate on being poured into water. The product, after being dried over calcium chloride, weighed 1.98 g. (equivalent to 1.87 g. of xanthhydrol).

The alcoholic-acetic acid solution and washings did not give any precipitate on being further tested for xanthhydrol and were therefore poured into excess of water. The precipitate was collected and dissolved in about 30 c.c. of hot methylated spirit. Fine colourless needles (0.12 g.), which separated from the cooled solution, did not melt at 225°, and gave a copious evolution of ammonia on fusion with potash (this product is possibly formed from urea and xanthhydrol by the condensation of one molecule of each). When excess of water was added to the methylated spirit solution, a solid (0.26 g.) was obtained which began to melt at 90° but was not completely molten at 220°; it probably consisted mainly of xanthen and xanthone.

*Reaction between Xanthhydryl Chloride and Ethyl Alcohol.*—Lime-dried ethyl alcohol (about 50 c.c.) was added to a light petroleum solution of xanthhydryl chloride (prepared from 5 g. of xanthhydrol). The solution, which became successively brown and green, was shaken for a few minutes, and the solvent then distilled off. The green residue was dried in a current of air (yield, 4.1 g.). A portion of it (about 0.2 g.), tested for xanthhydrol, did not give a precipitate after 4 hours. The remainder was extracted four times with light petroleum. The soluble portion (3.05 g.) was yellow-brown and melted at 85—90°; it was dissolved in light petroleum and refluxed (charcoal) for  $\frac{1}{2}$  hour. The pale yellow solution thus formed was filtered and evaporated; yield, 2.65 g., m. p. 91—93°; mixed m. p. with xanthen 97—99°. The green insoluble portion (0.58 g.) melted at 143—146°; it dissolved in acetone to a green solution, from which

the colour was removed by means of charcoal. The purified product had m. p. 171—172° and mixed m. p. with xanthone 173—174°.

One of us (A. M. W.) is indebted to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the cost of the materials.

# LXXVII.—*The Apparent Hydration of Ions. Part IV. The Densities and Viscosities of Saturated Solutions of Silver Nitrate in Nitric Acid.*

By JOHN WILLIAM INGHAM.

THE investigations in this series already described have dealt with solutions of alkali-metal and ammonium chlorides in hydrochloric acid (Parts I and II, J., 1928, 1917, 2381; Part III, J., 1929, 2059). The present paper deals with an extension of the work to solutions in nitric acid, the solute being silver nitrate, a choice which allows of accurate analytical control and is also convenient for comparison with the salt and acid pairs previously examined. The silver ion, having a radius of 1.13 Å.U. (Goldschmidt, *Trans. Faraday Soc.*, 1929, 25, 253), which is between those of the sodium and potassium ions ( $\text{Na}^+$  0.98,  $\text{K}^+$  1.33), might be expected to show hydration effects of an intermediate nature. The nitrate ion, which resembles the chlorine ion in probably being not hydrated but differs from it in having a more complex and less symmetrical structure, might show specific effects due to these features. Differences might also be expected for these two ions on the basis of Sugden's theory (J., 1926, 174) that anions have not all the same activity as depolymerisers of the solvent.

The experimental work consisted of the determination of the densities and viscosities at 25° for a series of solutions of acid content covering the range 0—12*N*, and saturated with silver nitrate. A parallel series of determinations with acid alone was also made. The same apparatus was used as in the previous work, but a slight modification was made by placing the gauge for the Scarpa viscometer in the thermostat and substituting water for alcohol in it, thus making the control more certain. The results are in Tables I and II, concentrations being in mols./litre. The viscosities of the pure nitric acid solutions were determined both by the Scarpa and by the Ostwald U-tube method.

Col. 8 of Table I gives the sum of Cols. 4, 5, and 6; on the assumption that the solutes are completely dissociated and that the hydrogen ions are present as  $H_3O^+$  ions (or, alternatively, that they have no effective size as free individuals), these figures give the relative numbers of particles having effective volume, the water molecules being treated as unpolymerised and no allowance being made for hydration of the silver ions. Col. 6 in Table II gives the corresponding figures for the pure acid solutions, the values in this case being identical with "Total solution."

### Discussion of Results.

*Densities and Solution Volumes.*—The data in Col. 8, Table I, and Col. 6, Table II, show a close parallelism and, when plotted against acid normalities, give graphs which are superimposable except in the region 0–5*N*, where the solutions containing silver nitrate have slightly higher numbers of "effective particles" (the maximum divergence being 0.3 unit/litre). The saturated solution of silver nitrate in pure water, having 55.33 for this number, may be compared with pure water itself, for which the value is 55.35. If the solution volume of the water were the same in the two cases, then that of the silver nitrate would be exactly twice as much. Caution must, however, be observed in making such deductions,

and due regard must be given to the possibility of an alteration in the values for the water molecule itself. For instance, a change of the condition of the solvent, such as depolymerisation, might lead to an adjustment of the volume effectively shown. Similarly, the packing of ions amongst the water molecules and the interactions of "hydration" will undoubtedly lead to modifications of the volume which the solvent molecule apparently occupies. These various effects may all be regarded as readjustments of the amount of "free space" in the liquids. This free space is normally included in the apparent solution volumes of the constituents of a solution, whether solute or solvent. Usually, in dealing with aqueous solutions, a constant value is assumed for the water, based upon the density of the pure solvent, and any variations are arbitrarily expressed as those of the solute: an example is that of lithium chloride (Green, J., 1908, 93, 2023), discussed by the author in Part II (*loc. cit.*). On the other hand, the type of expression suggested by Masson (J., 1911, 99, 1132), and used in the present series of investigations, makes provision for changes in the apparent solution volume of the solvent in the solution as compared with the pure liquid. The solution volumes deduced by these methods all include a proportion of "free space" except for the two smallest ions  $\text{Li}^+$  and  $\text{Na}^+$ , in which cases the apparent solution volumes were found to be less than the gram-ionic volumes calculable from lattice radii. These are the ions which definitely show hydration effects. The case of the ammonium ion was especially interesting, for it gave an unexpectedly high solution volume of 19.64 c.c. (Part III), compared with the value 7.43 c.c. deduced from the ionic radius. At the same time, this ion was shown to have a negative effect on the viscosity. It is suggested that the appropriation of this large amount of free space, accompanied by a repulsion of the solvent molecules, causes the ammonium ion to show a lower viscous effect than its apparent solution volume would otherwise indicate. The ammonium ion, in fact, behaves as a "loose spot" (compare Part II).

The application of Masson's formula,  $d_r^s = K + k_1a + k_2b$ , to the data of Table I may now be considered. The series of densities resembles that for the  $\text{NaCl-HCl}$  and  $\text{KCl-HCl}$  mixtures (Part I), there being a minimum value; since, however, the data for silver nitrate cover a much wider range of salt concentrations, it is not surprising that the formula has a more restricted application. Constants were determined by (i) the method of least squares and (ii) Campbell's method (see Part III, *loc. cit.*), the corresponding equations being

$$(i) \ d_r^s = 1.0350 + 0.02647a + 0.1299b;$$

$$(ii) \ d_r^s = 1.0306 + 0.02702a + 0.1305b.$$

The second of these is preferred, and the densities calculated by means of it compare well with those observed except for the end values of the series; *e.g.*,

$\bar{d}_4^{25}$ (obs.)	2.2969	1.7376	1.6343	1.4669	1.4236
„ (calc.)	2.2986	1.7368	1.6343	1.4669	1.4236
$\bar{d}_4^{25}$ (obs.)	1.4014	1.3742	1.3690	1.3695	1.3741
„ (calc.)	1.4017	1.3737	1.3690	1.3706	1.3808

The solution volumes corresponding to the constants of the equations differ only slightly according to the equation used, thus:

	AgNO <sub>3</sub> .	HNO <sub>3</sub> .	H <sub>2</sub> O.
(i)	38.66	35.32	17.41
(ii)	38.14	34.92	17.48

The values may be compared with those derived from other sources. Jabczyński, in a paper on the dimensions of ions in aqueous solutions (*Rocz. Chem.*, 1923, **3**, 362), has discussed the data for many salts, including nitrates and chlorides. He gives the solid volume of silver nitrate as 39.04, and calculates the upper and lower limiting solution volumes to be  $w_1$  39.34 and  $w_0$  25.91, respectively, these being deduced from data by means of empirical formulæ, and the solution volumes being calculated from density data by means of the ordinary equation  $w = \frac{1}{N} \left( 1000 - \frac{1000d - MN}{d_0} \right)$ , where  $d_0$  is the density of pure water. The lower limiting values  $w_0$  were, for the chlorides of sodium potassium, caesium, and rubidium, shown to agree with the molecular volumes calculated from the lattice radii of the ions as given by Bragg (*Phil. Mag.*, 1920, **40**, 169), but the revised data for the radii nullify this agreement, which in any case did not extend to other salts. The agreement found between the upper limiting values  $w_1$  and the solid volumes in the case of many salts, including silver nitrate, is apparently significant, although too much importance must not be attached to it, since the result is obtained by neglecting the effect of changes of the packing arrangements upon the volume occupied by the water. All that can be safely concluded is that, in solutions of high concentration, the solution volume of the salt approaches that of the solid in many cases, and if the ionic radii remain the same, the "free space" associated with the ions in solution is of the same order as that for the solid state. The mean value deduced for silver nitrate in the mixed salt and acid solutions, *viz.*, 38.40, is thus seen to be satisfactory. The fact that the value remains constant over the greater part of the series may be attributed to the relatively small variation in total solute strength, so that the apparent volume of the nitrate ion, which accounts for the major portion of the total volume of the salt, remains constant. This

would not be the case in a simple series of solutions of silver nitrate alone, varying over the same range of salt concentration, *viz.*, 0—10*N* (app.), as in the mixtures. The same argument applies to the acid itself, so the acid volume deduced for the mixed solutions will not be expected to apply to any considerable part of Table II. Actually, it does apply for the concentration region 6—9*N*, for which solutions the densities can be fairly accurately calculated by the formula  $d_{25}^{25} = 1.0306 + 0.02702a$ , but outside these limits there is rapid divergence.

The difference (3.28) between the means of the above values of the volumes, *viz.*,  $\phi'_{\text{AgNO}_3} = 38.40$ ,  $\phi'_{\text{HNO}_3} = 35.12$ , is taken as the volume of the silver ion, and  $\phi'_{\text{HNO}_3}$  will be provisionally assumed to be the value of  $\phi'_{\text{NO}_3}$  also.\* The value for the silver ion falls between those obtained for Na<sup>+</sup> (1.58) and K<sup>+</sup> (12.25) in Part I. Furthermore, if these values are used to derive values for the nitrate ion from the limiting values of sodium and potassium nitrates given by Jabickyński, *viz.*,  $w_1(\text{NaNO}_3) = 37.87$ ,  $w_1(\text{KNO}_3) = 47.61$ , the values for this ion are 36.29 and 35.36, respectively, the latter being in very close agreement with the value deduced above. In this connexion, it may be noted that lithium nitrate ( $w_1$  30.24) is not in agreement. This again is probably due to the method of obtaining the solution volumes without regard to changes of the water volume. In the case of lithium chloride (Part II, *loc. cit.*), it was shown that for a 5.407*N*-solution, the solution volume (22.43) obtained by using a density for water of 1.01275 was considerably higher than either the solid volume (20.94) or the solution volume (20.24 at 5*N*) calculated by Green (*loc. cit.*). A difference in the assumed density of the solvent water of about 1% therefore makes a considerable difference to the calculated salt volumes, and this is most marked for lithium salts, so the above apparent discrepancy of lithium nitrate is probably capable of a similar explanation.

The solution volumes of the silver and nitrate ions, *viz.*, 3.28 and 35.12 respectively, may be compared with ionic volumes deduced from lattice radii. For the former ion, the values given by Goldschmidt (*loc. cit.*), 1.13, and by Pauling, 1.26 (quoted by Goldschmidt), lead to gram-ionic volumes of 3.665 and 5.079 respectively. The value 3.28 now found for the solution volume is thus, as with lithium and sodium ions, less than that calculated from the lattice radius. The nitrate ion has a structure with the centres of the four atoms in one plane, the oxygen atom centres being at the corners of an equilateral triangle, and that of the nitrogen atom being at the mid-point (Bragg, *Phil. Mag.*, 1926, 2, 258). The

\*  $\phi$  is used for the volume of ions added to 1 c.c. of solution;  $\phi'$  is used for the gram-ionic volume of an ion.

inter-atomic distances of the oxygen atoms are given as 2.25 Å.U. and their radii as 1.35 Å.U. These dimensions imply a very close packing of the oxygen atoms round the central nitrogen atom, with considerable deformation of the former. These results have been confirmed and amplified in a comprehensive survey of the type of compound  $ABX_3$  by Zachariassen (*Norske Videnskaps-Akad.*, 1928, 1, *mat.-nat. Klasse*, 4). Thus, in lithium nitrate the distance from an oxygen centre to the nitrogen centre is 1.25 Å.U., which is practically the same as in the Bragg structure. It appears to be well established that both the nitrate ion and the carbonate ion, which has almost identical dimensions, preserve well-defined identities. The exact volume occupied by such an ion is not easy to determine, but as an upper limit that of the triangular prism con-

FIG. 1.

taining it may be taken. This is calculated to be 34.4 for the gram-ion. Actually, this will be somewhat high, and if the lower limit be chosen as the volume of three oxygen atoms ( $r = 1.32$ ), giving 17.5, it seems probable that the true volume will lie between these two limits. The solution volume determined is actually quite close to the upper limit thus obtained, and it will be shown that the volume influence of this ion upon viscosity is of the same order.

*Viscosities.*—The graphs of the data shown in Fig. 1 may be compared with those in Fig. 2, Part II, for hydrochloric acid solutions alone or containing sodium chloride. Aqueous hydrochloric acid solutions have higher viscosities than those of nitric acid of equal normality. Nitric acid appears to have a simpler behaviour, the curve being linear above 5*N*. Starting from pure water and comparing the two acids, it is found that the viscosity differences at corresponding normalities (i) at first increase from 42 ( $\times 10^{-5}$ ) units

at  $N = 1$  to 73 at  $N = 3$ ; (ii) they then diminish until the value 43 is again reached at  $N = 8$ , after which (iii) there is a rapid increase to 146 at  $N = 12$ . These effects might be interpreted as being due to (i) a more rapid depolymerisation of the water by nitrate than by chlorine ions in the earlier stages of  $1-3N$ ; (ii) the influence of the larger size of the former ion tending to a greater viscosity effect and hence a making up of some of the ground lost during the initial period; (iii) the entry of some specific effect in the solutions of high concentration of hydrochloric acid which is not paralleled in those of nitric acid or else is offset by a difference in the numbers of particles of all kinds, which numbers are considerably less in the case of nitric acid. The effective numbers of particles as defined by Col. 6, Table II, for nitric acid, and falling from 55.35 to 44.60, show much greater variation than for hydrochloric acid, for which (from Green's data) the range is 55.35—53.24 for the corresponding range 0—12*N*. Another possible factor causing such differences of behaviour would be incomplete ionisation of the nitric acid in solutions of high concentration, since, as will be shown later, the increase of viscosity caused by adding a given ion is partly dependent upon the strength of the field into which it is placed. There is, however, no evidence that nitric acid is less dissociated than hydrochloric acid and, in fact, the behaviour in dilute solutions suggests the complete dissociation of both acids (MacInnes and Cowperthwaite, *Trans. Faraday Soc.*, 1927, 23, 400).

The most noteworthy feature in the graphs for the silver nitrate-nitric acid solutions is the obvious similarity to those for sodium chloride in hydrochloric acid, both sets showing the approach to a minimum viscosity as salt is replaced by acid. It should be noted that the minimum does not occur at the point of minimum total solute concentration.

The linear relation for nitric acid of concentrations exceeding 5*N* is expressed by

$$\eta = 0.006822 + 0.0009077C$$

for the Scarpa series (if the mean of the Scarpa and Ostwald series is taken, the first constant becomes 0.006787). If this equation is compared with one of the form deduced by Einstein (*Ann. Physik*, 1906, 19, 289), viz.,  $\eta = \eta_0 [1 + \text{constant} \times \phi]$ , and if it be assumed that the nitrate ions contribute the main effect in altering the viscosities in proportion to their volume, so that  $\phi = C\phi'/1000$ ,  $\phi'$  is given by  $[0.0009077 \times 1000]/[0.006787 \times (\text{constant})]$ . If the value 4.5 be taken for the constant in the Einstein equation (compare Hatschek, *Trans. Faraday Soc.*, 1913, 9, 80),  $\phi_{\text{NO}_3}$  becomes 29.7 c.c. and  $\eta_0$  would be 0.006787. It might be argued that the latter quantity represents the fundamental viscosity of depolymerised

water at 25°, and hence it might be used to calculate the degree of polymerisation in ordinary water by comparing it with the viscosity of ordinary water and employing the equation  $\eta = \eta_0 (1 + 2.55\phi)$ , which with the constant 2.55 might be considered applicable to the case of the uncharged water polymerides. This calculation, with  $\eta_w = 0.00891$ , gives  $\phi$  as 0.1225 c.c., or 122.5 c.c. per litre, corresponding with a polymerisation of 12.3%. The significance of the value of  $\eta_0$  as thus suggested is open to question, for at present there is no evidence of its applicability to solutions other than those here considered. Further, the equation  $\eta = \eta_0 (1 + 4.5\phi)$  is not satisfactory either for the data for the mixed solutions of silver nitrate and nitric acid or for correlating hydrochloric acid and the mixed chloride solutions. It may be compared with the equation of Smoluchowski (*Kolloid-Z.*, 1916, 18, 194) put in the form  $\eta = \eta_0 \{1 + 2.5\phi (1 + x)\}$ , where the term  $(1 + x)$  takes account of the effect of the charge on the particles and presumably varies with the total number of these. If it is accepted that the volume 29.7 c.c. represents the effective value for the nitrate ion, then the factor  $(1 + x)$  for nitric acid solutions of 5*N* upwards remains constant and equal to 4.5/2.5. This again assumes the fundamental significance of  $\eta_0$ . It is probable, therefore, that the linear relationship for nitric acid is due to a balance of a number of effects, and is not to be interpreted fully on these simple lines.

Since a satisfactory interpretation of the data for the mixed solutions could not be obtained on the above lines, recourse was had to the empirical equation,  $\eta_2 - \eta_1 = \frac{1}{2}(\eta_2 + \eta_1)2.5\phi$ , employed in previous parts of this series. According to this formula a change of viscosity occasioned by the addition of a quantity of ions of nett volume  $\phi$  is proportional to that volume and to the mean viscosity of the solutions concerned. It appears that introduction of the mean viscosity in this way is equivalent to making allowance for the effect of the charges on the ions, but in a different way from that of Smoluchowski. Thus the effect of an addition  $\phi$  is greater in solutions of high total-ion strength than in those of lower concentration. By applying this to the solutions of nitric acid alone, in the first case, and using successive pairs of values from Table II, the  $\phi'$  values of the nitrate ion are calculated. Thus, from the fourth and fifth experiments (Scarpa values)

$$\eta_1 = 0.00989; \quad \eta_2 = 0.01049; \quad \eta_2 - \eta_1 = 0.00060; \quad \eta_2 + \eta_1 = 0.02038; \quad C_2 - C_1 = 0.934;$$

$$\phi' = \frac{\Delta\eta \times 1000 \times 2}{2.5 \times (\eta_2 + \eta_1)\Delta C} = \frac{0.00060 \times 2000}{2.5 \times 0.02038 \times 0.934} = 25.23.$$

and the values for the complete series are as follows:

$C$ .....	0	0.987	2.010	2.810	3.744	4.863	5.667
$\phi'$ .....	11.7	15.5	18.0	25.2	24.4	30.9	
$C$ .....	5.667	7.257	8.900	11.92			
$\phi'$ .....	27.8	27.9	27.3				

The mean value for  $C > 5N$  is  $\phi' = 27.6$ , which may be compared with that derived directly from the linear relationship discussed above, viz., 29.7: these values fall between the limits already adduced for the volume of this ion and they approximate to the solution volume found. These facts, in conjunction with the fair constancy of the values in the above table for solutions of concentrations above  $3N$ , are taken to indicate an absence of hydration effects for the nitrate ion. The initial rise in the series is attributed to the depolymerising action of this ion, whereby the apparent  $\phi'$  value is reduced. The tendency for the values to fall, over the range  $5-12N$ , may be connected with the falling off in the total number of particles present. An alternative explanation might be that incomplete ionisation in the very concentrated solutions causes an apparent reduction of the effective volume—an actual reduction due to changes in the packing arrangements of the ions and water molecules and equivalent to a loss of free space is not excluded. In this connexion, the difference between nitric and hydrochloric acids is noteworthy. It was shown that with the latter (Part I) the  $\phi'$  value of the chlorine ion (22.43) which could be used to account for the viscosities of solutions of  $3-6N$  on the above lines was quite inadequate for the values at higher concentrations, and the apparent  $\phi'$  values would rapidly increase with increasing acidity, this being due apparently to some specific effect such as the formation of a complex molecule (?  $H_3OCl$ ) which has no parallel in the nitric acid solutions.

The value 28 being accepted for the effective volume of the nitrate ion in solutions containing that ion in concentrations from  $7$  to  $10N$ , the data of Table I may be used to calculate the apparent  $\phi'$  values for the silver ions in the mixed solutions of total concentrations between these limits. Thus, for the first pair of solutions there is a fall in viscosity accompanying a fall in concentration of  $2.540$  in the nitrate ion and of  $4.762$  in the silver ion, and the calculation is made as follows :

$$\begin{aligned}\eta_1 &= 0.02989; \Delta\eta = 0.01137; \\ \eta_2 &= 0.01852; (\eta_1 + \eta_2) = 0.04841;\end{aligned}$$

$$1000 \phi = \frac{0.01137 \times 2000}{0.04841 \times 2.5} = 187.9 \text{ c.c. per litre.}$$

The total  $\phi$  of  $187.9$  c.c. per litre is reduced by that of the nitrate

ions, *viz.*,  $2.540 \times 28 = 71.1$  c.c., and the difference ( $187.9 - 71.1 = 116.8$  c.c.) divided by the fall in the silver-ion concentration (4.762) gives the effective volume of the silver gram-ion, *i.e.*,  $\phi'_{Ag} = 24.53$  c.c. This may be taken to represent the mean effective volume of the hydrated silver ion for the particular range considered, and the apparent hydration may be calculated after subtracting the volume of the silver ion, 3.28, derived from the densities. Each successive pair of solutions in Table I might thus be treated, but in that part of the table embracing the minimum point of viscosity,  $\Delta\eta$  becomes inconveniently small, hence in this region wider steps have been used. Further, for certain pairs, *e.g.*, the sixth and seventh solutions,  $\eta$  increases whilst  $C_{NO_3}$  increases and  $C_{Ag}$  diminishes, so the  $\phi$  value calculated is the nett effect  $\phi_{NO_3} - \phi_{Ag}$ , and the subsequent calculation of  $\phi_{Ag}$  must be modified accordingly. The series of values relating to the different parts of the table may now be considered, the ordinal numbers referring to the successive pairs of solutions. The values in brackets are indirectly derived, being weighted values deduced from others first obtained from wider steps of the table;  $h$  is the hydration factor or apparent hydration.

	1.	2.	3.	4.	5.	6.	7.	8.	9.
$\phi'_{Ag}$ .....	24.5	24.5	27.5	[25]	20	19	22]	26.2	26.6
$h$ .....	1.21	1.21	1.38	1.24	0.95	0.90			

This series of values may be compared with that obtained for sodium ions in sodium chloride-hydrochloric acid solutions (Table VI; Part I), which commences at 32.0 for the pure saturated solution and falls to 23.5 at the point of minimum viscosity. After this point is reached, in both cases the values begin to rise, but, as the concentrations of the salts are then becoming low, the values may be subject to considerable error partly owing to the smallness of the effects actually attributable to these ions, and partly because other specific effects coming into play in solutions of higher acidities are automatically included in the values for the metal ions. Only the first portion of the series of figures for silver nitrate is therefore useful for the discussion of the hydration. The calculated hydration factors are lower than those obtained for sodium ions at corresponding parts of the series. The initial tendency to rise may be due to the very considerable fall in total solute strength of the solutions in the early parts of the series. This effect is very slight or non-existent in the case of sodium ions. The method of treatment given places the silver ion between the ions of sodium and potassium as regards hydration, in agreement with the idea that the order should be that of the ionic radii, the smaller the radius the greater being the tendency for hydration.

*Summary and Conclusions.*

Determinations have been made at 25° of the solubility of silver nitrate in aqueous nitric acid of concentrations up to 12*N*. The densities and the viscosities of the solutions have been measured together with those of a comparable series for the acid alone.

The formula  $d = K + k_1a + k_2b$  applies to the densities of the mixed solutions of total solute concentration below 9*N*, *a* and *b* being the concentrations of acid and salt respectively. The constants *K* and *k*<sub>1</sub> also apply to the pure acid solutions of concentrations 6–9*N*. The corresponding solution volumes are discussed and compared with those derived by other investigators. The silver ion behaves like lithium and sodium ions in having an apparent volume less than that calculated from its radius in the crystal lattice.

The viscosity data are interpreted by means of the empirical formula  $\eta_2 - \eta_1 = \frac{1}{2}(\eta_2 + \eta_1)2.5\phi$ . A change of viscosity caused by the addition to a solution of ions of volume  $\phi$  is proportional to this volume but also depends upon the mean viscosity of the solutions considered. It is suggested that this latter factor takes account of the electrical effects, and hence the equation allows of the volume effect being separately estimated. The formula, which has previously been applied only to chlorides and their ions, is now found to give a satisfactory account of the data for nitric acid and for its mixed solutions with silver nitrate. The volume effect of the nitrate ion remains substantially constant except in 0–5*N*-solutions of the acid alone, where apparent variations due to the depolymerising action of the ion are indicated. This depolymerisation of the water is more easily effected by the nitrate ion than by the chlorine ion. The volume of the nitrate ion determined from the viscosities approximates to the solution volume calculated from the densities and is also in agreement with values deduced from the data for the size of this ion in crystals; hence it is concluded that this ion is not hydrated. Nitric acid shows a less complex behaviour in solutions of high concentration than does hydrochloric acid, and this suggests the absence of complex ions in the former case.

The silver ions in the mixed solutions show effects attributable to hydration, which is less than that previously found for sodium but greater than for potassium, and this is in accordance with the expected results deduced from the sizes of the ions. Hydration factors for silver ions varying from 1.4–0.90 are found, whereas those for sodium ions were 1.7–1.2.

LXXVIII.—*Experiments on the Constitution of the Aloins. Part II.*

By CHARLES STANLEY GIBSON and JOHN LIONEL SIMONSEN.

SOME years ago Robinson and Simonsen (J., 1909, 95, 1085) suggested tentatively for barbaloin the formula (I), based chiefly on the following facts: (i) the careful investigations of Jowett and Potter (J., 1905, 87, 878) had shown that barbaloin has the composition  $C_{16}H_{18}O_7$  and contains four hydroxyl groups; (ii) the oxidation of acetylbarbaloin with chromic acid yields a mixture of acetylrhein and acetylaloe-emodin; (iii) rhein was shown to be a dihydroxy-anthraquinonecarboxylic acid, and aloe-emodin the corresponding primary alcohol. At the time, it was considered probable that rhein was an *isochryszazinc*carboxylic acid, but the further work of Robinson and Simonsen, in the publication of the results of which they were anticipated by other workers (Oesterle and co-workers, *Arch. Pharm.*, 1909, 247, 417, 532; 1911, 250, 305), showed that rhein (II) and aloe-emodin (III) are derivatives of chrysazin.

This conclusion obviously necessitated a revision of the suggested constitution for barbaloin and it has only recently been possible to resume the investigation. In the meantime, Léger (*inter alia*, *Ann. Chim.*, 1916, 6, 318; 1917, 8, 265) has published the results of a prolonged investigation of the constitution of barbaloin and of other members of this group. He concludes that the composition of barbaloin is not  $C_{16}H_{18}O_7$  with four hydroxyl groups but  $C_{20}H_{18}O_9$  having five hydroxyl groups. Elementary analysis of either the parent substance or of certain of its simple derivatives does not distinguish between these two formulæ, and Léger was led to make the change by the important observation that when barbaloin is treated with alcoholic hydrochloric acid under specified conditions *d*-arabinose is formed in addition to aloe-emodin. He naturally concluded that barbaloin is the arabinoside of aloe-emodin.

having the constitution (IV), although the actual position of attachment of the sugar residue was not definitely proved.

The suggestion that barbaloin was a glucoside was not new, since Rochleder and Czumpelik (*Monatsh.*, 1863, **44**, 493; 1866, **47**, 119) had observed the formation of a sugar in addition to a yellow crystalline substance by the action of alcoholic hydrochloric acid on barbaloin: Tschirch and Pedersen (*Arch. Pharm.*, 1898, **236**, 206), however, were unable to confirm this. Léger conclusively proved that *d*-arabinose is formed when barbaloin is kept with alcoholic hydrochloric acid for a period of six months, and we have confirmed this. The rate of hydrolysis, if such it be, is extraordinarily slow and very little action appears to have taken place after a week's continuous digestion, although the barbaloin is completely in solution. Léger also observed that aloe-emodin and *d*-arabinose are produced when barbaloin is oxidised with sodium peroxide. In this reaction the sodium peroxide must be assumed to act as a hydrolytic agent, although the yield of aloe-emodin does not exceed 9%.

We have confirmed in all respects Léger's excellent experimental work, but it appears to us that there are a number of cogent reasons for doubting the correctness of the constitution he assigned to barbaloin. The more important of these may be summarised. As already mentioned, elementary analysis does not readily distinguish between the two formulæ which have been suggested, and if the tendency for barbaloin to retain solvent of crystallisation be taken into consideration the differences between the carbon and hydrogen contents lie within the limits of experimental error ( $C_{16}H_{18}O_7$  requires C, 59.6; H, 5.6%.  $C_{20}H_{18}O_9$  requires C, 59.7; H, 4.6%). Molecular-weight determinations have led to contradictory results. By the cryoscopic method, using phenol as the solvent, Jowett and Potter obtained the value 310. On the other hand, Seel and Kelber (*Ber.*, 1916, **49**, 2364) obtained the abnormal value of 197 with phenol; by the ebullioscopic method, however, they obtained the average values of 408 with acetone and 440 with ethyl alcohol. Although the last-mentioned results support the  $C_{20}$  formula, the analytical data for the chloro- and bromo-barbaloins, which are highly crystalline and readily purified substances, agree much more closely with the  $C_{16}$  formula; this is seen from the following

analytical results from the papers of Jowett and Potter and of Léger :

Chlorobarbaloin.				
	% C.	% H.	% Cl.	% Br.
Found .....	45.9	3.4	24.9, 25.1	
Calc. for $C_{16}H_{15}O_7Cl_3$ .....	45.3	3.1	25.1	
Calc. for $C_{20}H_{14}O_8Cl_4$ .....	44.4	2.6	26.3	
Bromobarbaloin.				
Found .....	34.1	2.7		42.9, 41.8, 43.1
Calc. for $C_{16}H_{15}O_7Br_3$ .....	34.3	2.7		42.9
Calc. for $C_{20}H_{14}O_8Br_4$ .....	33.4	1.9		44.6

Jowett and Potter determined the molecular weight of the bromo-compound in phenol by the cryoscopic method and obtained the value 535 ( $C_{16}H_{15}O_7Br_3$  requires  $M$ , 559).

We have obtained analytical results for the bromo-compound (Found : Br, 42.6%) in agreement with those of previous investigators : the compound can be recrystallised without change from pyridine and digested for a short time with diethylaniline; further, its acetyl derivative both before and after treatment with sodium acetate in alcoholic solution has the same composition agreeing with the  $C_{16}$  formula. We are unable, therefore, to accept Léger's suggestion that the marked deficiency in halogen content for the  $C_{20}$  formula may be explained by the instability of the bromo- and chloro-compounds and their tendency to lose hydrogen halides.

Even more remarkable, in our opinion, is the resistance which barbaloin as a simple arabinoside shows to hydrolytic agents, a property which is shared by bromobarbaloin. The latter can be heated in a sealed tube at  $100^\circ$  with alcoholic sulphuric acid (20% by weight) without change. Again, barbaloin and its halogen derivatives dissolve in alkali, yielding bright yellow solutions: these would not be expected if the parent substance were a dihydroxyanthraquinone glucoside with two free phenolic hydroxyl groups, since such substances give red solutions.

We were therefore led to take up again the study of the chemistry of barbaloin and the results so far obtained appear to indicate that Léger's formula cannot be correct.

The action of reducing agents on barbaloin was first investigated, but with unsatisfactory results. The alcohol cannot be reduced with hydrogen in the presence of platinum oxide,\* and on treatment with sodium and alcohol or with hydriodic acid and phosphorus it yields bright red products resembling the phlobaphenes in properties. Acetylation-reduction yielded a colourless gum which could not be purified.

Results of a greater interest have been obtained from a detailed study of the bromination of barbaloin. It has long been known

\* We are indebted to Dr. H. King for carrying out this experiment.

that barbaloin on bromination with bromine water yields a bromo-barbaloin which is either tribromo- or tetrabromo-barbaloin according as the  $C_{16}$  or the  $C_{20}$  formula be adopted. Léger prepared a second bromo-compound, by bromination in hydrobromic acid solution, which differed completely in its properties from the ordinary bromobarbaloin and was considered by him to be the tribromide having the formula  $C_{20}H_{15}O_9Br_3$ . We have prepared this bromo-compound and confirmed its composition, but, on acetylation, contrary to expectation, it yields an amorphous *hexa-acetyl* and not a penta-acetyl derivative. The presence of six hydroxyl groups in this bromo-compound has been confirmed by the preparation of a *pentamethyl* ether by methylation with methyl sulphate, and as this ether can be acetylated it still contains a hydroxyl group. The analytical data (see p. 559) appear to indicate also that a methyl group is introduced into the nucleus, and the pentamethyl ether may therefore be formulated  $C_{20}H_8O_3Br_3Me(OH)(OMe)_5$ . The introduction of a methyl group into the nucleus does not require comment at this stage, since it is not infrequently observed when methyl sulphate is employed as a methylating agent.

These results rendered necessary the careful investigation of ordinary bromobarbaloin, which according to Léger is a tetrabromo-derivative. The difference in physical properties of the two bromo-compounds is very marked: the tribromo-compound is very sparingly soluble and microcrystalline, whereas the tetrabromo-compound is readily soluble and highly crystalline. This differentiation is much greater than that usually observed between tri- and tetra-bromo-derivatives. Our confirmation of the analytical results of previous workers for ordinary bromobarbaloin has been supplemented by molecular-weight determinations kindly carried out by Dr. Sugden by a new ebullioscopic method which he will describe. With acetone as the solvent, the molecular weight was found to be 538, in fair agreement with the calculated value 559 ( $C_{16}$  formula). When the bromo-compound is acetylated with acetyl chloride, a tetra-acetyl derivative, which has been previously described, is obtained, but if acetic anhydride is employed a different *acetyl* derivative is formed. Although this is amorphous, the analytical data show conclusively that it must contain five acetyl groups. The presence of five hydroxyl groups in this bromo-compound was confirmed by the preparation of a *pentamethyl* ether. This, like the acetyl derivative, is amorphous, but the analytical results indicate clearly that its composition is  $C_{16}H_{10}O_2Br_3(OMe)_5$ .

The result of the investigation of the bromo-compounds leads to the apparently anomalous position that, whereas by bromination in aqueous solution derivatives of a substance having the composition

$C_{16}H_{18}O_7$ , are obtained, bromination in the presence of hydrobromic acid yields derivatives of a substance having the composition  $C_{20}H_{18}O_9$ . It seems to us that these results can be reconciled only by assuming that the bromo-compound prepared in hydrobromic acid is a true derivative of barbaloin. As suggested by Léger, barbaloin has, therefore, the composition  $C_{20}H_{18}O_9$ , but it contains not five but six hydroxyl groups, so the formula may be written as  $C_{20}H_{12}O_3(OH)_6$  and that of the tribromo-compound as  $C_{20}H_9O_3Br_3(OH)_6$ .

With regard to the bromo-compound prepared in aqueous solution we suggest that it is an *oxidation product* formed by the loss of four carbon and two oxygen atoms and that it has the composition  $C_{16}H_{10}O_2Br_3(OH)_5$ . The methods adopted for its preparation (by the action of bromine water) and for the preparation of the analogous chloro-compound\* (potassium chlorate and hydrochloric acid or chlorine in hydrochloric acid) are such as would readily permit of oxidation occurring simultaneously with halogenation, and the yields are very poor in both cases. The suggestion that the lower-melting bromo-compound is not a normal bromination product of barbaloin is supported indirectly by a number of comparative experiments which we have carried out. We have been unable to prepare the bromo-compound except by the use of bromine water; bromination of barbaloin in acetic acid solution containing sodium acetate yields only the sparingly soluble bromo-compound,  $C_{20}H_{15}O_9Br_3$ , and in chloroform solution a substance resembling this in properties, but having a somewhat higher bromine content, is obtained. The last substance requires further study, but we are of the opinion that it is probably a tetrabromo-derivative.

To facilitate differentiation between these two bromo-derivatives, we suggest that the higher-melting compound,  $C_{20}H_{15}O_9Br_3$ , should be known as *tribromobarbaloin*, and the lower-melting derivative as *tribromonorbarbaloin*.

The only evidence which we have discovered directly at variance with the suggestion now made is the observation of Léger that tribromonorbarbaloin and trichloronorbarbaloin yield tetrabromo- and tetrachloro-aloe-emodin, respectively, on oxidation with sodium peroxide in alkaline solution. This reaction needs further investigation: it probably involves more complex changes than the simple hydrolysis required by Léger's formula. This view is supported by the fact that we have not been able to oxidise either acetyltribromobarbaloin or acetyltribromonorbarbaloin to an anthraquinone derivative with chromic acid.

\* We have prepared this chloro-compound and its composition is  $C_{16}H_{15}O_7Cl_3$ .

It is difficult to determine how far the results of the molecular-weight determinations which Dr. Sugden has kindly carried out on tribromonorbarbaloin pentamethyl ether bear on the present problem. These gave the average value of 844, the calculated molecular weight being 629. As has been mentioned, the substance is amorphous and separates from its acetone solution as a gum; the results of the molecular-weight determinations, however, are very concordant. For the present, we are inclined to regard the results as abnormal and due to association. Tribromobarbaloin itself is too sparingly soluble for molecular-weight determinations, but it is proposed to determine those of suitable derivatives.

If the views now stated are correct, the constitutions of barbaloin and of the other aloins must be more complex than has hitherto been assumed. The experimental investigation is being developed in various directions and it should be mentioned that Dr. A. Robertson is studying the synthesis of glucosides of rhein and of aloe-emodin.

#### EXPERIMENTAL.

The barbaloin used throughout this work was purified by two crystallisations from ethyl alcohol and dried over sulphuric acid. It was free from isobarbaloin.

*Tribromobarbaloin*,  $C_{20}H_{15}O_9Br_3$ .—To a solution of barbaloin (5 g.) in hydrobromic acid ( $d$  1.5; 25 c.c.) cooled to  $0^\circ$ , bromine (8 g.) in hydrobromic acid (25 c.c.) was gradually added. No appreciable rise of temperature took place and after 4 hours the mixture was kept at room temperature for 4 days. The mixture was poured on ice, and the voluminous yellow precipitate (5 g.) separated and dried in air. When this was mixed with hot aqueous alcohol (60%, 50 c.c.), a clear reddish-brown solution was obtained, and this, after being boiled for a few minutes, deposited a fine yellow crystalline solid (the filtrate, *A*, was reserved). The bromo-compound was conveniently purified by extraction with acetone in a Soxhlet apparatus; it then separated from the solution as a bright yellow powder. When slowly heated, the compound decomposed with vigorous evolution of gas at  $291^\circ$  after darkening at  $284^\circ$ ; on rapid heating, it decomposed without previous change at  $296^\circ$ . The compound is anhydrous and does not lose weight at  $110^\circ$  (Found: C, 37.7; H, 3.0; Br, 37.8, 37.6. Calc. for  $C_{20}H_{15}O_9Br_3$ : C, 37.5; H, 2.3; Br, 37.5%).

Tribromobarbaloin is extremely sparingly soluble in all the ordinary organic solvents and insoluble in water. It dissolves in much formic acid or acetic acid and separates slowly from the solutions; under these conditions, it appears to undergo some change, since the melting point falls to  $265^\circ$ . It is readily soluble in mineral

acids, the solution in concentrated sulphuric acid being reddish-yellow and slightly fluorescent. It is not attacked by the latter reagent (50%) when heated for a short time, nor does it undergo any change when heated at  $110^{\circ}$  with a methyl-alcoholic solution of hydrogen bromide (3%) in a sealed tube. It is readily soluble in alkalis, yielding golden-yellow solutions. Its alcoholic solution gives with ferric chloride a deep reddish-brown coloration; this becomes paler on warming and the original deeper colour reappears on cooling.

From the filtrate *A*, a small quantity of tribromonorbarbaloin was deposited on dilution with water.

*Acetyltribromobarbaloin*,  $C_{20}H_9O_3Br_3(OAc)_6$ .—The acetylation of tribromobarbaloin was investigated under various conditions, but a homogeneous product was obtained only by the following method. A solution of the bromo-compound (2 g.) in acetic anhydride (20 c.c.) to which two drops of sulphuric acid had been added was boiled for 2 hours. The cooled reaction mixture was poured into water; the heavy oil which was precipitated slowly solidified. The dried and finely powdered solid was purified by means of ligroin (b. p.  $60-80^{\circ}$ ), from which it separated as an almost colourless powder; this was not definitely crystalline. It softened at  $173^{\circ}$  and melted at  $185-187^{\circ}$  to a yellow resin (Found: C, 43.4; H, 3.5; Br, 26.4.  $C_{32}H_{27}O_{15}Br_3$  requires C, 43.1; H, 3.0; Br, 26.9%).

*Acetyltribromobarbaloin* is readily soluble in all the ordinary organic solvents with the exception of ligroin and cyclohexane. It is readily attacked by chromic acid in acetic acid-acetic anhydride solution, yielding an amorphous powder which is insoluble in alkali and has not been purified.

*Tribromobarbaloin Pentamethyl Ether*.—Tribromobarbaloin in acetone was treated with potassium hydroxide solution (20%) and a large excess of methyl sulphate. The colourless oil that separated was converted into a flocculent solid when poured into water. The dried solid was triturated with ether, which left undissolved any partly methylated material; on evaporation, the filtered extract gave the methyl ether as a gum. In two experiments a solid was obtained which crystallised in well-defined prisms; it was very sparingly soluble in ether and apparently free from halogen, but it was not obtained in quantity sufficient for identification.

The *pentamethyl ether* separated as a colourless powder, m. p.  $128-130^{\circ}$ , when water was added to a solution in methyl alcohol-acetone [Found: C, 43.0; H, 4.0; Br, 33.3; OMe, 22.9.  $C_{28}H_{27}O_9Br_3$  requires C, 43.1; H, 3.7; Br, 33.2; (OMe)<sub>5</sub>, 21.4%]. It was somewhat sparingly soluble in methyl alcohol and insoluble in ligroin and water, but readily soluble in ether, ethyl alcohol,

acetone, and ethyl acetate. It was only very slowly attacked by potassium permanganate in hot acetone solution.

*Acetyltribromobarbaloin Pentamethyl Ether*.—When a solution of the preceding ether was treated with acetyl chloride, and the excess of acid chloride removed, the product obtained could not be freed from a red substance which was also formed. A pure product was, however, obtained by using acetic anhydride containing a few drops of pyridine. The *acetyl* derivative, a colourless powder, was purified by precipitation from its solution in methyl alcohol by water. It had m. p. 102—105° after softening at 90° and was readily soluble in all organic solvents except ligroin (Found: C, 44.1; H, 4.1; Br, 31.4; Ac, 6.4.  $C_{28}H_{29}O_{10}Br_3$  requires C, 43.9; H, 3.8; Br, 31.4; Ac, 5.6%).

*Tribromonorbarbaloin*,  $C_{16}H_{15}O_7Br_3$ .—This was prepared by the bromination of barbaloin with bromine water in the manner described in the literature. After crystallising from alcohol and drying under reduced pressure, it had m. p. 193—194°, sintering at 188° and decomposing at 223° (Found: Br, 42.6. Calc.: Br, 42.9%). It can be recovered unchanged from its yellow solutions in alkalis on acidification.

*Acetylation of Tribromonorbarbaloin*.—Tribromotetra-acetylnorbarbaloin,  $C_{16}H_{11}O_3Br_3(OAc)_4$ , was obtained when tribromonorbarbaloin was acetylated with acetyl chloride. After crystallising from aqueous alcohol (70%), it had m. p. 137—139° (Found: Br, 32.5; Ac, 24.0. Calc.: Br, 33.0; 4Ac, 23.7%). It was insoluble in cold alkalis, but was hydrolysed to the parent bromo-compound by alcoholic sulphuric acid. It yielded an amorphous, dark brown powder when oxidised with chromic acid in acetic acid-acetic anhydride solution.

*Tribromopenta-acetylnorbarbaloin*,  $C_{16}H_{10}O_2Br_3(OAc)_5$ , was obtained when tribromonorbarbaloin was acetylated with acetic anhydride in the presence of sulphuric acid. It was sparingly soluble in cold aqueous alcohol (60%) and readily soluble in hot aqueous alcohol; from this solution it was deposited as an amorphous, granular, yellow powder, m. p. 139—140°, softening at 128° (Found: C, 40.5; H, 3.0; Br, 31.0.  $C_{26}H_{25}O_{12}Br_3$  requires C, 40.6; H, 3.2; Br, 31.2%).

*Tribromonorbarbaloin Pentamethyl Ether*,  $C_{16}H_{10}O_2Br_3(OMe)_5$ .—Tribromonorbarbaloin was fully methylated only after two treatments with methyl sulphate and alkali in acetone solution. The *ether*, which separated as a colourless powder, m. p. 112—113° after softening at 101°, was readily soluble in organic solvents and was purified by the careful addition of water to its solution in acetic acid. The white powder, m. p. 115—116°, obtained became yellow

on exposure to air. It was stable to potassium permanganate in acetone solution. Two distinct preparations were analysed [Found : C, 39.5, 40.1; H, 3.6, 3.9; Br, 38.6, 37.8; OMe, 21.4.  $C_{21}H_{25}O_7Br_3$  requires C, 40.0; H, 4.0; Br, 38.1; (OMe)<sub>5</sub>, 24.6%].

The methyl ether cannot be reduced with zinc dust in the cold, but, on warming in acetic acid solution, bromine is eliminated, the product being an amorphous solid which has not been purified. The ether is insoluble in alkali, gives with nitric acid an intense purple-violet coloration and with sulphuric acid a deep purple, is somewhat readily attacked by potassium permanganate in acetone solution, and when oxidised with lead peroxide yields a substance which gives a green colour with sulphuric acid.

We desire to express our indebtedness to Messrs. Burroughs, Wellcome and Co. and to Dr. H. A. D. Jowett for generous gifts of material which have made this investigation possible. To Professor R. Robinson, F.R.S., we are also greatly indebted for the considerable help and suggestive criticism which he has freely given during the progress of the work. Part of the expense of the investigation has been met out of a grant from the Government Grant Committee of the Royal Society, which we gratefully acknowledge.

## LXXIX.—*The Action of Nitric Acid on Some Metals.*

By ERNEST SYDNEY HEDGES.

INVESTIGATION of the kinetics of the dissolution of metals in acids with evolution of hydrogen (compare Centnerszwer, *Z. physikal. Chem.*, 1929, **A**, **141**, 297) has shown that the reactions involved are more complex than the simple electronic exchange often represented in text-books of electrochemistry. When nitric acid is the reagent, the numerous reduction products afford even greater complexity of reaction and the matter appears to have received less attention, although it is of technical importance.

Previous investigators (Acworth and Armstrong, *J.*, 1877, **31**, 60; Freer and Higley, *Amer. Chem. J.*, 1899, **21**, 377) have studied primarily the gaseous products of reduction of nitric acid at various concentrations by different metals (see summary by Bancroft, *J. Physical Chem.*, 1924, **28**, 474). Divers (*J.*, 1883, **43**, 465) classified metals into two groups in respect of their action on nitric acid: copper, mercury, silver, and bismuth produce water, nitrous

acid, and the nitrate of the metal, whilst zinc, cadmium, magnesium, aluminium, lead, iron, and the alkali metals do not yield nitrous acid, but give ammonia and generally also hydroxylamine. One of these groups includes metals which do not disengage hydrogen from hydrochloric acid, and the other comprises metals which do so.

For many years two rival theories have existed. According to one view, the first product of reaction of a metal such as copper with nitric acid is hydrogen, which, however, does not appear as such, but, being in the nascent state, reduces the nitric acid to a variety of reduction products depending on the conditions of reaction. In support of this, it is urged that free hydrogen is obtained when magnesium acts on very dilute nitric acid. Acworth and Armstrong (*loc. cit.*) incline to this view and write  $\text{Cu} + 2\text{HNO}_3 = \text{Cu}(\text{NO}_3)_2 + 2\text{H}$  to represent the first stage. Supporters of the other view regard the metal itself as the reducing agent and deny the production of hydrogen.

In the present paper a study has been made of the influence of rotation on the rate of reaction of some metals with nitric acid, and the results show that these metals fall definitely into two groups, the members of which are respectively electronegative and electropositive to hydrogen: the hydrogen theory probably holds for the first group and the oxidation theory for the second.

#### EXPERIMENTAL.

The experiments described below were suggested by the accidental observation that some nitric acid in which an immersed copper sheet had been rotating for some hours had not acquired a blue colour. It was then found that Veley (*J. Soc. Chem. Ind.*, 1889, 8, 858; *Phil. Trans.*, 1891, A, 182, 279) had already observed that a rolling sphere of copper dissolved more slowly in nitric acid than a stationary sphere, and that the cause of the phenomenon was the removal of nitrous acid, which acts as an autocatalyst, from the surface of the dissolving metal.

In the following experiments, metal sheet 1 mm. thick was cut into strips 7 cm. long, which were 1 cm. wide over a length of 4 cm. and 0.6 cm. wide over the remaining 3 cm. A length of 5 cm. of the strip was immersed in the acid, so that the immersed portion comprised all the 1 cm.-wide part and 1 cm. of the 0.6 cm.-wide part. By means of a small hole bored at the upper end, the strip was screwed to a nickel rod which could be rotated at speeds up to 3000 r.p.m. by means of an electric motor. The reason for narrowing the upper portion of the strip was to reduce the area in contact with the liquid line where preferential corrosion occurs (Hedges, *J.*, 1926, 831). The method is somewhat crude, but is probably

better than the more usual way of immersing the support in the acid and covering all except the desired portion with wax or some other protective coating : small quantities of such materials may exert a profound influence on the reaction (compare Hedges and Myers, J., 1924, **125**, 604). All the nitric acid used was freed from nitrous acid by being warmed to 30° whilst a vigorous stream of air bubbles passed through it. The metals were cleaned by etching with nitric acid. The experiments were conducted in a thermostat at 30° and the loss of weight of the metal after 1 hour's immersion was determined. In general, it was found that repetitions of the same experiment gave results agreeing within 3—4%, although occasionally larger discrepancies appeared. The figures given in the tables represent the mean of two results differing by not more than 5%. This degree of concordance is quite sufficient, since the changes studied are of a much higher order.

*Influence of Speed of Rotation on Rate of Dissolution.*—(1) *Copper in 25% \* nitric acid.*

Speed (r.p.m.) ...	0	80	100	180	360	450
Loss of wt. (g.) ...	1.312	0.259	0.131	0.079	0.014	0.003

The velocity of dissolution is greatly reduced by quite moderate rates of rotation, and at 450 r.p.m. has become exceedingly slow. The results indicate that the velocity of dissolution of copper in pure nitric acid is very low and that some product of the reaction which normally accumulates at the surface of the metal is an active catalyst. In the process of rotation, this catalyst is washed away from the surface as fast as it is formed, and consequently the reaction is slower than in the stationary state. If this explanation holds, it should be possible to increase greatly the velocity of dissolution of a rotating copper sheet by direct addition of the supposed catalytic reaction product to the nitric acid solution. For this purpose, experiments were conducted on the effect of adding nitrous acid (in the form of sodium nitrite) and copper nitrate at constant speed of rotation of the copper. The results are given below.

*Effect of adding sodium nitrite (constant speed 450 r.p.m.).*

Amt. added, % .....	0	0.1	0.5
Loss of wt. (g.) .....	0.003	0.171	0.622

*Effect of adding copper nitrate (constant speed 360 r.p.m.).*

Amt. added, % .....	0	0.2	1.0	10
Loss of wt. (g.) .....	0.014	0.004	0.004	0.007

Evidently, in agreement with Veley's conclusions (*loc. cit.*), nitrous acid is the reaction product responsible for the high speed of reaction in the stationary state. Copper nitrate, even in relatively

\* Percentages relate to acid of *d* 1.42 (by vol.).

large amounts, did not increase the velocity of reaction, an observation which is contrary to that of Rennie, Higgin, and Cooke (J., 1908, 93, 1162), who state that the reaction is greatly accelerated by copper nitrate. These authors did not rotate the metal but stirred the liquid—an inefficient means of replenishing the layer of liquid in contact with the solid.

(2) *Silver in 25% nitric acid.*

	Stationary.	At 450 r.p.m.	At 450 r.p.m., with 1% of NaNO <sub>2</sub> .
Loss of wt. (g.) .....	1.174	0.000	1.187

Rotation of silver at 450 r.p.m. inhibited dissolution by nitric acid completely, and the solution gave no reaction for silver ions when tested with hydrochloric acid. Addition of 1% of sodium nitrite to the rotating system brought the velocity of dissolution to practically the same value as that of stationary silver.

(3) *Tin in 25% nitric acid.*

	Stationary.	At 450 r.p.m.	Stationary with 1% of NaNO <sub>2</sub> .
Loss of wt. (g.) .....	0.270	0.390	0.114

(4) *Zinc in 10% nitric acid.*

	Stationary.	At 450 r.p.m.
Loss of wt. (g.) .....	1.476	3.222

(5) *Magnesium in 5% nitric acid.*

	Stationary.	At 450 r.p.m.	Stationary with 0.5% of NaNO <sub>2</sub> .
Loss of wt. (g.) .....	0.270	0.480	0.240

The results for tin, zinc, and magnesium show a striking difference from those for copper and silver. The rate of dissolution is *increased* when the metal is rotated, and nitrous acid has no accelerating effect; indeed, substitution of nitrous acid for some of the nitric acid reduces the velocity of dissolution of tin.

*Further Examination of the Copper-Nitric Acid System.*—Veley (*loc. cit.*) found that copper did not dissolve in dilute nitric acid containing a substance such as urea which could destroy the nitrous acid as fast as it is formed. The author's experiments confirmed this observation, but also showed that copper dissolves readily in concentrated nitric acid even when saturated with urea, and that dissolution started in the dilute solutions on gentle warming. In the following experiments, concentrated nitric acid (*d* 1.42) was saturated with urea, and the solution diluted with distilled water in the proportion stated; 5 c.c. of the mixture were put into a test-tube immersed in a large beaker containing water, the temperature

of which was raised by  $1^{\circ}$  per minute. A small piece of copper was dropped into the mixture at  $25^{\circ}$ .

$\text{HNO}_3\text{-CH}_4\text{ON}_2$ mixture, c.c.	$\text{H}_2\text{O}$ , c.c.	Result.
5	—	Immediate dissolution.
4	1	" "
3	2	Dissolution after 2—3 secs.
2	3	Dissolution after 5 secs.; reaction stopped by shaking tube.
1.5	3.5	No reaction at $25^{\circ}$ ; reaction starts at $27^{\circ}$ , and ceases if temp. is decreased.
1	4	As in preceding case, but $37^{\circ}$ is now the critical temperature.

Similar phenomena were observed when hydrogen peroxide or potassium permanganate was added to remove the nitrous acid, and the results indicate that these reagents are in general less effective than rapid stirring in removing the nitrous acid. In the more concentrated solutions at  $25^{\circ}$ , and in dilute solutions of nitric acid at higher temperatures, nitrous acid is produced by the reducing action of copper at a rate greater than that at which urea or hydrogen peroxide can react with it.

This conclusion made it of interest to determine whether a considerably higher speed of rotation could prevent the dissolution of copper by concentrated nitric acid ( $d$  1.42), and it was found that, although the reaction could not be stopped, its velocity was greatly reduced. For this purpose, a piece of copper foil 1 cm.  $\times$  1 cm.  $\times$  0.01 cm. was pierced and suspended by a glass hook which was lowered into an empty beaker and rotated at 2000 r.p.m. Concentrated nitric acid was then poured into the beaker. At rest, a piece of metal of these dimensions dissolved completely in the acid in less than 30 seconds, but when it was rotated at 2000 r.p.m., after an interval of about 6 mins. (during which the solution developed a green colour) the foil always left the hook, being still partly undissolved. The piece of copper left had a black skin and appeared to be passive, dissolving in the acid extremely slowly even when at rest. Some specimens were not completely dissolved after 60 mins. An interesting behaviour was observed when one of these specimens was removed from the nitric acid and allowed to drain. After a few seconds, momentary effervescence appeared on the surface, the black film disappeared, and the metal was found to have lost its passivity towards nitric acid. This behaviour resembles exactly that of electrolytic iron which has been rendered passive by concentrated nitric acid, removed, and allowed to drain (Evans, J., 1927, 1020). Evans considers that the phenomenon is caused by the tendency of the protective film to leave the metal-liquid interface and collect at the air-liquid interface.

These results suggest that, in the absence of nitrous acid, nitric acid produces a protective oxide film on copper, which is thus rendered passive in a similar way to the well-known action of concentrated nitric acid on iron. The black film mentioned above resembled that observed by the author on copper which had been rendered passive by immersion in concentrated nitric acid at  $-11^{\circ}$  (J., 1928, 975).

*The Anodic Dissolution of Copper in Nitric Acid.*—The dissolution of a copper anode in nitric acid is also affected greatly by the presence of nitrous acid. For example, during passage of a current of 50 milliamps. for 1 hour, a stationary anode lost 0.790 g. of copper, but when rotated at 400 r.p.m. it lost only 0.270 g.; when 2% of sodium nitrite was added, however, it lost 1.408 g.

In the following experiments, a rotating anode of the type previously described (J., 1927, 1028) was used, the cathode was of platinum foil, and the anode and cathode compartments were separated by means of a porous pot. The experiments were conducted in 25% nitric acid at  $30^{\circ}$ . The following table shows the loss of weight of the anode both when stationary and when rotated at 400 r.p.m. at various current densities. The last column gives the loss of weight to be expected in accordance with Faraday's law.

Current, milliamps.	Loss of weight, g.		
	Stationary.	At 400 r.p.m.	Calc.
0	1.312	0.01	0.000
25	1.158	0.096	0.592
50	0.790	0.270	1.185
100	1.000	0.280	2.369
500	1.314	0.586	11.848

It will be observed that in every case the rotating anode dissolves more slowly than the stationary anode, although at the higher current densities the difference is relatively less. At 25 milliamps. the loss is about twice as great as that calculated from Faraday's law, which means that much of the dissolution is controlled by local short-circuited electrolytic cells in the metal, the electrical energy of which is not registered on the external circuit. At higher current densities the loss is much less than that required by this law, the discrepancy increasing with the intensity of the current. In these cases, evolution of gas at the anode was observed, so that only a portion of the electrical energy is involved in the formation of cupric ions. Thus it appears that copper readily becomes passive, though incompletely so, under anodic polarisation, and the more readily so in absence of nitrous acid. At the end of the experiments, these electrodes had a black or grey film over their surface.

*Difference of Potential between Stationary and Rotating Copper Anodes.*—The difference of electropotential between the electrodes and a reference normal calomel electrode was measured by a static method, the measuring instrument being a string electrometer. The method was similar to that already described (J., 1927, 1077). The measurements were carried out both with stationary and with rotating (400 r.p.m.) electrodes, over the *C.D.* range 5–50 milliamps./cm<sup>2</sup>, and throughout this range the rotating electrode was positive (noble) to the stationary electrode by 0.16 volt. This result is in the direction to be expected from the presence of an oxide film on the rotating electrode.

### *Discussion.*

The metals investigated fall into two classes accordingly as the velocity of dissolution in nitric acid is increased or decreased by rotation. The presence of nitrous acid does not appreciably affect the rate of dissolution of members of the first group, but it accelerates very greatly that of metals of the second group. These groups are coincident with those of Divers (*loc. cit.*), who used as a basis of classification the nature of the reduction products. Members of the first group are electronegative to hydrogen, and those of the second group are electropositive.

The electronegative metals can normally displace hydrogen from acids and their behaviour provides no reason to doubt that they initially displace hydrogen from nitric acid; the hydrogen reduces the nitric acid to oxides of nitrogen and sometimes to ammonia and hydroxylamine. When the nitric acid is extremely dilute, hydrogen can be obtained in the free state by the dissolution of magnesium.

On the other hand, there is no *a priori* reason why the second group, consisting of electropositive metals, should displace hydrogen from nitric acid, since they do not do so from other acids.

The passivity phenomena observed when copper is rotated in concentrated nitric acid, the observations on the anodic dissolution of copper, the difference of potential between stationary and rotating copper electrodes, and the formation of visible black films on the copper all suggest that an oxide film is formed on copper by the action of nitric acid. There is also the fact that nitrous acid is produced and accelerates the reaction; part of this acid reacts with the copper oxide, for, particularly in the early stages, the soluble product contains green copper nitrite as well as the blue copper nitrate, and part of it is decomposed to oxides of nitrogen, which are the gases evolved.

The suggested reactions may be represented thus :

- (1)  $\text{Cu} + \text{HNO}_3 = \text{CuO} + \text{HNO}_2$ ;
- (2) (a)  $\text{CuO} + 2\text{HNO}_2 = \text{Cu}(\text{NO}_2)_2 + \text{H}_2\text{O}$ ;
- (b)  $\text{CuO} + 2\text{HNO}_3 = \text{Cu}(\text{NO}_3)_2 + \text{H}_2\text{O}$ ;
- (3)  $\text{Cu}(\text{NO}_2)_2 + 2\text{HNO}_3 = \text{Cu}(\text{NO}_3)_2 + 2\text{HNO}_2$ ;
- (4) (a)  $3\text{HNO}_2 = \text{HNO}_3 + 2\text{NO} + \text{H}_2\text{O}$ ;
- (b)  $\text{HNO}_2 + \text{HNO}_3 = 2\text{NO}_2 + \text{H}_2\text{O}$ .

In dilute acid 4 (a) gives nitric oxide as the main product, whilst in concentrated acid 4 (b) preponderates and the main gaseous product is nitrogen peroxide : a mixture is usually produced.

If, by rotation or by addition of such a substance as urea, the nitrous acid formed in (1) can be removed continuously, the metal becomes covered with a film of copper oxide and dissolves only slowly. Nitrous acid may be said to "activate" the copper, perhaps in the same way that chlorine ions activate passive iron. In any case, the mechanism of this process of activation is not clear, but in some way the activating agent appears to loosen the protective film.

The theory outlined above supposes that cupric oxide can afford a sufficient degree of protection to the underlying metal, although ordinarily this substance is readily soluble in nitric acid. To test this point, some rough experiments were carried out on the rate of dissolution in nitric acid of samples of cupric oxide prepared in different ways. The method was to add 1 g. of the powdered oxide to 100 c.c. of 25% nitric acid, which was efficiently stirred at a constant rate by means of a glass stirrer, and to note the time taken for complete dissolution. An ordinary commercial sample dissolved in 3 mins. A sample prepared from copper sulphate by precipitation with sodium hydroxide and ignition of the residue was completely dissolved in 5 mins. A sample prepared by igniting cupric nitrate was incompletely dissolved after 60 mins. It is possible, therefore, for a form of cupric oxide to be sufficiently resistant to nitric acid to form a poorly protective film of the type required. The fact that the films are sufficiently thick to be easily visible is an indication of the low degree of protection afforded compared with that of the oxide film on passive iron. As fast as the relatively porous cupric oxide film is dissolved it is repaired by the nitric acid.

Thus, nitric acid appears to oxidise copper and silver superficially, causing them to become passive, and the action of nitrous acid, both on the ordinary chemical reaction and on the anodic dissolution, may be described as one of "activation," though in what way it removes the protective film is not at present understood.

Although in the dissolution of electronegative metals in dilute nitric acid the displacement of hydrogen appears to be the first reaction, in concentrated acid the oxidation reaction may preponderate. Tin and iron form two excellent illustrations. Tin dissolves in dilute nitric acid, giving stannous nitrate, and the hydrogen reduces the nitric acid mainly to ammonia; in concentrated nitric acid a hydrated stannic oxide is produced, but has not the requisite physical properties for forming a good protective coating. Similarly, iron dissolves readily in dilute nitric acid, but in concentrated nitric acid receives a thin film of ferric oxide which protects it from further action, and the iron is said to be passive.

*Summary.*

The rate of dissolution of copper and of silver in nitric acid is decreased and can be almost prevented by rotation of the metal: the cause of this phenomenon is that nitrous acid (one of the products of reaction) is not allowed to accumulate at the metal surface. Direct addition of nitrous acid causes the rotating metal to dissolve rapidly. On the other hand, tin, zinc, and magnesium dissolve more rapidly in dilute nitric acid when rotated, and nitrous acid has no accelerating effect. Copper which has been rotated rapidly in concentrated nitric acid acquires a black film and becomes "passive" towards nitric acid, dissolving slowly even when subsequently at rest: it shows passivity phenomena in other respects. A copper anode also dissolves more slowly in nitric acid when rotated than when at rest for a given current density, but addition of nitrous acid accelerates the rate of dissolution. A rotating copper anode is electropositive by 0.16 volt to a stationary copper anode. The results suggest that the first action of nitric acid on copper or silver is one of oxidation, forming an oxide film which prevents further rapid attack, *i.e.*, the metal becomes passive; nitrous acid acts as an activating agent. The initial product of reaction of tin, zinc, or magnesium with dilute nitric acid is probably hydrogen. The results are discussed in relation to the passivity of iron.

LXXX.—*The Measurement of the Dielectric Constants of Organic Liquids.*

By ALFRED OWENS BALL.

THE interest aroused within recent years in the measurement of dielectric constants of liquids has been caused not only by the extension of accurate conductivity measurements to non-aqueous solutions and the development of the Debye-Hückel theory of strong electrolytes, but also by the use of the values of this property for determining dipole moments. In both cases a demand has been created for simple and rapid routine methods of proved accuracy and for trustworthy data relating to a few standard liquids for calibration purposes. These requirements can be satisfied in the case of good insulators, for which the heterodyne method is probably the best and simplest (Herweg, *Verh. deut. physikal. Ges.*, 1919, 21, 272; *Z. Physik*, 1920, 3, 36; Whiddington, *Proc. Camb. Phil. Soc.*, 1921, 20, 445; Grützmacher, *Z. Physik*, 1924, 28, 342) and for which benzene may be used for calibration purposes on the basis of the work of Hartshorn (*Proc. Roy. Soc.*, 1929, A, 123, 664). In the case of liquids which are not good insulators, however, the author is of the opinion that, although the resonance methods (including, as a special type, the heterodyne method) are simpler in operation, they are more likely to be affected by small and unsuspected errors due to conductivity than are the alternating-current bridge methods. Also, there appears to be no liquid possessing any appreciable conductivity for which really concordant results have been recorded, and the discrepancies may be attributable to any of the following causes: (1) experimental errors of the operator; (2) errors inherent in the method employed, these errors being possibly a function of the conductivity and of the frequency at which the determination is made; and (3) a real variation in the dielectric constant with the frequency.

The work described in the present paper was originally commenced in order to determine the dielectric constants of a few organic liquids with a view to correlation with conductivity measurements made in these laboratories (Philip and Oakley, on nitromethane, *J.*, 1924, 125, 1189; Martin, on benzonitrile, *J.*, 1928, 3270). In view of the considerations outlined above, however, it was decided to attempt to determine the dielectric constants of a few standard liquids over a range of frequency and temperature by means of an alternating-current bridge. This method has the further advantage over the resonance method that it is more convenient for absolute measurements when no calibrating liquid is

available (see p. 582). It was also intended to use these same liquids to compare the results afforded by the bridge method and one or more resonance methods at a constant high frequency. The results of using this method at audible frequencies are now recorded.

### *Alternating-current Bridge Systems.*

An alternating-current bridge may be used to determine the impedance operator of a system in the same manner as a direct-current bridge is employed to determine resistance. A theoretically perfect capacity of magnitude  $C$  has an impedance operator  $-j/\omega C$ , where  $j = \sqrt{-1}$ , and if an alternating potential is applied to it, the current vector will lead the voltage vector by  $\pi/2$ . In practice, however, owing to conductance of current through the medium, or absorption, or resistance of plates and contacts, the angle of lead is less, and the impedance operator cannot be represented in this way.

It is very important to emphasise the equivalence of capacity and resistance circuits to an imperfect condenser. The condenser is determined as its impedance operator, that is to say (in theory), as the quotient of the vector of the current carried by the vector of the voltage applied. Let the numerical value so found be  $a + bj$ . Now a capacity  $C_1$  and a resistance  $R_1$  in series have an impedance operator  $R_1 + \frac{1}{j\omega C_1}$ , and if this be put identically equal to the value  $a + bj$ , the two resultant expressions obtained by equating the real and the imaginary terms can be solved for  $C_1$  and  $R_1$ . Further, a capacity  $C_2$  and a resistance  $R_2$  in parallel have an impedance operator  $\frac{1}{1/R_2 + j\omega C_2}$ , and again unique values of  $C_2$  and  $R_2$  can be found which will make this expression assume the value  $a + bj$ . On the other hand, however, the impedance operator of a circuit consisting of a capacity and shunt resistance together with another resistance in series will involve three constants, and any number of solutions may therefore be obtained which will give it the value  $a + bj$ . That is to say, if a given imperfect condenser really consists of a capacity with resistances both in series and in parallel, it is impossible to determine the capacity simply by measuring the impedance operator of the whole system. Such a case as this might be imagined as one in which there was a conductance leak between the plates of the condenser, together with a terminal or contact resistance. The important point is that, from the impedance operator of a condenser, it is only possible to calculate values of two capacities, such that either the one, together with a resistance in parallel, or the other, with a resistance in series, will have an impedance operator identical with

that of the condenser in question. It is customary to term the resistances in these two cases the "equivalent shunt resistance" and the "equivalent series resistance" respectively, but it must not be forgotten that the corresponding capacity values are also merely "equivalent," and that neither can definitely be said to be the true capacity involved unless information is available regarding the internal physical structure of the system.

It is important, therefore, to consider the type of condenser to be measured, and to ascertain whether it approximates sufficiently closely to one or other of the above systems for the capacity values deduced thereby to be valid. Now, the great majority of organic liquids possess, even when highly purified, an appreciable conductivity, and the most serious imperfection in the condenser is the consequent (relatively) low shunt resistance. If, then, there is any further resistance in series, the equivalent shunt capacity of the system will not be equal to the actual capacity, the error involved being easily calculated in the following manner.

Suppose the condenser consists of a capacity  $C_1$  in parallel with a resistance  $R_1$ , both being in series with another resistance  $R_2$ .

Then its impedance operator will be  $Z_1 = R_2 + 1 / \left( \frac{1}{R_1} + j\omega C_1 \right)$ .

This condenser is now to be assumed equivalent to a system consisting of capacity and resistance in parallel. Let this capacity and resistance be  $C$  and  $R$  respectively, in which case the impedance operator is  $Z = 1 / \left( \frac{1}{R} + j\omega C \right)$ . Since the two systems are equivalent,

$Z$  and  $Z_1$  must have the same value, and hence after equating the two expressions the following solutions are obtained for the equivalent shunt resistance  $R$  and the equivalent shunt capacity  $C$ :

$$R = \frac{(R_1 + R_2)^2 + \omega^2 C_1^2 R_1^2 R_2^2}{(R_1 + R_2) + \omega^2 C_1^2 R_1^2 R_2^2}$$

$$C = \frac{C_1 R_1^2}{(R_1 + R_2)^2 + \omega^2 C_1^2 R_1^2 R_2^2}$$

Now, the dimensions of the condensers used in this work are such that, with a representative liquid, the capacity and shunt resistance are of the order of 0.001 microfarad and  $10^4$  ohms respectively. Under these conditions, and for a frequency of 1000, the term  $\omega^2 C_1^2 R_1^2 R_2^2$  will be negligible compared with  $(R_1 + R_2)^2$  provided that  $R_2$  is small, and in that case

$$C = C_1 \left( \frac{R_1}{R_1 + R_2} \right)^2 = C_1 \left( 1 - \frac{2R_2}{R_1} \right) \text{ (approx.)}$$

From this it appears that it is justifiable to regard the experi-

mental condenser as consisting of a capacity and a resistance in parallel, but only provided that the internal resistance of plates and contacts, together with the resistance effects due to absorption, is sufficiently small. It is shown later (p. 588) that this condition is satisfied by the dielectric containers in use.

Returning now to alternating-current bridge measurements, it is seen that a method is required that will permit of the measurement of a capacity of the order of 0.001 microfarad when shunted by a resistance varying down to less than 10,000 ohms, i.e., a condenser of very large loss angle. The simplest way of determining a pure capacity by an alternating-current bridge is that of De Sautig, adapted for alternating current by Wien (*Ann. Physik*, 1891, **44**, 697), in which two condensers are balanced against two resistances. But in this system no allowance is made for the difference in power factor of the condensers being compared, and, in consequence, the minima obtained are very flat, and indeed in many cases impossible of detection.

Of the methods that have been suggested to correct for this difference in power factor, it is only proposed to consider the parallel resistance method, first elaborated by Nernst (*Z. physikal. Chem.*, 1894, **14**, 622) and Turner (*ibid.*, 1900, **35**, 385), and subsequently used by Philip (*ibid.*, 1897, **24**, 18), Linebarger (*ibid.*, 1896, **20**, 131), Tangl (*Ann. Physik*, 1903, **10**, 748, 1903), Richards and Shipley (*J. Amer. Chem. Soc.*, 1919, **41**, 2002), King and Patrick (*ibid.*, 1921, **43**, 1835), Grimm and Patrick (*ibid.*, 1923, **45**, 2794), and Harris (J., 1925, **127**, 1049). The procedure is usually to introduce the experimental condenser into the first arm of the bridge and then to restore balance by adjustment of a standard condenser and a compensating shunt resistance in the second arm. It must be emphasised, however, that in the case of condensers of very large loss angle this method is subject to certain inaccuracies, because the full bridge system is that shown in Fig. 1. The capacities  $C_3$  and  $C_4$  across the ratio arms III and IV are due (i) to the residual capacity of the component resistances and their connecting leads, and (ii) to the earth capacities from the detector points if the Monasch earth point is used (*Electrician*, 1907, **59**, 416, 460, 504). Now the balance equations for this system are  $C_1R_3 = C_2R_4 + R_3R_4(C_3/R_2 - C_4/R_1)$  and  $1/R_1R_4 - 1/R_2R_3 = \omega^2(C_1C_4 - C_2C_3)$ ; if it is balanced first with  $R_1$  and  $R_2$  large,  $C_1R_3 = C_2R_4$ ; and if the experimental condenser  $C_x$  is then introduced across arm I and the new reading of  $C_1$  is  $C_1'$ , then  $(C_1' + C_x)R_3 = C_2R_4 + R_3R_4(C_3/R_2 - C_4/R_1)$ , and therefore  $C_x = (C_1 - C_1') + R_4(C_3/R_2 - C_4/R_1)$ . At balance,  $R_1$  and  $R_2$  are approximately equal, and in the bridge used  $R_3 = R_4 = 1000$  ohms.

In the extreme case when  $R_1$  approaches the value  $10^4$ , it is evident that the measured value of  $C_x$  will be in error by one-tenth of the difference  $C_3 - C_4$ , and if the earth capacities from the detector points are involved in this quantity by the use of the Monasch device, the error may be considerable. But even if the Wagner earth point is used, it is impossible to be absolutely certain that the residuals in the ratio arms III and IV are equal, and, moreover, inductance effects constitute an equally likely source of error. It

FIG. 1.

is advisable, therefore, that  $R_1$  and  $R_2$  should be maintained constant during the course of a measurement, and the condenser completely determined by substitution in arm I of the bridge. That is to say, a system is set up such that arm I consists of a capacity and resistance in parallel, the capacity being greater and the resistance less than the equivalent shunt capacity and resistance of the experimental condenser, which is then inserted across this arm, and balance is restored by adjustment of the capacity and resistance in this same arm only.

It should be noted also that the Monasch earth device is quite definitely an approximation, and is valid only when the impedance

of the capacity arms I and II is large compared with that of the ratio arms III and IV. Since this condition does not hold in the present work, the Wagner method of correcting for earth capacities has been used throughout (*Elekt. Z.*, 1911, 32, 1001; 1912, 33, 635).

#### *The Compensating Resistances.*

The chief requirement of the compensating resistance is that its residual capacity (and inductance) should be constant over the range of operations—which, in the case of the present work, is from a few thousand ohms upwards. Wire resistances of known residuals were not, unfortunately, available, and the Nernst-Turner types of liquid resistance were not entirely satisfactory over the lower part of the range, owing, first, to heating effects of the current, and secondly, to capacity changes which were by no means negligible even when the electrodes were heavily platinised to reduce the polarisation capacity. At first, attempts were made to calibrate for these residuals by means of a platinum-film resistance, but eventually the main substitution was effected by means of a carbon-film resistance, one of the liquid resistances being retained in parallel merely for purposes of fine adjustment. The carbon film used consisted simply of a thick line drawn on a piece of ground glass with an ordinary black-lead pencil, contact being established over any required length of the film by two amalgamated copper wires dipping into small drops of mercury. Provided that the film and mercury contacts are freshly prepared and quite clean, the resistance thus obtained is perfectly definite over a considerable length of time. It is further necessary to provide a distance control for the resistance, and the system used is shown in Fig. 2. A and B are wire electrodes heavily platinised, and C is a solid glass rod controlled from a distance by a cord passing over a pulley. By adjusting the position of A in the narrow tube D the total resistance of the cell can be made large compared with the effective resistance of the whole arm of the bridge with which it is placed in parallel, and thus the movement of the plunger in the wide limb E can be made to afford as fine an adjustment as is required. The electrolyte is the usual solution containing boric acid and mannitol (Magnanini, *Z. physikal. Chem.*, 1890, 6, 58; Nernst, *ibid.*, 1894, 14, 631). This resistance is always in circuit, and the electrode A is not moved during the course of a measurement. It is only necessary, therefore, to ascertain whether the movement of the plunger causes any change in the residual capacity of the system. This was done by rebalancing the bridge a number of times, the setting of the auxiliary liquid resistance being altered very slightly each time over a part of its range for which it was known to have no residual error. The position of the

plunger for balance was thus different each time, but even when the electrode A occupied its minimum position during the test (and hence carried the maximum current) no change in the capacity reading of the bridge could be detected. This determination was made especially because it was thought probable that polarisation

FIG. 2.

FIG. 3.

capacities might be set up owing to the small area of the wire electrodes.

#### *The Standard Condenser and Measuring Systems.*

As previously shown, the measurement of the capacity of a condenser filled with a liquid of relatively high conductivity is only possible by means of a substitution method, both the capacity and

the resistance being substituted in the same arm of the bridge. It has also been noted already that, since the dielectric constant is a ratio, it is not necessary to know the capacity of the dielectric container in absolute units, and hence the only requirement of the measuring system is that equal intervals on the scale should correspond to equal capacity changes. Since, however, this is an ideal to which practical systems can only be made to approximate, it is necessary that the appropriate calibration corrections be determined, and applied to every reading.

The standard measuring instrument available for the present work was a Sullivan variable air condenser, having a total range of about 1200  $\mu\mu$  farad. The scale was divided into 180° and was fitted with a vernier reading directly to tenths, and permitting a rough estimate of the second decimal place by means of a lens. It may be noted that, except in the case of liquids of high conductivity, the sharpness of the bridge setting always exceeded the accuracy with which the condenser scale could be read.

Now, a convenient value of the air capacity of a condenser of the Sayce and Briscoe type as used was found to be of the order of 50  $\mu\mu$  farad  $\equiv 7^\circ$ , and this could therefore be determined with an accuracy of at most 1%, this error being consequently involved in all subsequent dielectric measurements. Since it was desired to reach an ultimate accuracy of at least 0.2%, it was necessary to use either a larger capacity or a more open scale. The former was found to be impracticable with the type of condenser in use, and a measuring system was therefore set up similar to that suggested by Hartshorn (*Proc. Physical Soc.*, 1924, 36, 399). The standard variable air condenser  $C_1$  was placed in parallel with a fixed mica condenser  $C_2$ , both being in series with another fixed mica condenser  $C_3$ .  $C_2$  and  $C_3$  were made by Sullivans and had nominal capacity values of 0.002 microfarad and 0.00175 microfarad  $\equiv 290^\circ$  and  $250^\circ$  respectively. These condensers were guaranteed constant in capacity and power factor and of very small temperature coefficient, and in use they gave complete satisfaction.

The system constructed in this manner has a much more open scale than the standard condenser alone, but the relation between the capacity of the system and the scale reading of the standard is non-linear. The capacity of the system is  $C = (C_1 + C_2)C_3 / (C_1 + C_2 + C_3)$ , and for a straight-line relationship to hold between  $C$  and  $C_1$  it would be necessary that  $C_1$  should be negligibly small in comparison with  $C_2$  and  $C_3$ , but in this case not only does the net capacity of the system become inconveniently large, but the degree of constancy required of the fixed condensers will be correspondingly greater. It was therefore decided to use the system as described

and to perform the calibration in the following manner. A small constant capacity of about  $2.5^\circ$  was measured over successive portions of the scale of  $C_1$ , the actual scale differences ranging from about  $14^\circ$  to  $20^\circ$ . Each particular scale reading  $C_1$  was then reduced to the corresponding (approximate) value of  $C$  by the formula  $C = 250(C_1 + 290)/(C_1 + 290 + 250)$ , the nominal values of  $C_2$  and  $C_3$  being used, and since the reduced scale differences so obtained were then found to be constant to a first approximation, it was possible to draw up an ordinary calibration curve showing the correction to be applied at any point on the reduced scale. To demonstrate the order of accuracy attainable in this way, a series of 16 measurements was made on the air capacity of one of the dielectric containers. It was found that, excluding one reading (8.335) which was probably due to an error of observation, the values ranged between 8.299 and 8.323, with a mean of 8.310. It is certainly safe to ascribe an error of less than  $0.01^\circ$  to the arithmetic mean, i.e., an error of about 0.1%.

The measuring system as elaborated in this way gave a total capacity variation of about  $25^\circ$  corresponding to the complete range of  $C_1$ . Since the dielectric containers had an air capacity of about  $6-8^\circ$ , it is evident that, for the determination of dielectric constants above 3, the scale had to be extended by the customary device of placing one or more small fixed condensers in parallel with the whole measuring system, so that their capacity could be added to the latter when required. The condensers used each consisted of a small glass tube about 10 cm. long and 1 cm. in diameter sealed off at the lower end and held in position inside a larger tube filled with mercury. Into the inner tube was also placed some mercury (the quantity depending on the magnitude of the capacity required) so that the level was below that in the outer, thus minimising the effect of any slight displacement. A condenser with a glass dielectric in this manner has of course a definite temperature coefficient, and a small power factor: the former was controlled in practice by maintaining the room at a fairly constant temperature and checking the capacity value before and after each series of measurements; the latter was of no importance since it is only the effective shunt capacity of the condenser which enters into consideration.

The method of connexion adopted for these condensers should be noted. The mercury in the outer tube served as a shield, and was kept permanently connected to the screen terminal of the standard condenser, while contact was established between the other terminal and the mercury in the inner tube by a length of quill tubing filled with mercury and having a platinum wire sealed through the lower extremity. The condenser was inserted into

the measuring circuit when required by depressing a copper wire in the quill tubing, and thus, since the shield was permanently in circuit, the *change* of capacity on making contact was maintained constant and independent of any external effects.

The scale of the measuring system as extended in this way was about  $50^\circ$ , thus enabling liquids to be dealt with up to a dielectric constant of about 6, and the question then arose as to the advisability of extending it by more fixed condensers so that it covered the range up to  $\epsilon = 40$ . The accuracy of the results obtainable, however, is governed (see p. 577) by the accuracy with which the air capacity can be determined, and since this is subject to an error of about 0.1%, there is no need to determine any other capacity to a much greater accuracy than this. Now a liquid of dielectric constant 6 will afford a capacity of about  $40^\circ$ , and since such a capacity can be determined by direct comparison with the standard condenser to within  $\pm 0.05^\circ$ , it is evident that there will be no loss of accuracy in determining the liquids of higher dielectric constant in this way. It is necessary, however, to know the numerical relation between the two measuring systems, and this was found in the following manner. If measurements are made on a number of condensers (all having a capacity of about  $40^\circ$ ) with system I, a series of capacity readings  $C_1, C_2, C_3$ , etc., will be obtained which are all proportional to the absolute magnitude of the capacities concerned, the constant of proportionality being  $K$ . Similarly, if the same condensers are measured on system II (i.e., by direct substitution against the standard air condenser) a series of values  $C'_1, C'_2, C'_3$ , etc., will be obtained with a proportionality constant  $K'$ . Then  $C_1/C'_1 = C_2/C'_2 = C_3/C'_3 \dots = K/K'$ ,  $K/K'$  being the conversion factor between the two systems.

Now the error in determining  $C'$  is about 0.1%, and in  $C$  about 0.02%, and the following table gives an indication of the accuracy of the mean value of the ratio  $K/K'$ . The actual capacities measured were the three dielectric containers filled with appropriate liquids as indicated.

TABLE I.

Condenser.	Liquid.	$C$ .	$C'$ .	$K/K'$ .

The discrepancy observed for condenser I filled with dimethyl-ethyl carbinol at  $0^\circ$  is possibly due to the abnormally large temperature coefficient of the liquid at this point. The dielectric constant is 5.94 at  $25^\circ$  and 8.16 at  $0^\circ$ , so the error in the value 1.0243 could be caused by about  $0.1^\circ$  difference in the temperature of the cell when measured on the two systems.

The relation between these two measuring systems  $S_1$  and  $S_2$  having been obtained, the air capacity of each dielectric container can now be evaluated in terms of  $S_2$  by multiplying the value as determined on  $S_1$  by the conversion factor. For instance, the air capacity of condenser I in terms of  $S_1$  is  $8.311 \pm 0.005$ , and since the conversion factor is  $1.0276 \pm 0.0003$ , the value on the scale of  $S_2$  will be  $8.531 \pm 0.008$ . As measured directly on the scale of  $S_2$ , however, it is found to be  $8.54 \pm 0.03$ , and hence the increase in accuracy that has been obtained is obvious.

In conclusion, it must be observed that with an air capacity of  $8^\circ$ , the standard condenser will only cover the range of dielectric constant up to about 20, and therefore the scale was extended by means of auxiliary fixed condensers in just the same manner as was done for the system  $S_1$ . In this case, however, two Sullivan mica condensers were used of the same type as those described previously and of nominal value 0.001 and 0.002 microfarad respectively, and this extended scale was capable of dealing with dielectric constants up to 60. The method of connexion of these auxiliary condensers was the same as that noted previously, the screen terminal of each being kept permanently in circuit, and connexion being made as required by means of small mercury cups connected to the other terminals.

#### *The Experimental Condenser.*

The satisfactory design of the dielectric container is difficult, and probably most of the discrepancies occurring in the literature are to be attributed to errors in this respect. The essential features of an ideal condenser may be summarised thus (compare Hartshorn, *loc. cit.*) :

1. Its volume capacity should be reasonably small, since many of the organic liquids requiring investigation are expensive and difficult to prepare in bulk.
2. The electrostatic capacity should be as large as possible in order to secure the maximum accuracy of which the measuring system is capable.
3. It must be mechanically rigid, so that it may be handled without fear of any displacement of the conducting system and consequent alteration in capacity.
4. It must be easily cleaned and dried.

5. It must permit of accurate temperature control, and (of somewhat less importance) should be of such shape that it acquires the temperature of the thermostat fairly rapidly.

6. In this work, one other condition has been added that is not always required, *viz.*, that the condenser should be an absolute one, *i.e.*, it should afford direct proportionality between dielectric constant and measured capacity. This point needs explanation. Imagine the ideal case of two conductors placed in a vacuum at an infinite distance from all other conductors. If their capacity could be determined and then the whole of the surrounding space filled with some medium of dielectric constant  $\epsilon$ , the capacity would be increased accurately in the ratio  $\epsilon : 1$ . The same would hold good of two conductors within a closed conducting shield: the measured capacity would be  $C_{12} + C_1 C_2 / (C_1 + C_2)$ , where  $C_{12}$  is the inter-capacity between the conductors, and  $C_1$  and  $C_2$  are the capacities between each conductor and the shield separately, and then, provided the whole of the space within the shield were filled with the medium concerned, not only  $C_{12}$  but also  $C_1$  and  $C_2$ —and hence the effective measured capacity—would be proportional to the dielectric constant. If, however, the medium does not fill the whole space, this exact proportionality will no longer hold.

In practice this ideal case cannot be realised owing, first, to the leads which have to pass outside the shield to the measuring system, and secondly, to the need of some mechanical support which will fix the two conductors in a rigid position relative to each other and to the screen. It is possible, however, to overcome the difficulty of the leads by arranging that they make and break contact at the surface of the conductor by means of a very small movement, so that if they are of thin wire and pass through correspondingly small apertures in the shield, the change in their own capacity when contact is made becomes vanishingly small compared with the capacity being measured. It is quite a different matter with the second defect. Obviously no system can be devised which shall have no solid dielectric at any part of the field of force, although it is possible to dispose the solid in such a way that it only influences the shield capacities and does not intercept any of the lines of force between the two conductors. If in such a case measurements are made so that  $C_{12}$ ,  $C_1$ , and  $C_2$  can all be found individually (Giebe and Zickner, *Arch. Elekt.*, 1922, 11, 109; Hartshorn, *Proc. Physical Soc.*, 1924, 36, 399) and the lead correction is eliminated as above, the values of  $C_{12}$  thus found will be directly and accurately proportional to the dielectric constant of the medium, just as in the preceding hypothetical cases. It is at this point, however, that one great merit of the bridge method becomes apparent, *viz.*, that by means

of the Wagner or Monasch earth device, these shield capacities can be eliminated, so that one measurement is sufficient to determine  $C_{12}$ , as opposed to the three which are required by the other method. This represents not only a certain increase in accuracy, but a considerable saving in time, even in the case of the dual setting necessitated by the Wagner arm.

An alternative way of obtaining direct proportionality between measured capacity and dielectric constant is to determine a virtual capacity. This was the method adopted by Nernst for his absolute dielectric-constant determinations (*Z. physikal. Chem.*, 1894, 14, 634).

The virtual condenser method is not, however, well suited for routine determinations since, not only has the condenser to be filled and emptied a number of times for each determination, but also the use of four capacity readings instead of two to calculate the dielectric constant increases the probable error. On the other hand, the design of an absolute condenser has usually been achieved only at the expense of using a large volume of liquid. The majority of workers have therefore favoured some kind of relative condenser which can be calibrated in terms of liquids of known dielectric constants.

Consider the system discussed previously of two conductors within a closed conducting shield, and let us suppose this time that some part of the space is filled with a solid dielectric. Then, in general, any elementary tube of force from one conductor to the other will pass partly through a vacuum and partly through the solid, and the total element of capacity between the conductors due to this tube will be the series addition product of these portions. That is, if  $\Delta C_v$  and  $\Delta C_s$  represent the capacities due to vacuum elements and solid elements, respectively, the total contribution made to the capacity of the system by this tube of force will be  $1 / \left( \frac{1}{\Delta C_v} + \frac{1}{\Delta C_s} \right)$ . Let this be written as  $1 / \left( \frac{1}{c_v} + \frac{1}{c_s} \right)$ . The total capacity between the conductors will then be  $c_1 = \Sigma 1 / \left( \frac{1}{c_v} + \frac{1}{c_s} \right)$ , the summation being performed over all the tubes of force. If now a liquid of dielectric constant  $\epsilon$  is introduced, it may be assumed as a first approximation that the shape of the field of force remains unaltered, and the new capacity will be  $C_1 = \Sigma 1 / \left( \frac{1}{\epsilon c_v} + \frac{1}{c_s} \right)$ . The validity of this assumption will be examined later.

For the purposes of measurement it is necessary to express  $\epsilon$  as a function of  $c_1$  and  $C_1$ , but it is evident that in this general case there is no deducible relationship. There are two cases, however,

in which a simplification is practicable. (1) If the term due to  $c_s$  vanishes throughout the summation we have  $C_1 = 1/\Sigma \frac{1}{\epsilon c_v}$  or  $C_1 = \epsilon \times \text{constant}$ , corresponding to the case of an absolute condenser already discussed. (2) If either  $c_v$  or  $c_s$  vanishes for each individual term of the summation,

$$C_1 = \Sigma 1 / \left( \frac{1}{\epsilon c_v} \right) + \Sigma 1 / \left( \frac{1}{c_s} \right) \\ = \epsilon \Sigma c_v + \Sigma c_s$$

thus affording a simple linear relation between  $\epsilon$  and  $C_1$ . This evidently means that such a linear relationship holds if, and only if, each tube of force passes through only one medium. If the lines of force pass at any point from the solid to the liquid, it will not be possible to write  $C_1 = A\epsilon + B$ , where  $A$  and  $B$  are constants depending only on the geometrical configuration of the system and the dielectric constant of the solid medium. The importance of this limitation was definitely recognised by Nernst (*Z. physikal. Chem.*, 1894, 14, 633), although subsequent workers have sometimes ignored it.

The majority of routine measurements by previous investigators have been made with condensers for which the capacity has been assumed to be a linear function of the dielectric constant, i.e.,  $C = \epsilon c_v + c_s$ , the calibration constants  $c_v$  and  $c_s$  being determined from the air capacity and the capacity when filled with some liquid of known dielectric constant. This method suffers from certain drawbacks in our present state of knowledge. First, in view of the limitations under which strict proportionality between measured capacity and dielectric constant has been shown to exist, it does not appear very satisfactory to use only one liquid for calibration purposes over the whole range. Theoretically, the calibration should be performed with a number of liquids such that the range of dielectric constant to be investigated is covered fairly uniformly, and if then it is found that the capacity values so determined are linearly related to the corresponding known dielectric constants it will be permissible to equate the dielectric constant of any other liquid to  $(C - c_s)/c_v$ . Otherwise, an attempt may be made to represent the results by some empirical expression containing more than two constants, or the capacity may be plotted against the dielectric constant and the value for any unknown liquid read off from the graph. But here the second drawback to this relative condenser method makes itself felt. Not only are there too few liquids of accurately known dielectric constant to show whether strict linear relationship does hold or not, but it is evident that,

even if it does, the accuracy of the results obtained can never exceed that assumed for the calibrating liquids.

It was pointed out by Hartshorn (*loc. cit.*) in his work on benzene that the obvious criteria to be satisfied by such calibrating liquids are stability, ease and certainty of purification, reasonable cheapness, and (most important) fairly low conductivity, and the number of liquids satisfying these conditions is extremely limited. There are a few from about 2 to 2.5, of which benzene is undoubtedly the best; over the higher ranges, however, apart from chloroform (5), pyridine (12), and nitrobenzene (35), the author has failed to find any which have not some serious drawback to their use as calibrating standards.

Table II gives the results (corrected to 0°, 25°, and 50°) obtained by some of the previous workers for benzene, chloroform, and nitrobenzene.

In view of these discordant results it was obviously necessary to use some type of absolute condenser for the present work, and it was found that they fall into two main classes: (1) the virtual capacity type referred to previously; (2) condensers in which some attempt has been made to ensure that the whole of the lines of force giving rise to the measured capacity pass through the homogeneous medium. In general it is by no means apparent that

the condensers used by such workers as Grützmacher, Graffunder, Isnardi, or Jezewski were strictly absolute, and although in the absence of detailed dimensions it is difficult to discuss the probable magnitude of the deviation, the author is of the opinion that the greater part of the above discrepancies are to be attributed to this cause, together with the closely allied error introduced by the leads.

For reasons already stated, it was decided to exclude virtual capacity condensers from the scheme of the present work. Some time was spent initially with parallel-plate condensers, but satisfactory results were not obtained. Eventually it was decided to adopt the design first introduced by Sayce and Briscoe (*loc. cit.*) as a basis for further work. Three modifications were constructed, of which the first was uncorrected for the end effect, and the second and third had two completely different devices for eliminating this error.

*Condensers.*—*Condenser I* (Fig. 3). This consisted essentially of two concentric glass tubes sealed one within the other, the inner surface of the outer and the outer surface of the inner being silvered over the straight portion of each so that the annular space between them served as the dielectric container. The outer tube was 22 mm. in diameter and the air gap was about 1 mm. Contact with the silver film was made by platinum wires sealed through the walls into side tubes A and B; it should be noted that for good contact these wires must be sealed on to the walls again at some other point besides that at which they pass through into the side tube. Silvering was performed as follows. The lower internal seal was first coated with paraffin wax by drawing up through the tube C a mixture of equal parts of wax and xylene at about 60°. After a few moments, the hot liquid was allowed to drain away leaving a film which, when cold, successfully resists the attack of the silvering solution. The latter was introduced in the same manner, at least three layers were deposited, and the condenser was washed by drawing through it a rapid current of distilled water. It was then dried, and the paraffin wax removed with warm xylene, the tube E being subsequently sealed off.

This cell has the advantage that the water of the thermostat can circulate through the inner cylinder *via* openings C and D, and extremely rapid and efficient temperature control can therefore be maintained.

*Lead capacities and method of shielding.* In normal use the condenser is sunk in a thermostat so that the water level comes to within about 2 cm. of the taps. Imagine that it is immersed in a silvering bath to this level so that a metallic film is deposited, not only round the body of the cell, but also round the glass tubes down

which the leads pass to the mercury contacts. In these circumstances the following capacities will come into play: (1) the capacity between the two silver films on each side of the annular space; (2) the capacity between each film and the shielding film through the glass wall; (3) the capacity of each platinum mercury contact with the shield; (4) the capacity of each copper lead with the shielding film around the glass side tubes; (5) the capacity between the leads over the length from the shielded tubes to the point at which they are connected to the bridge system. If now the screen is earthed and the bridge balanced by means of the Wagner earth point in the usual manner, capacities 2, 3, and 4 will not be measured, and the only capacity in circuit will be  $C_1 + C_5$ . Suppose now the leads to be raised in the side tubes so that they just do not make contact with the mercury. The capacity in circuit will then be  $C_5' + 1 \left( \frac{1}{C_a} + \frac{1}{C_b} + \frac{1}{C_1} \right)$ , where  $C_a$  and  $C_b$  respectively are the small capacities between the leads and the mercury contacts.  $C_1$  is large compared with  $C_a$  or  $C_b$ , and to a first approximation these may be assumed equal, so that the capacity in circuit may be written  $C_5' + C_a/2$ . Now this capacity  $C_a$  across the broken contact will fall off fairly rapidly as the degree of separation increases, and by making actual measurements on the capacity between a similar lead and the surface of mercury in a small U-tube, it was shown that with a 1-cm. gap the capacity could not be detected. Further the change from  $C_5$  to  $C_5'$  due to this 1 cm. increase in the length of the lead between the cell and the bridge is also much less than can be detected—the leads being about 10 cm. apart.

The change that occurs on separating the leads from the mercury contacts by about 1 cm. affords therefore an accurate measure of the capacity.

This result has been arrived at by assuming a metallic shield around the outside of the dielectric cell. It is found in practice, however, that identical results are obtained whether an earthed screen is provided, or whether the cell is merely placed in the water of the thermostat, and the latter earthed. Tap water has a sufficiently high conductivity from this point of view for it to be regarded as a conductor and not as an insulator.

*The end effect.* It is true that in this cell there is no solid dielectric at any point between the two films which constitute the plates of the condenser (referred to subsequently as the condenser films), but there is sufficient uncertainty regarding the distribution of the field at the extremities to prevent its being regarded *a priori* as a satisfactory form of absolute condenser; it appears possible that

some of the lines of force may bend round so that they pass not only through the dielectric medium but also through the glass walls, although in view of the earthed shield on the other side of each wall, this error is not likely to be large. Condensers II and III

FIG. 4.

FIG. 5.

were therefore constructed with a view to eliminating this possibility entirely.

*Condenser II* (Fig. 4). In this cell the two glass cylinders corresponding to those in condenser I were sealed together at the top only, the outer being drawn off at the bottom to a fairly wide-bore capillary. About 8 cm. below the seal, another intermediate cylinder

was joined as shown, and this had a small hole indicated at D. The annular space below the point F at which this cylinder terminates was about 10 cm. long with an air gap of 1 mm. Silvering solution was poured into the side tube E until it filled the whole cell to the level of the platinum contact C, a large air bubble, however, being trapped between the inner cylinder and the intermediate one above the hole in the latter. The inside of the inner cylinder was also silvered up to the level of the contact C. The contacts A and B were connected to the bridge in the usual manner, and C was kept permanently earthed.

It is evident that the capacity being measured between the contacts A and B is constituted solely by the field between the condenser films below F, *i.e.*, the end effect in condenser I has here become divided in two between the earthed film and each condenser film respectively, and these earth capacities are, of course, not measured. In other words, the whole of the lines of force giving rise to the capacity between A and B pass through the lower annular space only. This contains an absolutely homogeneous medium and the only points at which distortion of the field can occur due to the dielectric constant of the medium are the extremities of the two condenser films—and these are too remote for there to be any effect on the field at F.

If this view is correct, the measured capacity should be independent of the level of the liquid filling the cell provided it rises at least 1 cm. or so above the point F. This was tested and found to hold even for liquids of high dielectric constant.

*Condenser III* (Fig. 5). In this cell the end effect is eliminated, not by an earthed cylinder intermediate between the extremities of the two condenser films, but by two earthed cylinders placed above and concentric with them, in such a way that the air gap is as small as possible. In other respects the construction was similar to the two preceding cells. Silvering solution was poured into the side tube D until it rose in the annular space to the point E. After deposition of the silver had been completed, the condenser was inverted and another film was deposited from the side tube F up to the annular space so that there was only about 1 mm. gap between it and the previous film. A and B were the contacts connected to the bridge and C was earthed. For measuring purposes, the level of the liquid in the side tube was adjusted until it had risen at least 1 cm. above the point E.

Two other errors may arise through faulty condenser design, *viz.*, (a) the series resistance error discussed on p. 572, and (b) polarisation capacities.

(a) For the investigation of the first, condenser I was silvered

without a preliminary treatment with paraffin wax, so that the silver film was continuous between the contacts A and B, and the resistance between these points was then measured and found to be about 7 ohms for one deposit of silver, 4 ohms for two, and 2 ohms for three. It was evident that the terminal or contact resistance was small, and that the effective series resistance was that due to the internal resistance of the films.

Measurements were also made on condensers II and III, by pouring in a quantity of saturated potassium chloride solution so that the condenser films were short-circuited at the bottom; in each case the resistance (for three layer deposits) was about 2 ohms.

Now, of the liquids for which accurate results are quoted subsequently, nitrobenzene had the highest conductivity, and the equivalent shunt resistance of the condensers was therefore a minimum when filled with this at 80°, the actual value being about 5000 ohms. Hence (see p. 572), the error caused by a 2-ohm series resistance was less than 0.1%, and at lower temperatures and for other liquids it was, of course, still smaller.

(b) The possibility of an error due to polarisation capacities was investigated in the case of the liquids of higher conductivity by varying the intensity of the oscillator output, and hence the current density through the cell, over at least a five-fold range. No change in the measured capacity was detected.

#### *Apparatus and Procedure.*

*The Generator.*—The triode valve oscillator has now completely supplanted the older types of generator, not only by reason of its ease of manipulation, but by virtue of the purity of wave form obtainable. The actual instrument used was made by Cambridge & Paul. It had a variable capacity unit, by means of which the frequency could be varied between 100 and 5000, and also 3 secondary windings which permitted of the output intensity being varied within fairly wide limits. Satisfactory results were obtained either with an R valve, or a dull emitter valve, or (if more power was required) with a valve of the LS5 type. In general, however, with liquids of any appreciable conductivity, it was found much better to reduce the intensity as far as possible in order to minimise heating effects in the bridge.

*The Detector.*—A 1000-ohm Brown telephone was used, but since it was found that a low output from the oscillator did not give sufficient sensitivity, a two-valve amplifying circuit was introduced between the bridge and the telephone. The components used were two D.E.L. 410 valves and a Marconi Ideal Transformer of ratio 4:1; this amply intensified the effect, but the quality of the note

suffered considerably from the introduction of harmonics. These, however, were almost entirely eliminated by shunting the telephone with a condenser of suitable value to by-pass the notes of higher frequency. Too large a capacity will begin to reduce the intensity of the fundamental, and an optimum value was sought at which the selective reduction of the overtones was a maximum. For a fundamental note of 1000 frequency, a 0.15 microfarad capacity gave satisfactory working.

*Bridge Components.*—The ratio arms were two Sullivan 1000-ohm non-reactive coils guaranteed equal to each other to within 0.01%. The standard condenser (see p. 577) was fitted with a wooden arm so that it could be controlled from a distance of 8 or 9 feet. The capacity in the second arm of the bridge required to balance that in the measuring arm was made up by a 0.001 microfarad Dubilier variable air condenser, together with two fixed mica condensers of 0.001 and 0.002 microfarad capacity respectively. The compensating resistances were as previously described (p. 575).

*The Wagner Earth-point System.*—This system (referred to subsequently as the Wagner arms) was constructed in the case of liquids of low conductivity to imitate the main bridge system, *i.e.*, one arm consisted of a 1000-ohm fixed resistance, and the other of a variable capacity shunted by a variable liquid resistance. In the case of liquids of higher conductivity, it was found preferable to make the total impedance of the Wagner arms large compared with that of the bridge, and hence a fixed 0.01 microfarad condenser was used in one arm, while a variable wire resistance (max. 10,000 ohms) in series with a variable condenser (max. 1 microfarad) constituted the second. It is, of course, not necessary that the Wagner arm components should be of the same degree of perfection as those used in the main bridge system.

*Bridge Set-up.*—The oscillator was placed about 8 feet from the nearest bridge component and was surrounded by an earthed screen, while the amplifier was similarly screened and placed about 6 feet away on the further side of the bridge, the observer being situated just beyond. Connexion between the oscillator, bridge, and amplifier was made by means of armoured flex, the sheath being earthed. All the bridge component shields were connected to one or other of the oscillator points, and were mounted on blocks of paraffin wax.

It was found that the bridge was reasonably free from external influences—in particular the balance point was independent of the observer's position provided he did not approach to within less than 2 feet, and the capacity balance could often be accurately reproduced over a period of hours. Direct action from the oscillator

was negligible, reversal of the connexions to either the bridge or telephone terminals causing no change in the balance point.

*Temperature Control.*—A gas-heated thermostat was used for temperatures above  $18^{\circ}$ , and maintained constant to within  $\pm 0.02^{\circ}$ . Temperatures below  $18^{\circ}$  were suitably controlled by using a bath of large volume insulated with felt, and by working at a temperature within a few degrees of that of the room, the latter also being maintained as constant as possible. Under these conditions, the thermometer reading could be kept within  $0.05^{\circ}$  over at least  $\frac{1}{2}$  hour. The bath at  $0^{\circ}$  was maintained with tap water and ice (p. 586), the exact temperature being observed on a thermometer. In a number of cases the results quoted have been reduced to even temperatures by using the appropriate temperature coefficient, but such corrections were not used for differences of more than  $\frac{1}{2}^{\circ}$ . The thermometer was calibrated against another standardised at the N.P.L.

*Method of Measurement.*—The following scheme was adopted systematically for all the measurements recorded. The bridge and Wagner arms were first set to approximate balance with the condenser to be determined in circuit, and since, with practice, this could be done fairly accurately, the need for a large number of successive adjustments was avoided. The current was then switched on, each balance corrected to a minimum, and then an accurate bridge balance made from a distance. The standard condenser was set at least twice (once from each direction), and it was usually found (except in the case of liquids of high conductivity) that these readings agreed as closely as could be observed on the vernier. The experimental condenser was removed from circuit, the bridge rebalanced as before, only the measuring system and compensating resistances in the same arm being altered, and finally the condenser was re-connected and the original balance checked to make sure that no shift in the bridge reading had occurred.

It should be noted that a definite displacement of the Wagner arms by an amount considerably greater than the sensitivity of their balance makes no perceptible difference to the bridge reading.

### Results.

(1) *Intercomparison of the Dielectric Containers.*—Table III gives the dielectric constants of a number of liquids as determined at  $25^{\circ}$  in the three cells described previously. The values are quoted only for the purpose of showing the relationship between these condensers, and are not necessarily (except in the case of benzene) to be taken as accurate data for the liquids in question, since no special purification was undertaken beyond that necessary to obtain a reasonably low conductivity, i.e., less than  $10^{-7}$ . The

reproducibility of the results was checked throughout by making two distinct sets of observations on each condenser after emptying and refilling it. As an example, the capacities on the second measuring system for the mixture of toluene and amyl alcohol in condenser III were :

1st Series .....	86.61	86.60	86.63	} Mean 86.61
2nd Series .....	86.61	86.62	86.58	

The air capacities of all three condensers on  $S_1$  were :

Condenser.	Number of observations.	Range of observations.	Mean.
I	15	8.299—8.323	8.310
II	16	5.952—5.969	5.956
III	14	7.920—7.945	7.933

Hence the dielectric constant for this mixture relative to air was  $86.61/7.933 \times 1.0276 = 10.626$ .

The dielectric constants relative to air (Table III) show that condensers II and III are in fair agreement, the latter affording results consistently high by about 0.1—0.15%, and that the results given by condenser I are distinctly low—by about 0.5% over the upper range.

For the dielectric constants relative to benzene, the agreement between condensers II and III is extremely good, and hence it appeared probable that the discrepancy between them on the air basis might be due to an error in the air capacity determination of one of them. The benzene measurements were therefore repeated with two samples of specially purified material, and the results obtained were :

Sample.	Condenser.	Capacity.	$\epsilon$ .
A	II	13.536	2.273
B	II	13.534	2.273
A	III	18.048	2.275
B	III	18.043	2.275

These values were then taken as standard, and the dielectric constant of benzene at  $25^\circ$  assumed to be 2.273 (Hartshorn, *Proc. Roy.*

*Soc.*, 1929, A, **123**, 664); the air capacities calculated on this basis were 5.955 and 7.939.

The agreement between observed and calculated values is exact in the case of condenser II, and for condenser III the difference is less than 0.1%, the calculated value falling well within the range of observations. This discrepancy is too small to justify any conclusions being drawn, and the values calculated from the benzene capacities are therefore taken as standard; on this basis, both condensers II and III afford direct proportionality (within 0.1%) between dielectric constant and measured capacity.

Thus, these two condensers, which have different devices for eliminating the end effect, afford concordant results over the whole scale investigated, within the limits of experimental error. Condenser I, however, which is uncorrected for the end effect, does not agree with them over the whole range either with air or with benzene as unity. Further comment on the discrepancies shown by Condenser I is postponed, but it is claimed that both Condensers II and III are free from errors due to the end effect.

It was also necessary to consider the temperature variation of these condensers. It may be assumed that the silver film expands at the same rate as the glass, and if the coefficient of expansion of glass is taken as  $10^{-5}$ , a change of  $100^{\circ}$  will only produce 0.1% change in the dimensions of the cell. Further, such change as does occur will increase the area of the plates and also the distance between them, and these two effects will tend to neutralise each other with regard to capacity changes. It is to be expected, therefore, that the change in capacity over  $100^{\circ}$  range should be too small to be detected, and this is borne out by the following results.

In the first place the air capacities of condensers I and II were measured at  $0^{\circ}$ ,  $25^{\circ}$ , and  $80^{\circ}$ , the mean values being:

	$0^{\circ}$ .	$25^{\circ}$ .	$80^{\circ}$ .
Condenser I .....	8.309	8.311	8.308
Condenser II .....	5.952	5.956	5.957

Secondly, the benzene capacities for the first condenser were measured at  $25^{\circ}$  and  $50^{\circ}$ , and the air capacities calculated on this basis, assuming the dielectric constant of benzene to be 2.273 at  $25^{\circ}$  and 2.223 at  $50^{\circ}$  (Hartshorn, *loc. cit.*), are 8.303 and 8.302 respectively.

It is concluded, therefore, that this type of dielectric container has no appreciable temperature coefficient of capacity, and for the purpose of the next section the air capacities have been assumed to be

	II.	III.

*Purification of benzene.* The first of the samples referred to above had been purified by Harris (J., 1925, 127, 1063) for dielectric-constant determinations. It had been standing over sodium wire in the meanwhile, and was distilled once before use. The second sample was purified by the author from A.R. benzene by Richards and Shipley's method (J. Amer. Chem. Soc., 1914, 36, 1825).

(2) *The Dielectric Constants of Certain Purified Liquids at 0—80°.*—(a) *Standard liquids at 25°.* *Benzene.* The results obtained for two samples of specially purified benzene have been summarised on p. 592. They were subject to a probable error of about 0.1% on the air-capacity determination, and of 0.05% on the benzene, thus affording a mean value of  $2.274 \pm 0.004$ : the figure  $2.2725 \pm 0.0005$  which has been accepted from Hartshorn's work (*loc. cit.*) lies well within these limits.

*Chloroform.* Three samples of different origin (one from B.D.H. and two from Hopkin and Williams) were purified by the same method. Each was shaken for 15 minutes with concentrated sulphuric acid, washed twice with dilute sodium hydroxide solution and five times with water, dried over ignited potassium carbonate, and fractionated until a main fraction was obtained boiling within less than 0.1°. This was kept over calcium chloride in a dark cupboard, and immediately before use was decanted, shaken for a few minutes with a little solid sodium hydroxide, and distilled.

The results obtained are given in Table IV. The probable error in the air capacity as adjusted by the benzene values is certainly less than 0.1%, and in the chloroform capacities 0.02%, the total error therefore being 1 part in 800 parts; the mean value accepted for chloroform at 25° is  $4.724 \pm 0.006$ .

*Nitrobenzene.* Sample A. This had been purified by Harris, and distilled completely at practically constant temperature. It was therefore merely dried over calcium chloride and distilled twice in a vacuum, having then a conductivity of the order  $10^{-7}$  mho. (In the author's experience, the easiest way to obtain good conductivities is to use as high a vacuum as possible for the final distillations: throughout this work 1 mm. or less has been employed for all liquids of high boiling point.)

Sample B. This was B.D.H. material. It was fractionated four times in a vacuum, only one-third of the original bulk being retained. It was then dried over calcium chloride and distilled twice in a vacuum;  $\kappa = ca. 10^{-7}$ .

Sample C. This was synthesised from some of the benzene purified as above, care being taken to prevent the temperature rising above 50° during nitration; the nitrobenzene layer was separated, shaken once with water and four times with sodium

carbonate solution, steam-distilled in the presence of sodium carbonate, dried over calcium chloride, and then twice distilled in a vacuum;  $\kappa = \text{ca. } 0.5 \times 10^{-7}$ .

The results obtained are given in Table V. The probable error in the nitrobenzene capacity determinations can safely be taken as 0.05%, but in this case, as opposed to that of chloroform, there is an additional error of 1 part in 3000 parts due to the conversion factor between the two measuring systems (p. 580). The total probable error will therefore be less than 1 part in 600 parts, and the mean value accepted for nitrobenzene at 25° is  $34.89 \pm 0.05$ . Although two samples were dried over phosphoric oxide for one week and six weeks respectively, no change in the dielectric constant was noticed (see Table V).

*Benzonitrile.* The material used was kindly provided by Dr. Martin, and had been purified in the same manner as that used for his conductivity work (*loc. cit.*). The results obtained for two different samples are given in Table VIII. These values showed no variation with frequency or current intensity, and the probable error is the same as for the nitrobenzene determinations.

(b) *Temperature variations.* Determinations of the dielectric constant of chloroform at temperatures between 0° and 50° were made in condensers II and III with each of the three specimens described, and the mean of the six results at each temperature is given in Table VI. Similar determinations were made for nitrobenzene at temperatures between 10° and 80° (Table VII).

In each case, when these results were plotted against temperature on a very open scale, they lay on a smooth curve within the limits of experimental error quoted.

(c) *Frequency variations.* Determinations of the dielectric constants of both chloroform and nitrobenzene at 25° and 50° were made at frequencies between 500 and 2500, but in no case was any change detected.

# LXXXI.—*The Photolysis of Aqueous Hydrogen Peroxide Solutions. Part I. Experimental Methods.*

By ARTHUR JOHN ALLMAND and DERRICK WILLIAM GRAHAM STYLE.

THE decomposition of hydrogen peroxide solutions by light has been the subject of a number of previous investigations (Tian, *Compt. rend.*, 1910, 151, 1040; 1913, 156, 1601, 1758, 1879; *Ann.*

*Fac. Sci. Marseille*, 1915, **22**, 197; *Ann. Physique*, 1916, **5**, 248; Henri and Wurmser, *Compt. rend.*, 1913, **156**, 1012; **157**, 126, 284; *J. Physique*, 1913, **3**, 305; Matthews and Curtis, *J. Physical Chem.*, 1914, **18**, 166, 521; Kornfeld, *Z. wiss. Phot.*, 1921, **21**, 66; Anderson and Taylor, *J. Amer. Chem. Soc.*, 1923, **45**, 650, 1210; Rice and Kilpatrick, *J. Physical Chem.*, 1927, **31**, 1507), but in spite of this work, and although the reaction is, chemically, very simple, very little can be said about its mechanism, many points remain obscure, and there are some very curious contradictions. One of the more obvious may be mentioned: Henri and Wurmser published, in the same year, two papers (*loc. cit.*) dealing with the quantum efficiency of the reaction in the region 200–300  $\mu\mu$ ; in the one, using full light from a cadmium spark, they found  $\gamma$  to have an average value of 130; in the other, using the dispersed light from a zinc spark, they found  $\gamma$  over practically the same spectral region to vary between 4.4 and 5.8.

Our work has been essentially directed to an investigation of the relations between degree of decomposition and absorbed light over a wide range of concentration, far greater than any hitherto worked with. In the majority of the experiments, the active light has been monochromatic or confined to a fairly narrow spectral region. Except quite incidentally, we have not touched the subject of the effect of additions to the photolyte, whether inhibitors or accelerators.

#### EXPERIMENTAL.

*Hydrogen Peroxide.*—Three different varieties were employed. Some early experiments with dilute solutions were carried out on a specimen of perhydrol (Merck) intended for tropical export, and containing a nitrogenous thermal inhibitor. For much of the work, Merck's ordinary perhydrol (inhibitor-free) was used. When first insolated by 365  $\mu\mu$  light, this showed a strong bluish-green fluorescence, which decreased normally on dilution. Continued insolation completely destroyed this fluorescence, and its disappearance was accompanied by a marked decrease in the photosensitivity of the perhydrol, but by an equally marked increase in its rate of thermal decomposition. It is probable that the impurity causing the fluorescence was derived from the wax with which the perhydrol bottles are internally coated: this is yellow and has a distinct oily smell. It may be added that we found it very difficult to inhibit the photodecomposition of the concentrated perhydrol. Small additions of sulphuric acid to the cell contents were without effect, whilst 1 g. of concentrated acid only reduced the velocity by 30–40%.

The remainder of our experiments were carried out on hydrogen

peroxide prepared in the laboratory by the method of Kilpatrick, Reiff, and Rice (*J. Amer. Chem. Soc.*, 1926, 48, 3019), modified in certain respects. In the actual distillation of the first product, 200 c.c. were placed in the glass distilling flask, and the remainder added in 50-c.c. portions as the distillation proceeded. The flask had a volume of 500 c.c. and its neck was provided with two ground joints, one of which carried a thermometer suspended by platinum wire from the stopper, the other a tap-funnel for the addition of more solution. The outlet tube was bent upwards and terminated in a ground joint making connexion with the silica condenser, to which was attached, by another joint, the silica receiver. No lubricant other than condensate was employed on any of the joints, and practically no leakage resulted under the water-pump vacuum conditions (2 cm. of mercury) employed. The first 80% of the distillate consisted of a weak solution of hydrogen peroxide (0.1—0.3*M*) and was discarded. The final concentrated fraction was freed from traces of chloride by redistillation over small quantities of silver sulphate. The solutions thus prepared were 9—14*M*.

*Extinction Coefficients.*—These were determined for the chief lines of the quartz-mercury arc by the spectrometer-thermopile-galvanometer method, the transmissions of a small quartz cell filled with distilled water and with the peroxide solution being compared. For 365  $\mu\mu$  the cell was 4.62 cm. deep (internal) and several concentrations were measured. For 313 and 303  $\mu\mu$ , a 2.04-cm. cell was used, and one concentration only was investigated. For the shorter wave-lengths, the cell was 1.026 cm. deep and various concentrations were used. Table I contains the molecular extinction coefficients for redistilled Merck's perhydrol, calculated by the equation  $\log_{10} I_0/I = \alpha c d$ , where  $d$  is expressed in cm. and  $c$  in mols./litre. The measurements with the 365  $\mu\mu$  line were made by Mr. J. W. T. Spinks.

TABLE I.

$\lambda$ , $\mu\mu$ .	$c$ .	$\alpha$ .	$\lambda$ , $\mu\mu$ .	$c$ .	$\alpha$ .	$\lambda$ , $\mu\mu$ .	$c$ .	$\alpha$ .
365	11.63	0.00647	365	3.08	0.00655	280	0.0753	4.06
365	9.45	0.00669	313	0.459	0.39	265	0.0758	10.03
365	7.57	0.00663	303	0.459	0.86	265	0.0287	10.48
365	5.96	0.00668	297	0.238	1.31	265	0.01125	10.33
365	4.78	0.00683	289	0.238	2.16	254	0.0287	21.9
365	3.70	0.00673	280	0.238	3.73	254	0.01125	19.6

In one paper, Henri and Wurmser quote  $\alpha_{280} = 3.0$  and  $\alpha_{256} = 20$ . From the data in another of their papers can be calculated  $\alpha_{283} = 1.5$ ,  $\alpha_{275} = 4.9$ , and  $\alpha_{257} = 16$ . Kornfeld (*loc. cit.*) found 0.422 for 311  $\mu\mu$ . The agreement with these values is seen to be fairly good. On the other hand our figures are very different from those recently published by Urey, Dawsey, and Rice (*J. Amer.*

*Chem. Soc.*, 1929, 51, 1371), the two sets of  $\alpha$  values only approaching one another at the shortest wave-lengths measured by us; the discrepancies seem too great to be accounted for by the fact that our solutions were more concentrated.

*Reaction Cell.*—The type of apparatus employed was determined by the use, in the majority of our experiments, of such concentrated peroxide solutions as to make it impossible to follow the reaction with any accuracy by titration. The method used was to pump off, collect, and measure the oxygen formed, a procedure already adopted with success in this laboratory in the case of the photolyses of formic and of oxalic acid (J., 1926, 2834, 2854). The method offered the additional advantage of reducing to a minimum the possibility of contamination during the reaction by added inhibitors or accelerators. A Toepler pump of about 300 c.c. capacity was used for the evacuation of the reaction cell, the latter being provided with a tap and ground joints so that it could be opened for filling and cleaning and for attaching to the pump for evacuation before and after insolation. Early experiments showed the importance of keeping the photolyte away from contact with glass. Attempts to use a composite cell, built up of quartz plates and a glass block, the inner surface of the latter being coated with paraffin wax, failed, as the wax peeled off when the cell was evacuated. An attempt to construct a cell consisting of quartz plates fused on to a reinforced block of paraffin wax also failed, as the cell slowly caved in and developed leaks on evacuation. Finally, a fused silica cell was designed, with which, or its successor, the great majority of our results were obtained. This, with the adjacent parts of the Toepler pump, is shown in Fig. 1a.

ABCD is of clear fused quartz, the part A, through which the light beam passed, being 5 cm. long with circular plane parallel end-plates of 3 cm. diameter. B is a hemi-cylindrical dome, giving an adequate surface of liquid for evolution of oxygen, and ensuring that the level of the photolyte shall always be well above that of the beam of light. C is a bulb, serving to retain any peroxide carried up by "bumping" or by too violent an evolution of gas. Into the ground socket D fits the glass tap E, provided with another ground socket at its upper end, allowing of connexion with the evacuation apparatus. F is a trap in which, during evacuation, vaporised hydrogen peroxide and water vapour are condensed by immersion in an ether-solid carbon dioxide mixture. It is provided with a stopper G for removing this condensate when necessary. H is a tap for admittance of air, and connexion with the pump (300 c.c. barrel) is made through the tap K. Ramsay tap-grease was used for all taps and joints.

*Measurement of Evolved Gas.*—Fig. 1b shows the simple means employed for the measurement of the evolved gas. The inverted U-tube L was of about 3 mm. internal diameter (and thus of internal volume 0.070 c.c./cm.) and its longer limb was 40 cm. long. The extension M permitted of the introduction of the delivery tube of the Toepler pump. The shorter limb was connected by pressure tubing, controlled by a screw clip, with the mercury reservoir N. Prior to the collection of a sample of gas, the whole tube was filled with mercury and the screw clip closed. The gas was then pumped off and delivered into M, the diameter of L being sufficiently small

FIG. 1.

to prevent the gas rising further. On the completion of the evacuation, the latter was drawn into L by manipulation of N and of the screw clip, its temperature and pressure measured, and the length of the column read off by means of a scale placed immediately behind L.

*Manipulation.*—In view of the importance of the nature of the surface in all work with hydrogen peroxide, the treatment to which the reaction cell was subjected was as far as possible standardised. Before being filled, it was first cleaned with nitric acid containing a small quantity of alcohol, grease on the ground joint being thereby removed, and, after a thorough washing with distilled water, it

was rinsed out several times with a portion of the reaction solution, and filled nearly up to the dome. The ground joint D (Fig. 1a) was then lightly greased and put in position, being held down by rubber bands passing over the tap E and round the bottom of the reaction cell. E was very carefully greased and put together. It was of the utmost importance that this tap should function well, as it sometimes had to be turned several hundred times in the course of a series of experiments done on a single filling. The whole was then attached to the pump and evacuated as far as possible, E being opened at intervals. Continual attention (tapping and shaking of the cell) was necessary to avoid explosive bumping and gas evolution. The degree of evacuation feasible was limited by the thermal decomposition of the peroxide. With Merck's perhydrol, this was slow and caused no trouble. With the solution prepared by us, where the dark reaction for the cell contents might amount to perhaps 0.02 c.c. of oxygen per min., the method of evacuation had to be carefully standardised and its results watched in order to detect the stationary state at which the rate of removal of oxygen was just equalled by its rate of production.

The moment of completion of the evacuation was noted and taken as the zero time of the dark reaction for which correction had subsequently to be made. With taps E and K closed, air was admitted by opening H, the cell detached, placed in the thermostat (see later), allowed to reach temperature equilibrium, and the insolation commenced. After the required interval (varying from a few minutes to a few hours) the cell was again attached to the pump, the tap H closed, and, after the evacuation of the air between E and K (sometimes carried out through H by a Hyvac pump in order to accelerate matters and reduce the "dark" correction), the gas in the cell was pumped off, collected, and measured as quickly as possible.

With perhydrol, the "dark" correction was usually only a few units %, and the duration of an insolation of the order of an hour. As already indicated, work with the solution prepared by us in the laboratory was far less easy. The quantum efficiencies were raised 10—20-fold, and the thermal reaction to an even greater extent. As the amount of decomposition permissible in a simple insolation was limited (a) by the desirability of avoiding any appreciable change in the concentration, and (b) by the possibility of too high a pressure loosening the joint D, it became necessary to reduce the time of insolation considerably, runs of 4 mins. not being uncommon. But clearly the time necessary for the evacuation and collection of the gas could not be reduced to anything like the same extent; even if the Hyvac pump was used whenever possible, 15—20 minutes

was about the shortest time required. Consequently, the thermal correction was considerable with this preparation—indeed, it was impossible to obtain results of value in the use of mercury light filtered by a chlorine filter (*q.v.*), where the intensities were comparatively low, for the thermal reaction considerably exceeded 50% of the total decomposition.

*Arrangement of Apparatus for Insolation Experiments.*—The general arrangement is shown in Fig. 2; A represents the source of light, B is a shutter, and  $C_1$  and  $C_2$  are crystal quartz lenses. D is a 5-cm. quartz water-cell, E the light filter, F a diaphragm with variable aperture (0.5—2.5 cm. diameter), and G a small thermostat containing the reaction cell H. Finally, K is the thermopile for the measurement of the incident and absorbed energy. All apparatus when necessary was firmly secured to an optical bench and, with the exception of the lamp and shutter, was covered by an internally blackened box,  $C_1$  being fitted into a hole cut in the side.

FIG. 2.

*Light Source.*—In every case this consisted of a K.B.B. quartz mercury lamp of the atmospheric pressure type; these had an advantage over the vacuum type for the present work because of their relatively high intensity, this being due to the short length of arc and to the fact that they can be overloaded and yet burn very steadily, provided that additional cooling be employed. We used 100—110-volt lamps, both of the horizontal and of the vertical pattern. Their normal rating is 2 amps. We burnt them at 3.5 amps. and 80 volts, a Tirrill regulator ensuring a steady supply voltage, and the lamps being cooled by an electric fan. The energy distribution of their radiation, a knowledge of which was necessary in consequence of the light filters not being monochromatic, was determined on several occasions during the work by a modification of standard methods already described (*J. Physical Chem.*, 1925, 29, 713). An example of the data obtained is given in Table II, *I* being the intensity relative to the 365  $\mu\mu$  line as unity.

*Light Filters.*—Four types of filter were used.

(a) Corning Glass Plate G.586 A.W. of 3.6 mm. thickness. Transmission — 0.77 of 365  $\mu\mu$  and 0.22 of 405  $\mu\mu$ ; 7% of the total radiation transmitted, when used in conjunction with the 5-cm.

water filter, was red and infra-red. This correction was determined by means of a thermopile and a Zeiss red-glass filter which cuts off sharply below 600  $\mu\mu$  whilst transmitting about 85% of radiation between this limit and nearly 2  $\mu$ . The violet 405  $\mu\mu$  light is not appreciably absorbed by hydrogen peroxide.

(b) 1 Cm. of 0.1% aqueous potassium chromate solution between quartz plates. The transmission was

579	546	436	405	313	303	297 $\mu\mu$
0.80	0.88	0.71	0.63	0.44	0.39	0.30

10.3% of the total transmitted radiation was red and infra-red. The visible light is not absorbed by hydrogen peroxide.

(c) 5 Cm. of chlorine gas at 1 atm. pressure in a plane-parallel vessel of fused silica. The transmission was

579	546	436	405	280	265	256	248 $\mu\mu$
0.875	0.85	0.40	0.145	0.04	0.42	0.63	0.60

Used in combination with the mercury lamp, the average wavelength of the ultra-violet transmitted light was 256  $\mu\mu$ . For a few experiments, a similar 2-cm. filter was employed.

(d) A mixture of chlorine gas and of saturated bromine vapour in a fused quartz cell. The latter was about 4.5 cm. deep and of poor quality, the end plates not being accurately parallel. The maximum ultra-violet transmission of this filter is near 275  $\mu\mu$  and one-sixth of the light transmitted lay below 300  $\mu\mu$ , as determined by exposing a thermopile alternately behind glass and quartz plates.

The spectral transmissions of these filters were determined in the usual manner by means of a spectrometer-thermopile-galvanometer combination.

*Thermostat.*—This was of simple construction. In the square ends of an open copper box, 10  $\times$  10  $\times$  5.2 cm., directly opposed central holes of 2.9 cm. diameter were cut. Around them, inside the box, was soldered a copper U, reaching to the top of the box and dividing it into two compartments. The circular apertures in the inner jacket were covered with quartz plates. This inner compartment held the reaction cell during insolation and was filled with distilled water. The outer jacket contained ice or water, depending on the temperature of the experiment which was 21°

unless otherwise stated. The temperature of the thermostat could readily be controlled by addition by hand of small quantities of hot water or of ice. A small heating coil was sometimes used.

*Energy Measurement.*—This was done by means of either a 1-cm. or a 2-cm. Moll thermopile (previously calibrated against a standard Hefner candle), the *E.M.F.* generated being measured by means of a potentiometer (Cambridge Instrument Company) and a moving-coil galvanometer (Gambrell). The over-all sensitivity was about  $5 \times 10^{-7}$  volt. Care was naturally taken that the whole of the beam under measurement fell directly on the surface of the thermopile, and all necessary corrections were applied for reflexion losses at the different quartz-air and quartz-liquid surfaces. Measurements of incident energy made at the beginning and end of any reaction usually agreed to within 1–2%. Measurement of the absorbed energy during the reaction proved to be undesirable for various practical reasons, one of which was the effect of intermittent illumination (*q.v.*). Consequently, the absorbed energy, though sometimes determined at the end of a reaction, was usually calculated.

*Intensity Variation.*—This was normally effected by altering the size of the aperture in the diaphragm F (Fig. 2) or the position of the lens  $C_2$ . The beam being convergent, the intensity was smaller the closer the lens to the cell and thermopile. In some cases, the average, as opposed to the true, intensity was varied by the use of an electrically driven rotating sector of variable aperture, running at a high speed (20–25 interruptions per sec.) and placed close to the aperture F, between it and  $C_2$ .

*Variation of Duration of Insolation.*—As it was found that, under certain conditions, the rate of the photolysis was proportional to the square root of the light intensity, it became desirable to carry out experiments under conditions of slowly intermitted radiation. The same sector, rotating with constant aperture, was used for this purpose, its rate of rotation being controlled by a simple gearing interposed between sector and motor, and consisting of six two-step pulleys rotating freely on one of two parallel stationary axes, and coupled with one another by suitable belting. The radii of the two steps in each pulley were in the ratio of 4:1. By changing the number of pulleys in use and suitably connecting them together, the sector speed could thus be varied between the extremes of  $1/4$  and  $1/4000$  of the speed resulting when motor and sector were directly coupled together. Alteration of the speed of the motor by a series resistance allowed of finer adjustments. In actual use, the maximum duration of a single light-period was 100 secs. In these experiments, the diaphragm F, with its immediately adjacent sector,

and the reaction cell G were so arranged as to be at conjugate foci of the lens  $C_2$ . This ensured that, at any particular point in the photolyte, the cut-off or switch-in of the light intensity was sudden and not gradual.

*Concentration Variation.*—Starting with the most concentrated solution, this was carried out by one of two methods, *viz.*, (i) replacement of some of the solution in the cell by distilled water; (ii) decomposition of some of the peroxide by insolation. The water used was made from ordinary laboratory distilled water by redistilling it from alkaline permanganate, passing the steam successively through a hot solution of potassium hydrogen sulphate, a 6-inch column of glass wool, and two trap-bulbs, and finally condensing it in a silica condenser and storing in a large waxed glass flask, sealed with a waxed glass plate. When the second method of dilution was used, the reaction cell was simply placed a few inches in front of the unscreened mercury arc and insolated for 24–48 hours. As already mentioned, this had the effect of destroying the fluorescent impurity in the perhydrol.

The concentrations of the various solutions were determined by titration with permanganate. For concentrated solutions, a 1-c.c. silica pipette was used and *N*-potassium permanganate; for the more dilute solutions, heavily waxed glass pipettes and permanganate solutions as dilute as 0.01*N* were employed. All concentrations are expressed as g.-mols. of hydrogen peroxide per litre.

*Temperature Coefficients.*—These were measured by carrying out a series of determinations with the thermostat adjusted at various temperatures from 2° to 26°, the limits being determined by the magnitude of the thermal reaction with the particular peroxide solution under examination. In order to avoid condensation of moisture on the surface of the front quartz window of the thermostat during measurements at low temperatures, a wide tube about 3" long, containing a small amount of phosphoric oxide and closed by a quartz plate, was firmly cemented on the front surface of the thermostat. This effectually prevented any condensation trouble.

*Experiments with Dilute Solutions.*—Several such series were studied. With the full light of the lamp, or chlorine-filtered light, a cell was used consisting of quartz plates sealed on by paraffin wax to a glass frame 5 mm. thick, through which a circular central cavity had been cut. The internal glass surface of this cavity was coated with paraffin wax, and a hole drilled into it from the edge of the frame allowed of filling and withdrawing of samples for titration. When 365  $\mu$  light was used, in order to shorten the experiment, the cell consisted of a small quartz flask immersed in a metal box, through which a rapid stream of tap water flowed, provided on

opposite sides with windows consisting of plates of Corning Glass G. 586 A.W. (see p. 602). A mercury arc was placed 10 cm. away from either window, and thus a reasonable rate of decomposition was secured. The reaction was followed in one case by titration, in others by measuring the oxygen given off under atmospheric pressure conditions. The latter procedure was capable of a fair degree of accuracy, as the runs were long, owing to the small amount of light absorbed, and the degree of supersaturation of oxygen could be kept so low as not to affect the results appreciably. In all cases where titration methods were used, the upper portion of the cell was blackened over, so that the surface insolated might remain constant throughout the run.

## LXXXII.—*The Photolysis of Aqueous Hydrogen Peroxide Solutions. Part II. Experimental Results.*

By ARTHUR JOHN ALLMAND and DERRICK WILLIAM GRAHAM STYLE.

### *A. Experiments with Merck's Perhydrol.*

*Effect of Intensity and of Intermittent Illumination.*—These measurements were all carried out on undiluted perhydrol (about 10*M*). Curve *a*, Fig. 1, shows the results of true intensity variation with a beam of 365  $\mu$  light. Intensity is expressed as cal./cm.<sup>2</sup>/sec., and velocity as g.-mols. decomposed per hour. The total area irradiated at the front of the cell was 5.6 cm.<sup>2</sup>, and the time of reaction was 1–3 hours. Above a certain minimum intensity, the velocity is seen to be proportional to  $I_0^{0.5}$ . This unexpected result led us to undertake measurements in which the average intensity was altered by varying the aperture of a rapidly rotating sector between the limits of 5 and 100% of its full value. The data obtained, shown in Curve *b*, Fig. 1, are seen to be of the same general nature as with true variation.

The existence of the square-root relation between velocity and intensity suggested the formation in light of a catalyst acting analogously to iodine atoms in the iodine–potassium oxalate reaction (Berthoud and Bellenot, *J. Chim. physique*, 1924, 21, 308), and the matter was investigated further by the method of Briers, Chapman, and Walters (J., 1926, 562), a rotating sector of constant aperture but of variable rate of rotation being used. It was necessary to lower very considerably the speeds initially used before any effect was noticed, and the velocity only began to fall off when the duration

of a single light (or dark) period had risen to about 1 sec. It was still decreasing when the illumination period had reached 51 secs. The results of two such experiments, carried out with rather different

FIG. 1.

and unmeasured intensities, are plotted in Fig. 2a. The broken line represents the theoretical curve plotted for a catalyst of life of 1 sec., calculated from the formula of Briers, Chapman, and Walters, whilst

FIG. 2.

the horizontal line gives the velocity for the same continuously acting intensity (*i.e.*, half the velocity observed in absence of the sector).

Experiments on direct (true) intensity variation were next carried out with chlorine-filtered light ( $256 \mu\mu$ ). The results (Table I)

show plainly that, for light of this wave-length, under the prevailing experimental conditions, velocity ( $v$ ) is directly proportional to absorbed intensity ( $I$ ). As, however, the results with 365  $\mu\mu$  light suggested proportionality between velocity and intensity at low

TABLE I.

$I \times 10^5$ ...	8.0	13.7	15.1	16.9	23.1	29.2	34.4	39.0
$v \times 10^5$ ...	0.805	1.42	1.53	1.78	2.46	2.96	3.44	4.10
$v/I$ .....	1.01	1.03	1.01	1.05	1.06	1.01	1.00	1.05

intensities, it seemed possible that, with 256  $\mu\mu$  light of very high intensity, the  $I^{0.5}$  relation might hold. The limit to the direct measurement by the thermopile of the absorption of the complex beam of chlorine-filtered light had already been reached. As, however, with 365  $\mu\mu$  light, variation of true and of average intensity had given the same type of result, it was decided to do experiments with 256  $\mu\mu$  light of high intensity, using a rapidly rotating sector to control the average intensity of the beam. The results are contained in Table II. The velocity measured with the smallest sector opening was very near to the *maximum* velocity observed during the experiments recorded in Table I.

TABLE II.

Relative sector opening .....	1	2	4
$v \times 10^5$ .....	3.86	7.2	11.3
Ratio .....	3.86	3.6	2.83

It may be mentioned that the limiting values of  $\gamma_{365}$  actually obtained in the experiments plotted in Curve  $a$  (Fig. 1) were about 4.6 and 13.5 and would, of course, have been still higher at lower intensities, whilst the constant value of  $\gamma_{256}$  corresponding to the data in Table I is about 5.7. This last solution was submitted to a single experiment with 365  $\mu\mu$  light, and proved to be just twice as reactive at the same incident intensity as the solution used in the experiments of Curve  $a$ , Fig. 1. At all ordinary intensities, then,  $\gamma_{365}$  exceeds  $\gamma_{256}$  for concentrated perhydrol.

*Effect of Concentration.*—The first series of measurements was carried out with 365  $\mu\mu$  light, the concentration of the perhydrol, initially 12.10*M*, being altered in steps by the addition of distilled water until it had fallen to 1.11*M*. The thermal reaction velocities were determined and subtracted from the total velocities in light in order to obtain the net light velocity, and the absorbed energy was measured. Table III contains the results,  $v_d$  being the dark and  $v_{365 \mu\mu}$  the light velocity, both as mols./hr., and  $\gamma$  the quantum efficiency. The net light velocity (the table contains the results of successive duplicate experiments) rises to a maximum and then

TABLE III.

Conc.	$v_d \times 10^5$ .	$v_{365 \mu\mu} \times 10^5$ .	$\gamma$ (mean).	Conc.	$v_d \times 10^5$ .	$v_{365 \mu\mu} \times 10^5$ .	$\gamma$ (mean).
12.10	0.13	8.82	9.52	4.57	0.43	11.83	20.1
		8.91		2.20	0.75	9.05	22.1

		11.86		1.11	0.71	5.69	23.4
6.92	0.35	12.38	16.6			5.61	
		12.52					

falls off as the solution is diluted,  $\gamma$  increases steadily throughout, and the thermal reaction velocity also increases with dilution, at all events over the greater part of the concentration range covered. The square of the quantum efficiency, when plotted against concentration, follows an equation of the type  $\gamma = (k_1 - k_2[\text{H}_2\text{O}_2])^{\frac{1}{2}}$ .

This remarkable increase of  $\gamma$  with dilution was quite unexpected, and it was thought that some positive catalyst had perhaps been introduced with the water used for dilution. A similar series was therefore carried out in which the dilution was effected by decomposing part of the peroxide by insolation as already described in Part I, measurements of velocity of decomposition being made both in 365  $\mu\mu$  and in 256  $\mu\mu$  light after each concentration change. It was at this stage that we first noticed the destruction of the fluorescent properties of the perhydrol as a result of prolonged irradiation. About 24 hours' insolation was required for effecting the first change in concentration (from 10.24 to 7.92M) and, as will be seen from Table IV, which contains the results of this series, the disappearance of the fluorescence was accompanied by a marked rise in the velocity of the thermal reaction, and by a decided fall in the photochemical reaction rates. Omitting the figures given by the most concentrated solution as not being comparable with the remainder, it will be seen that the results, as far as 365  $\mu\mu$  light is

TABLE IV.

		7.12		
1.44	0.30	6.50	21.32	4.92

concerned, are qualitatively similar to those given by the fluorescent solution used in the first series (Table III). Further, the velocity with the chlorine-filtered light increases in the same way with dilution, passes through a maximum and falls off, the quantum efficiency altering in the same manner, absorption always being

complete. The thermal velocity, however, decreases with increasing dilution, whereas, in the fluorescing solution, it rises.

The results being obviously irregular, a similar set of experiments was carried out, after the fluorescence had been destroyed by a preliminary insolation. The same general type of result was obtained, but in detail the figures were as erratic as before. Finally, the original method of dilution with distilled water was reverted to, the fluorescent impurity again being destroyed at the commencement of the experiment. The readings were carried to concentrations as low as 0.06 and 0.02*M*, with 365  $\mu\mu$  and 256  $\mu\mu$  respectively, and the results are contained in Table V and in Fig. 3.\* They confirm the former series in all essential points.

TABLE V.

Conc.	$v_d \times 10^5$	$v_{256 \mu\mu} \times 10^5$	$v_{365 \mu\mu} \times 10^5$	Relative $\gamma_{365}$
9.52	1.02	8.08	46.56	1.00
7.54	1.18	8.26	46.20	1.17
4.95	1.04	9.30	53.84	1.89
2.79	0.99	9.46	52.96	3.06
1.39	0.70	10.72	50.75	5.55
0.671	0.66	10.76	25.68	5.67
0.201	0.28	12.70	14.08	9.93
0.060	0.16	15.04	3.56	7.94
0.021		11.16		

*Temperature Coefficient.*—This was determined for the concentrated perhydrol and for the 365  $\mu\mu$  line only. Measurements were made at 11°, 14.5°, 21°, and 26°, and the thermal reaction velocity was roughly measured at 21° and 31°. The latter had a temperature coefficient of about 2.1 (no precise significance is attached to this figure), and at 21° accounted for 3% of the total reaction. From the smoothed curve passing through the plot of the corrected light velocities, a value of 1.39—1.40 was read off for the photochemical temperature coefficient.

#### B. Experiments with Hydrogen Peroxide prepared in the Laboratory.

The totally unexpected nature of the relations observed when using high light intensities and high concentrations of perhydrol made it very desirable to repeat the work with a material definitely free from any substance, such as the fluorescent impurity or its decomposition products, which might conceivably affect the results. Experiments were therefore carried out with hydrogen peroxide prepared ourselves by the method already described.

*Preliminary Experiments.*—These were done essentially in order

\* In Figs. 3, 4, and 8, the various graphs for relative quantum efficiency are in no sense comparable with others on the same diagram, each being plotted on its own arbitrary scale along the ordinate.

to confirm or otherwise the effect of concentration change noted above. Commencing with concentrated peroxide, and then working with weaker solutions prepared by dilution with water, the light velocities were determined for the  $365\text{ }\mu$  line and for light transmitted by the chlorine-bromine filter ( $275\text{ }\mu$ ). At the same time, as the thermal velocities were now sufficiently high, they also were accurately determined. The results are contained in Table VI, and in Fig. 4 are plotted, as functions of concentration, the relative

FIG. 3.

TABLE VI.

Conc. ....	13.44	7.19	4.04	2.21	0.98	0.475
$v_d \times 10^5$ .....	0.98	4.65	5.70	4.89	2.56	1.13
$v_{365\text{ }\mu} \times 10^5$ .....	17.66	69.7	98.8	74.0	41.4	25.6
$v_{275\text{ }\mu} \times 10^5$ .....	2.38	12.31	16.36	24.60	29.16	27.42

quantum efficiencies for the light reactions and the unimolecular thermal reaction velocity coefficient (*i.e.*, rate of decomposition per unit mass of peroxide). The results are similar to the former ones in general outline (the continued rise of  $\gamma_{365}$  appears, in the light of other data, to be perhaps due to experimental error).

*Effect of Concentration, Wave-length, and Intensity on Quantum Efficiency.*—Two systematic series of experiments were undertaken.

In the first, an 11.5*M*-solution was successively insolated with 365  $\mu$  light of a whole range of measured intensities, and then by light transmitted by the chlorine-bromine filter (275  $\mu$  region), a series of different intensities again being used. The solution was then diluted by addition of water to 5.45*M*, and insolated in a similar fashion, the whole process being repeated for concentrations of 2.45, 1.19, and 0.48*M*. The second series resembled the first,

FIG. 4.

except that beams of 365  $\mu$  and 307  $\mu$  (average) light were employed, the concentrations being 10.17, 6.05, 3.69, 1.92, 0.95, and 0.62*M*. The reason for not investigating the action of the three wave-lengths on the same solution was the necessity of minimising the changes in concentration caused by the photodecomposition. Just as in the measurements already described, no great accuracy is claimed for the figures, owing to certain disturbing factors imperfectly controlled (four experiments in the second series have been neglected on this account), nor are the absolute values of any

particular interest, in view of the whole nature of the reaction. Table VII contains typical specimens of the experimental data. In all cases, the area illuminated by the incident converging beam was 5.6 cm.<sup>2</sup>. Col. 1 gives the intensity in terms of incident quanta/hour/cm.<sup>2</sup>  $\times 10^{-18}$ , col. 2 the total quanta absorbed per hour  $\times 10^{-18}$ ; and col. 3 the total molecules of peroxide decomposed per hour  $\times 10^{-19}$ .

FIG. 5.

TABLE VII.

(a) Series I. 275 $\mu\text{m}$ ; 1.19M-H <sub>2</sub> O <sub>2</sub> .			(b) Series II. 365 $\mu\text{m}$ ; 3.69M-H <sub>2</sub> O <sub>2</sub> .		
(1).	(2).	(3).	(1).	(2).	(3).
0.0684	0.383	7.40	0.902	1.23	33.9
0.165	0.927	12.5	1.56	2.13	42.5
0.259	1.47	17.7	4.23	5.75	75.8
0.412	2.31	19.6	5.63	7.56	82.4
0.531	2.97	23.6	5.88	7.99	78.9

The results as a whole are shown in Figs. 5 and 6, where the square root of the number of quanta absorbed per hour is plotted

against the number of molecules decomposed per hour. In order not to confuse the diagrams, the actual experimental points in many cases are not put in, but merely the best line drawn through them. Further, in both diagrams, and in order to economise space, the curves for  $365\ \mu\mu$  light and for the most concentrated peroxide solution are not completely shown. It will be obvious that the quantum efficiency for any particular concentration and rate of

FIG. 6.

energy absorption can be read off by dividing the abscissa by the square of the ordinate.

It will be noticed that, with one exception, *viz.*,  $11.5M$ -peroxide and  $365\ \mu\mu$ , the curves are linear. Although it will appear later that, in one or two cases, this linearity is only apparent and due to experimental error and the scale of plotting, we are nevertheless justified in concluding that, in general, over our working range of concentration and intensity, any increase in velocity is proportional

to the corresponding increase in the square root of the intensity, whatever the wave-length of the light. It will further be noticed that the majority of the curves, if produced, do not pass through the origin, but cut the ordinate. This fact is reminiscent of Curve *a* (Fig. 1); its significance will be discussed later.

With regard to the relative values of the quantum efficiencies obtained at any given rate of absorption of quanta, it will be seen (a) that, in general,  $\gamma_{365}$  is greater than  $\gamma_{307}$  and  $\gamma_{275}$ ; (b) that the  $\gamma_{365}$  values are considerably higher in Series I (Fig. 5) than in Series II (Fig. 6); (c) that, as the concentration falls,  $\gamma$  increases in every case, and usually passes through a maximum at some intermediate concentration and falls off in dilute solution. Conclusions (a) and (c) are in accordance with the results obtained with perhydrol insolated by 256  $\mu\mu$  and 365  $\mu\mu$  light. The absolute values of  $\gamma$  naturally vary between wide limits, roughly 20–500, depending on wave-length, intensity, concentration, and the particular solution used.

*Effect of Intermittent Illumination.*—It was clearly desirable to see whether the "pure" hydrogen peroxide solutions behaved in the same manner as did perhydrol during intermittent insolation with light and dark periods of varied length. Measurements were done with 307  $\mu\mu$  light, a new cell with well-annealed surfaces being used, together with a temperature of 2° so as to minimise thermal decomposition. Three concentrations were employed, viz., 11.0, 6.4, and 3.3*M*. The method of experimentation was as already described, the duration of a single reaction always extending over at least 100 intermissions. The data are contained in Fig. 2*b*, where the broken line again represents the theoretical curve for a mean life of 1 sec., whilst the horizontal line denotes the decomposition for the same continuous intensity. The results are clearly subject to considerable error, but suffice to show that the mean life of the presumed catalyst rises with dilution and is about 0.4 sec. for 11*M*-solutions. No exact comparison between Figs. 2*a* and 2*b* can be made, for the light intensities used were not measured, whilst the solutions were of different origin. It would seem likely, however, that the mean life of the catalyst increases with the wave-length of the active light.

*Temperature Coefficients.*—These were determined for three concentrations and for three wave-lengths, two measurements being made at each temperature, viz., 2° and 22°. The temperature coefficient of the thermal reaction was necessarily measured at the same time. The results are contained in Table VIII, from which it would appear that any effect of concentration is within the limits of experimental error.

TABLE VIII.

Conc.	Temperature coefficients.			
	Thermal.	365 $\mu$ .	307 $\mu$ .	275 $\mu$ .
10.5 <i>M</i> .....	2.96	1.43	1.35	1.26
7.3 <i>M</i> .....	2.66	1.39	1.38	1.28

Mean values .....	2.83	1.42	1.38	1.28

Previous results for the photochemical reaction are as follows, T.C. denoting the temperature coefficient :

Worker.	T.C.	Conditions of experiment.
Tian	1.15	Thin layers of dilute perhydrol. Centre of gravity of absorbed light probably 260 $\mu$ .
Kornfeld	1.32	Dilute solutions of perhydrol. Uviol glass apparatus. Light chiefly absorbed 313 $\mu$ .
Matthews and Curtis	1.5	Uviol lamp radiation passed through several thicknesses of Uviol glass. Dilute perhydrol. Active light probably chiefly 365 $\mu$ . Thermal reaction not corrected for.
Anderson and Taylor	1.43	Pure dilute solutions. Full light of quartz mercury lamp in quartz vessels.

Our value for concentrated perhydrol and 365  $\mu$  was 1.39—1.40.

### C. Experiments with Dilute Solutions.

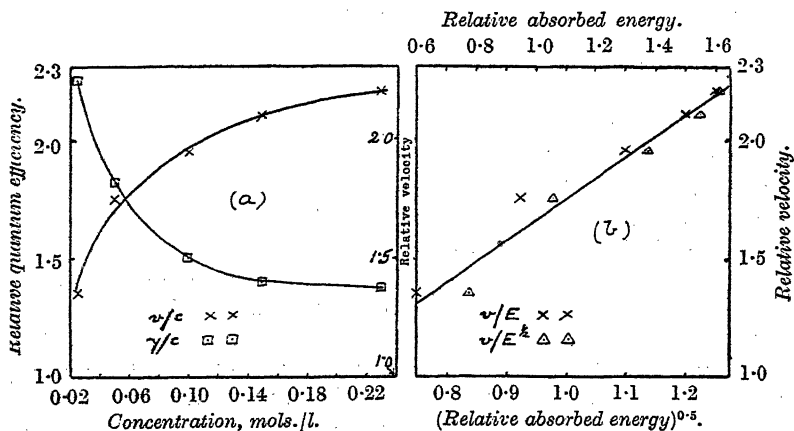

One of the most striking of the results recorded in sections A and B is the passage of  $\gamma$  through a maximum as the peroxide concentration is increased. It was clearly desirable to investigate rather more fully the behaviour of solutions of low concentration, particularly in view of the statement frequently made that the reaction is of the first order.

Some of our earliest experiments, carried out on dilute solutions of Merck's peroxide containing a nitrogenous inhibitor, were of this nature, the 5-mm. wax-lined cell (described at the end of Part I) being used, and the initial rates of reaction of a series of solutions of different concentrations being measured both in the full light of the lamp, and also in light which had been passed through a 2-cm. chlorine filter. They gave the same type of velocity-concentration curve. The results obtained with the chlorine-filtered light are shown in Figs. 7*a* and 7*b*. The former contains, plotted against concentration, the relative measured velocities and the relative quantum efficiencies, these being calculated from a knowledge of the energy distribution in the filtered beam and the extinctions of the different solutions. Fig. 7*b* shows the velocity plotted against (a) the light absorption, (b) the square root of the light absorption. Although the points are irregular, the best straight line drawn through the latter set passes through the origin on being produced.

A similar experiment (5-cm. chlorine-filter; 256  $\mu$ ) was carried

out on a dilute solution of the pure peroxide, which was initially 1.8M and decomposed during the insolation down to a final concentration of 0.1M. Here the behaviour was quite different,  $\gamma$

FIG. 7.

 FIG. 8.  
Concentration.

dropping throughout as the concentration fell (Fig. 8). Above 0.3M, absorption of the active light was practically complete. The curve has been drawn from the smoothed experimental data.

Finally, a number of experiments were carried out with dilute

solutions of the pure material and 365  $\mu\mu$  light, using the methods described at the end of Part I and following the reaction by measuring the evolved oxygen. The relative quantum efficiencies for three such experiments, calculated by dividing the velocities by the average concentration between each pair of points, are shown in Fig. 8. No very definite conclusion can be drawn from them and the experiments clearly need extension.

#### D. Summary of Experimental Results.

Figs. 5 and 6 exhibit the results of two comprehensive series of experiments in which the effects of variations in  $\lambda$ ,  $I_0$ , and  $[\text{H}_2\text{O}_2]$  on the photolysis were investigated, specimen detailed figures being tabulated in Table VII. In the majority of cases, the observed velocity can be plotted, within the limits of experimental error, linearly against the square root of the rate of absorption of energy, the curves appearing, when produced, either to pass through the origin or to cut the energy axis. Experimental error and the scale of plotting both forbid their closer analysis, which is best achieved by calculating from the original data relative values of the characteristic  $k_A$  constants (J., 1929, 1557) by means of the formula

$$-\Delta u = k_A \cdot I_0^{\frac{1}{2}} \cdot \frac{2}{\alpha^{\frac{1}{2}} c^{\frac{1}{2}} l} \cdot (1 - 10^{-\frac{1}{2} \alpha c l})$$

where, in the present case,  $-\Delta u$  is the number of molecules of peroxide decomposed per hour,  $I_0$  the total number of quanta incident per hour per  $\text{cm}^2$  on the illuminated area of the cell,  $c$  the concentration in mols./litre,  $\alpha$  the average extinction coefficient for the incident light, and  $l$  the depth of the cell (5 cm.). With the exception of four readings in Series II, which were clearly in serious error, all the data have been calculated in this way, the extinction coefficients used being 0.0066 for 365  $\mu\mu$ , 0.59 for 307  $\mu\mu$ , and 6 for 275  $\mu\mu$ . For the 275  $\mu\mu$  experiments, and for all but the two weakest solutions with the 307  $\mu\mu$  light, the term  $1 - 10^{-\frac{1}{2} \alpha c l}$  is practically unity, the expression simplifying to

$$-\Delta u = 2k_A I_0^{\frac{1}{2}} / c^{\frac{1}{2}} x^{\frac{1}{2}}.$$

Table IX contains in detail the values of  $k_A \times 10^{-11}$  calculated from the readings of Series I with 275  $\mu\mu$  light, arranged in each case in order of ascending values of  $I_0$  (not given; they varied between limits of 0.068— $0.531 \times 10^{18}$  quanta/hour/ $\text{cm}^2$ ).

The constancy of the  $k_A$  values for the three intermediate concentrations indicates that, over the whole intensity range covered, except for the lowest intensity with the 1.19M-solution, the velocity is proportional to  $I_0^{0.5}$ . This relation clearly does not hold either

TABLE IX.

for the weakest or for the strongest solution, and reference to Fig. 9 shows that the  $I_0$  rule is obeyed by the 11.5M-solution and possibly by the 0.48M-solution (points very scattered).

FIG. 9.

Table X contains a summary of all the results in the form of the mean values of  $k_A$  holding for any particular wave-length and concentration. In two further cases with concentrated solutions, apart from that just mentioned, the values were found to drift, as the intensity was raised, in a direction which showed that the  $I_0^{0.5}$  rule was breaking down at low intensities, and being replaced by the  $I_0$

rule. In addition, in Series I with  $365\text{ }\mu\mu$  light, the  $k_A$  values obtained with the lowest intensity used (figures in brackets) were always lower than those subsequently found, indicating again that the  $I_0^{0.5}$  rule was not being fully obeyed under such conditions.

Taking into account the various differences manifested in the above tables, we can summarise the main results of our experimental work as follows:

(1) Over wide ranges of  $I$ ,  $\lambda$ , and  $[\text{H}_2\text{O}_2]$ , the rate of photolysis is proportional to  $I_0^{0.5}$ . This behaviour is favoured by high intensities (Fig. 1, Tables II, IX, X); with low intensities, a tendency towards a reaction of the  $I_0$  type becomes apparent. At very high and at low concentrations (Fig. 9; Tables IX, X; also previous results of Tian and of Henri and Wurmser, *loc. cit.*), the velocity tends to be proportional to the intensity.

(2) The velocity at constant incident intensity passes through a maximum as  $[\text{H}_2\text{O}_2]$  is increased and then falls off (Tables III, IV, V, VI).

(3) In some cases,  $\gamma$  also passes through a similar maximum with increase in  $[\text{H}_2\text{O}_2]$  (Tables IV, V; Figs. 3, 4, 5, 6, 8). This is not always the case in the concentration range studied (Tables III, IV; Figs. 4, 5, 8).

(4) Under our experimental conditions  $\gamma$  tends to be high; there is a catalytic chain with a life of about 1 sec., becoming less with increase in concentration and probably also with increase in frequency (Fig. 2).

(5) Both  $\gamma$  (tables and diagrams) and temperature coefficient (Table VIII) under the prevailing conditions fall off as the frequency of the light is increased, the temperature coefficient doing so to an extent independent of concentration.

(6) A dilute solution of hydrogen peroxide containing inhibitor decomposes with a velocity which rises with increase in concentration at a rate proportional to the square root of the rate of the absorption of energy (Fig. 7).

(7) The velocity of thermal decomposition of peroxide solutions passes through a maximum and subsequently falls off as  $[\text{H}_2\text{O}_2]$  increases. In one case (Fig. 4), the corresponding unimolecular velocity coefficient-concentration curve also has a maximum; other data (Tables IV, V) give no such maximum. The temperature coefficient of the rate of thermal decomposition is normal, and is independent of  $[\text{H}_2\text{O}_2]$  over the concentration limits tested (Table VIII).

#### E. Discussion.

To explain these very complex relations (many of them unexpected, *e.g.*, the effect of intensity in the intermediate concentration

range, the relations between  $\gamma$  and  $\lambda$  and between  $[\text{H}_2\text{O}_2]$  and velocity) on a simple basis is clearly impossible, and we shall at present confine ourselves to a brief discussion of some of the more salient points.

(i) Any satisfactory theory of the photolysis of hydrogen peroxide solutions must first of all take into account the great similarity between the photochemical and thermal reactions. This is apparent throughout, and particularly so in Table VI, where, except for the lowest concentration employed, the thermal velocity and the velocity in  $365 \mu\mu$  light are practically proportional to one another within the experimental error.

(ii) The next point to emphasise is the effect of dust particles as demonstrated by the work of F. O. Rice and his collaborators. The photochemical, and hence presumably the thermal, reaction is a chain reaction, and the question arises as to whether it is the initiation or the continuation (or both?) of the chain which is a surface reaction. Recent workers (Williams, *Trans. Faraday Soc.*, 1928, 24, 245; Pana, *ibid.*, p. 486) on the thermal reaction conclude that it is initiated on the surface of the vessel or on dust particles.

(iii) We find the temperature coefficients of the photolysis to decrease with increasing frequency, but to be independent of concentration. This strongly suggests that they are concerned with the primary process only. Calculating the molar energy of activation ( $E$ ) by the method of Arrhenius, we find  $E_{365 \mu\mu} = 5850$ ,  $E_{307 \mu\mu} = 5380$ ,  $E_{275 \mu\mu} = 4120$  cals. With Tolman (*J. Amer. Chem. Soc.*, 1923, 45, 2285), we can equate  $E$  to  $N(\bar{\epsilon} - \bar{\epsilon})$ , where  $\bar{\epsilon}$  represents the average energy of all molecules of peroxide and  $\bar{\epsilon}$  the average energy (before absorption) of those molecules which are sufficiently activated by quantum absorption to be capable of initiating a reaction chain. The fraction of molecules ( $f$ ) in this potentially reactive state ( $\bar{\epsilon}$ ) in respect of light of a particular wavelength will be given by  $e^{-E/RT}$ , from which we obtain  $f_{365 \mu\mu} = 4 \times 10^{-5}$ ,  $f_{307 \mu\mu} = 9 \times 10^{-5}$ ,  $f_{275 \mu\mu} = 80 \times 10^{-5}$ .

If this view is correct, it appears that only a very small proportion of the absorbing molecules react subsequently to absorption, and that therefore the reaction chains must be exceedingly long—of the order of  $10^4$  to  $10^7$  links, leaving out of account any deactivation (by whatever means) experienced prior to the inception of the chain.

(iv) The  $I_0^{0.5}$  relation suggests that the catalyst (of mean life about 1 sec.) which is responsible for the reaction chain may consist either of hydroxyl groups or of oxygen atoms, produced in the liquid phase in accordance with one of the equations

and, when their rate of production per unit volume is sufficiently high, disappearing in accordance with either

or

Thermochemically, these two primary light actions are both possible, the former absorbing 56.5 Cals. (calculated from the work of Bonhoeffer and Reichardt, *Z. physikal. Chem.*, 1928, *A*, **139**, 75) and the latter 56.8 Cals. Referred to a single molecule, these figures correspond to a light quantum at about 500  $\mu$ , i.e., in the blue-green region of the spectrum, whereas the longest wave-length used by us was 365  $\mu$ .

(v) To account for the validity of the  $I_0$  relation at low intensities and concentrations, and also at high concentrations, additional hypotheses are necessary. For example, we have tested the assumption that, the hydroxyl group being the catalyst, it can be removed unimolecularly in certain circumstances by adsorption on dust particles, and, under other conditions, by combination with peroxide molecules to form unstable  $\text{H}_3\text{O}_3$  molecules which then rapidly react with one another. If the "chain" be supposed to be initiated by impact of such hydroxyl groups on the layer of peroxide molecules adsorbed on dust particles, and if a further type of "deactivating" collision involving peroxide molecules be introduced, then the majority of the experimental facts found by us can be brought into line. Some, however, remain unexplained. For example, the predicted behaviour of solutions of concentration 2*M* and less is not completely in accord with the (rather uncertain) experimental data, and further work is being done in this direction. Until the results of these experiments are available, it is of little use to discuss further either the explanation of our own results or their relation to the work of others.

(vi) Two particular points may be mentioned in conclusion.

(1) Our results with the dilute solution containing inhibitor (Fig. 7) can readily be explained on the mechanism referred to above.  
 (2) This point relates to the values for the empirical experimental constant  $k_A$ , contained in Table X. They vary with concentration, which merely shows at present that the photolysis is a complex one, but are also seen to rise with increasing frequency (see J., 1929, 1537) and not to decrease, as is the case with the values of  $\gamma$ . On the theory outlined above, they should be proportional to the square root of the coefficient ( $k_1$ ) which measures the efficiency of the primary dissociation process following on quantum absorption.

These  $k_1$  values are proportional to the  $f$  values calculated above, and we consequently have

$$(k_1)_{365\ \mu\mu} : (k_1)_{307\ \mu\mu} : (k_1)_{275\ \mu\mu} = 4 : 9 : 80$$

and hence

$$(k_A)_{365\ \mu\mu} : (k_A)_{307\ \mu\mu} : (k_A)_{275\ \mu\mu} = 2 : 3 : 9.$$

There is no quantitative coincidence between these ratios and the varying figures contained in Table X, but the fact that the admittedly incomplete theory gives even the found measure of agreement is of interest.

The experiments described in this and the preceding paper were carried out between October 1925 and April 1928. We are indebted to grants received from Brunner Mond and Company, Limited, and from Imperial Chemical Industries, Limited, which enabled us to purchase the electrical instruments, quartz cells, mercury lamps, and rotating sector used in the work. One of us (D. W. G. S.) wishes in addition to acknowledge the grant made to him by the Department of Scientific and Industrial Research whilst a student in training.

### LXXXIII.—*The Angles of Floating Lenses.*

By CHARLES GEORGE LYONS.

SEVERAL investigations have been made on the relationships between the statical equilibrium of an interface and the arrangement of the molecules at the boundary. Many of these studies were based on measurement of angles of contact; for example, Adam and Jessop (J., 1925, 127, 1863) studied the variation in these angles for water against various solid substances which had been used in film experiments. Practically all of these earlier researches were concerned with the contact angles of liquids against solids, and the liquid-liquid angles have been comparatively neglected.

The exact configuration of the molecules at the surface of a solid cannot be established except in the case of a single crystal, but at a liquid boundary the molecular orientation presents much less difficulty. It seemed probable, therefore, that the measurement of liquid-liquid angles of contact would yield definite information about the molecular basis of the interfacial equilibrium. These angles are most conveniently obtained as the angles of a lens of one liquid which is floating on another liquid, both being mutually

insoluble. Such angles were studied qualitatively by Quincke (*Phil. Mag.*, 1871, **41**, 454) and by Hardy (*Proc. Roy. Soc.*, 1912, **A**, **86**, 61), and quantitatively by Coghill and Anderson (*Bureau of Mines Tech. Papers*, 1924, 262); the last two authors, however, used an indirect method, calculating the angle from the dimensions of the lens on the assumption that its shape was governed solely by the surface-tension forces acting at its edges. As this assumption need not necessarily be true, it was decided to investigate these angles by direct measurement.

#### EXPERIMENTAL.

A drop of a liquid was placed on the surface of another in which it was insoluble, and the floating lens formed was held loosely in position by a wire just touching its surface.

FIG. 1.

The surface of the liquid was illuminated with a horizontal beam of light, and the lens was then viewed with a microscope whose axis was horizontal. Its image was projected on a camera, and a photograph of the magnified image was taken. The angles of contact and all other data were then easily and accurately measurable on the photographic plate.

As the lens was illuminated parallel to the surface of the liquid on which it was floating, there was a possibility of distortion of the image by the meniscus at the walls of the containing vessel. This distortion was avoided (see Fig. 1) by photographing the upper surface of the lens in a trough filled nearly to overflowing so that the meniscus curved downwards, and the lower surface in a glass cell in which the meniscus was attracted upwards.

The apparatus, when finally adjusted, was tested for distortion by three methods: (1) a circular object held vertically in the surface

of the liquid and perpendicular to the direction of vision was found to give a circular image; (2) by means of a graduated scale it was shown that the magnification ratio was the same vertically and horizontally; (3) pieces of wire bent into known angles gave images bearing these angles. The experimental arrangement therefore gave images of the lenses which represented their true shape.

To obtain the angles of a given lens, the microscope was focused on a medial section, and the angles were measured on the photographic plate with a protractor. The values obtained were probably accurate to  $\pm 2^\circ$ , the value of  $\gamma$ , the angle formed by the meniscus of the supporting liquid (see Fig. 2), being the most difficult to obtain, as it was usually small.

With this apparatus, lenses of oleic acid on aqueous solutions of various  $p_H$  were studied; also lenses of ethylene dibromide, carbon tetrachloride, and nujol (medicinal paraffin) on water, and of water on the last three liquids. The angles made by the liquid boundaries at the edge of the lens with the horizontal are given in Table I, in which surface tensions are given in dynes/cm., and Fig. 2 contains

TABLE I.

\* These solutions were obtained by the use of phosphate buffers.

diagrams of the shapes assumed by the lenses under different conditions. From these, it is seen that the shape can be varied within wide limits, the lower submerged surface being particularly sensitive to changes in the conditions. Alteration in the size of the lens within the diameter range 0.4—2.5 mm. caused no appreciable alteration in the angles.

### Discussion.

These results show that not only the shape but also the submergence of the lens changed when the surface tensions at the boundaries were varied. The fraction of the lens below the level of the surface of the bulk liquid ranged from 0.4 almost to unity for different pairs of liquids. The oleic acid series was especially interesting, for, as the underlying solution increased in alkalinity, the lens sank steadily into it, the lower surface becoming more and more curved and the value of  $\beta$  steadily rising.

The shape of the lens was shown in this way to be controlled chiefly by the interfacial tension between the two liquids. This tension gradually decreased from 16.0 dynes/cm. to a very small value as the alkalinity rose, while the individual surface tensions of the two liquids (against air) remained practically constant.

These results are qualitatively explicable on the simple theory of the lens equilibrium. This demands that the angles should be controlled solely by the surface-tension forces, in such a way that at the edge of the drop the three surface tensions are in statical equilibrium as shown by the triangle of forces (Neumann's triangle). These conditions may be written in the form of the two equations

$$\sigma_{12} \sin \alpha - \sigma_{23} \sin \beta + \sigma_{13} \sin \gamma = 0 \quad . \quad . \quad (1)$$

$$\sigma_{12} \cos \alpha + \sigma_{23} \cos \beta - \sigma_{13} \cos \gamma = 0 \quad . \quad . \quad (2)$$

where  $\sigma_{12}$  and  $\sigma_{13}$  are the surface tensions of the liquids (in air), and  $\sigma_{23}$  is their interfacial tension, the angles being as shown in Fig. 3. From these equations it will be seen that if the interfacial tension is decreased while the surface tensions remain nearly constant, the lower angle of contact,  $\beta$ , will gradually increase so that  $\sigma_{23} \sin \beta$  may still balance the vertical component of  $\sigma_{12}$ . This angle must

become re-entrant if the horizontal component of the surface tension of the lens liquid becomes greater than that of the supporting liquid. The observed changes in the oleic acid lenses as the interfacial tension is progressively decreased are in agreement with these predictions.

The increased submergence of the lens as the interfacial tension decreases follows directly from considerations of the free energy of the system. As the interfacial tension decreases, the surface energy at the liquid-liquid boundary decreases, and the area of this interface must increase at the expense of the other surfaces. This effect is analogous to the spreading of a liquid over a solid surface if the interfacial tension is low; and is only complicated because the surface of the supporting liquid is not an immobile plane as in the case of a solid.

*Failure of the Simple Theory.*—The fact that Coghill and Anderson's values of the angles did not agree with the simple theory, despite the fact that they were calculated on equations which should have secured agreement, indicated the need for a closer analysis of the lens equilibrium.

It is well known that the determination of surface tensions by Quincke's method (*loc. cit.*), based on the measurement of drops of liquid resting on a solid, gives values which are at least 10% too high. It was shown by Worthington (*Phil. Mag.*, 1885, 20, 51) that this is due to the neglect of the internal pressures caused by the curvature of the drop surfaces. Coghill and Anderson's equations must therefore involve errors of a similar magnitude.

The lenses used in this investigation were considerably smaller than those used by the earlier workers, and therefore this effect should be present in even greater intensity. An analysis of the results obtained confirmed this deduction, for, when the vertical and horizontal components of the surface tensions\* were evaluated in accordance with equations (1) and (2), it was found that their sum often differed considerably from zero. This is shown in Table II, in which cols. 4 and 8 should be zero if the equations were valid.

This effect of the internal pressure may be compared with the difference in the angle of contact between advancing, stationary, and retreating boundaries of a liquid on the surface of a solid. Nevertheless, there can be no direct comparison of the angles of a floating lens with the solid-liquid angles of contact, because the surface of the supporting liquid does not remain a plane.

\* The values of the surface tensions and interfacial tensions were chiefly taken from the International Critical Tables, Vol. 4. Those for the interfacial tensions between oleic acid and aqueous solutions of various  $p_H$  were Hartridge and Peters's values (*Proc. Roy. Soc.*, 1922, A, 101, 348), confirmed by the capillary-rise method with the actual solutions used in this investigation.

\* These solutions were obtained by the use of phosphate buffers.

Neither of these series of angles can as yet be correlated with the known orientation of the molecules at the interface, nor can the molecular mechanism which decides the values of the angles of contact be determined. But the significance of the angle  $\gamma$  is quite clear, for it depends solely on the depth to which the lens is submerged. The vertical component of the surface tension of the lower liquid must support the lens if its weight and buoyancy do not exactly balance, and this component can only be zero (*i.e.*,  $\gamma = 0$ ) when these two forces are equal and opposite.

If  $W_1$  is the weight of the lens,  $W_2$  that of the lower liquid displaced, and  $r$  the radius of the lens, then

$$2\pi r \sigma_{13} \sin \gamma = W_1 - W_2 \quad \dots \quad (3)$$

if the small correction for the lowering of the meniscus of the lower liquid at the edge of the lens be neglected.

From Table III it is seen that this equation holds for all the lenses studied in this investigation: cols. 4 and 5 should be identical if the equation is valid, and the differences actually obtained are within the limits of experimental error. The weights were calculated from the cross sections of the lenses measured on the photographic plates, their areas and centres of gravity being determined directly. Weights are given in dynes and  $r$  in mm.

In order to obtain a more definite analysis of the conditions of lens equilibrium, it is necessary to make assumptions which simplify the problem. The lenses which have been studied were not very large, and as their surfaces did not depart very much from segments of spheres, it is justifiable to assume that they actually had this shape. Under these conditions, the principle of virtual work may be used to make a more definite examination of the statical equilibrium of the lens.

Consider a lens of radius  $R$ , formed of two spherical segments of radii  $r_1$  and  $r_2$ , and heights  $h_1$  and  $h_2$  (Fig. 3). Then

$$R^2 = r_1^2 - (r_1 - h_1)^2 = 2r_1h_1 - h_1^2 = 2r_2h_2 - h_2^2 \quad (4)$$

Let the lens be given a small displacement increasing its radius to  $R + dR$  without transference of liquid from one segment to the other, *i.e.*, without altering the volume of either segment. Then  $R \cdot \Delta R = r \cdot \Delta h + h \cdot \Delta r - h \cdot \Delta h$ . The volume  $V$  of a segment of height  $h$  of a sphere of radius  $r$  is equal to  $\pi h^2(r - \frac{1}{3}h)$ , and therefore

$$\Delta V = \pi(2hr \cdot \Delta h + h^2 \cdot \Delta r - h^2 \cdot \Delta h)$$

By the conditions of the displacement,  $\Delta V = 0$ , hence  $\Delta r = -(2r - h)\Delta h/h$ , and by substitution in the above equation it follows that

$$R \cdot \Delta R = -r \cdot \Delta h = r \cdot \Delta A / 2\pi(r - h) \quad (5)$$

where  $A$  is the superficial area of the segment and is equal to  $2\pi rh$ . During this displacement work is done (1) by the surface tension forces, owing to change in superficial area of each surface of the lens and of the underlying liquid, (2) by the internal-pressure forces caused by the curvature of the lens surfaces, and (3) by gravity and the upward thrust of the displaced liquid, owing to the change in position of the centre of gravity of each segment of the lens. The magnitude and sign of these effects are now evaluated in turn, and the conditions of equilibrium are then obtained by equating their algebraic sum to zero.

(1) The total work done by the surface-tension forces is given by the algebraic sum of the products of the surface tensions and the change in area, *i.e.*, by

$$\sigma_{12}\Delta A_1 + \sigma_{23}\Delta A_2 - \sigma_{13}\Delta(\pi R^2) \cos \gamma$$

By substituting from (5), it is found that this work is equal to

$$2\pi R \cdot \Delta R[\sigma_{12}(1 - h_1/r_1) + \sigma_{23}(1 - h_2/r_2) - \sigma_{13} \cos \gamma] = 2\pi R \cdot \Delta R[\sigma_{12} \cos \alpha + \sigma_{23} \cos \beta - \sigma_{13} \cos \gamma] \quad (6)$$

Neumann's triangle [equation (2)] demands that the expression between the brackets should be zero for equilibrium. This follows necessarily where only the surface tensions are considered.

(2) Under the conditions governing the displacement given to the lens (*i.e.*, no volume change of either segment), the total work done by the internal pressures is found to be zero if the lens surfaces are accurately spherical segments, thus: The displacement of a ring of the surface subtending an angle  $\omega$  at the centre of curvature is  $\Delta r \cdot (1 - \cos \omega) + \Delta h \cdot \cos \omega$ ; the total work done by the internal pressure is therefore

$$\int \frac{2\sigma}{r} \cdot 2\pi r^2 \Delta(\cos \theta) [\Delta r \cdot (1 - \cos \omega) + \Delta h \cdot \cos \omega] \quad (7)$$

and on integration and substitution this integral is found to vanish.

(3) The height of the centre of gravity of a spherical segment above its basal plane is

$$\bar{h}_1 = R^4/4h^2(r - \frac{1}{3}h) - (r - h) \quad (8)$$

The work done by gravity on the lens is  $-gV_1\rho_1 \cdot \Delta h_1$ , and the work done by the upward thrust is therefore  $-gV_2(\rho_2 - \rho_1) \cdot \Delta h_2$ , where  $V_1$  and  $V_2$  are the volumes of the upper and lower segments of the lens, and  $\rho_1$  and  $\rho_2$  are the densities of the lens liquid and the supporting liquid, respectively.

By differentiating equation (8) and substituting from equations (4) and (5), it follows that the total work from both these causes is equal to

$$-2\pi R \cdot \Delta R \cdot g \cdot [\frac{1}{2}R^2\rho_2 - h_1\rho_1(r_1 - \frac{1}{3}h_1) - h_2(\rho_2 - \rho_1)(r_2 - \frac{1}{3}h_2)] \quad (9)$$

Now, from the principle of virtual work, the sum of expressions (6) and (9) must be zero; the conditions for equilibrium are therefore given by

$$[\sigma_{12} \cos \alpha + \sigma_{23} \cos \beta - \sigma_{13} \cos \gamma] - g[\frac{1}{2}R^2\rho_2 - h_1\rho_1(r_1 - \frac{1}{3}h_1) - h_2(\rho_2 - \rho_1)(r_2 - \frac{1}{3}h_2)] = 0 \quad (10)$$

This equation may be tested experimentally. All the relevant data are obtained from the photographic plates, and collected in Table IV (linear measurements being in mm., and tensions in dynes/cm.). Col. 6 reproduces the values of the first term in equation (10) as given in Table II (col. 8) for the examination of equation (2); col. 7 contains the (negative) values of the second term in equation (10) which is applied as a correction to equation (2). The smallness of the algebraic sum of cols. 6 and 7, as given in col. 8, shows that the agreement between equation (10) and experiment is good, and that this equation is a definite improvement on the simpler equation (2) derived from Neumann's triangle. Lenses of carbon tetrachloride, ethylene dibromide, and paraffin on water still show a serious discrepancy. In these cases, the photographic records indicated that the segments were markedly divergent from spheres

(the lenses of oleic acid on very alkaline solutions were also not spherical), and the discrepancy between theory and experiment must be attributed to this fact. When the lens surfaces approach segments of spheres satisfactory agreement is obtained. It is seen that Neumann's triangle is obeyed only for very large drops, in which forces other than the surface tensions are negligible.

FIG. 4.

*Floating Lenses at the Liquid-Liquid Interface.*—When water was placed at a light petroleum-aniline interface, it spread completely over it, but when the surface tension of the water was lowered by the dissolution of a small quantity of soap (0.01% of sodium palmitate) a floating lens was obtained of which the angles were  $\alpha = 30^\circ$ ,  $\beta = 76^\circ$ ,  $\gamma = 0^\circ$ . Lenses of aniline were similarly formed at the light petroleum-soap solution interface, the angles being  $\alpha = 14^\circ$ ,  $\beta = 52^\circ$ ,  $\gamma = 14^\circ$ .

It was thought the addition of calcium chloride to the soap solution might prove interesting from the point of view of the theory of emulsions. Actually, such addition did alter the angles of the lens, and when sufficient calcium chloride was added to carry the solution over the inversion point, the angles became  $\alpha = 25^\circ$ ,  $\beta = 24^\circ$ ,  $\gamma = 0^\circ$ , for a lens of aniline between light petroleum and the aqueous solution, and  $\alpha = 25^\circ$ ,  $\beta = 95^\circ$ ,  $\gamma = 35^\circ$ , when the aqueous solution was floating between the other liquids. The former case is the more interesting, for here it was clearly seen that the alteration of the lens shape was illustrative of the phenomenon of emulsion inversion (compare Fig. 4), the curvature of the lower surface being greatly diminished owing to the tendency to curve in the opposite direction.

When these observations were compared with those on oleic acid, where a large curvature was associated with a low interfacial tension, it was seen that this tendency towards inversion could be explained by the raising of the interfacial tension  $\sigma_{23}$ .

Bancroft and Tucker (*J. Physical Chem.*, 1927, **31**, 1681) have deduced that the character of an emulsion is determined by the sign of the difference  $\sigma_{23} - \sigma_{12}$ . If  $\sigma_{23} > \sigma_{12}$  the water will tend to be emulsified in the oil, but if  $\sigma_{23} < \sigma_{12}$  the oil will tend to be emulsified in the water. The present observations support these conclusions by direct experiment, since it is concluded that the raising of the interfacial tension  $\sigma_{23}$  is favourable to inversion from oil in water to water in oil.

The changes occurring when the soap solution lies between the aniline and the light petroleum were neither as large nor as definite as in the case just considered. This may now be attributed to the fact that  $\sigma_{23}$  and  $\sigma_{12}$  were affected in roughly the same proportion.

*The Mechanism of Emulsification by Soap.*—Practically all the theories advanced to explain emulsification have received much adverse criticism, and Bancroft and Tucker believe that the surface-tension relationship mentioned above affords the only criterion by which the character of the emulsion can be decided. An objection to this view is that it gives no clue to the molecular mechanism of emulsification.

An attempt has been made to elucidate the mechanism in the case of emulsification by soap. The explanation tentatively suggested is based on the results of experiments on film dissolution (Lyons and Rideal, *Proc. Roy. Soc.*, 1929, *A*, **124**, 343), and on a modification of the wedge theory of emulsions. This theory in its original form broke down when it was shown that the molecules in the interfacial film were by no means close-packed, for Griffin (*J. Amer. Chem. Soc.*, 1923, **45**, 1648) found that the area occupied by a soap molecule at the oil-water interface was 44 Å.U., whereas Harkins and Beeman (*ibid.*, 1929, **51**, 1674) showed that an emulsion could be formed with an interfacial area of 190 Å.U.

The film experiments proved that a residual bimolecular film of acid soap was the stable surface configuration on alkaline solutions. It was thought that such a bimolecular leaflet might also be present at the oil-water interface, in which case it would have a profound influence on the emulsifying power of the soap solution.

There was little evidence by which the probability of this assumption could be judged,\* but Briggs and Schmidt (*J. Physical Chem.*,

\* Miss Laing (*Proc. Roy. Soc.*, 1925, *A*, **109**, 28) had concluded that the existence of the bimolecular leaflet was proved by Griffin's results, but her conclusions were based on a misunderstanding.

1925, 19, 479) had noticed that the stability of an emulsion of benzene in soap solution was increased by the addition of 0.1% of free alkali, although further alkali decreased the stability. It seemed possible that this variation in the stability of the emulsions might be connected with the alteration in composition of the residual bimolecular film with change in the alkalinity of the solutions, and experiments were therefore devised to test this possibility. A series of soap solutions of known  $p_H$  was made by the addition of caustic soda to a 0.01% sodium palmitate solution. A preliminary electrometric titration had been carried out to ensure that the solutions were made of standard alkalinity. These solutions were shaken with benzene under standardised conditions, and the stabilities of the emulsions thus formed were compared. Although the experiments were only semi-quantitative, the results obtained were quite definite.

On solutions more acid than  $p_H$  8.0, both the benzene-in-water and the water-in-benzene emulsion had but little stability, but that of the former phase steadily increased from  $p_H$  8.0 to  $p_H$  10.0 at which it reached a maximum. The latter emulsion only attained an appreciable stability on solutions more alkaline than  $p_H$  10.0, and stability increased with alkalinity until salting-out of the soap occurred. Both phases were almost equally stable in the  $p_H$  range 10—12. It was also observed that the frothing power of a soap solution ran strictly parallel to the stability of the benzene-in-water phase, and also reached a maximum at  $p_H$  10.0.

The existence of the bimolecular leaflet at the surface of soap solutions seems well-established, and the similarity between frothing power and emulsifying power seemed to confirm the presence of this bimolecular leaflet at the benzene-water interface. A comparison was therefore made between the  $p_H$  values obtained in these emulsion experiments and in the film experiments, and it was found that they were identical.

On solutions where a benzene-in-water emulsion is the more stable, the film experiments showed that the lower layer of the equilibrium bimolecular leaflet was not completely packed. On very alkaline solutions, where a water-in-benzene emulsion is the more stable, the equilibrium bimolecular film had considerably less than half the area of the original unimolecular film. On solutions where the two layers were equally packed, the emulsions were of almost equal stability. These observations, therefore, support the view that emulsification depends on the presence of a bimolecular leaflet, while a unimolecular film shows little tendency to cause emulsion formation.

The mechanism of emulsification may now be pictured as follows.

When a soap molecule is first adsorbed at the interface it will be in the form  $\text{NaP,HP}$ , and will thus give a double film equally packed on either side. On solutions less alkaline than  $p_H 10$  the equilibrium lower (aqueous) layer will be less densely packed than the upper layer, and this equilibrium state must be reached by one of two processes, *viz.*, either a transference of molecules across the interface, or a curving of the boundary. In emulsion formation the latter effect predominates. In order to increase the packing of the upper layer and decrease that of the lower layer of the initially symmetrical film, the boundary curves with the upper layer inside, squeezing it and giving an oil-in-water emulsion. A similar analysis accounts for the stability of water-in-oil emulsions on very alkaline solutions where the lower layer is probably more closely packed than the upper. Over the range at which a symmetrical leaflet is stable, the boundary will not curve preferentially in either direction, and neither form of emulsion will be more stable than the other.

These experiments have shown that this tentative suggestion of the bimolecular leaflet at the oil-water interface is consistent with the known data on emulsification by soaps. There is not yet sufficient evidence to show whether a similar explanation can be applied to other cases.

#### *Summary.*

The shapes and angles of liquid lenses floating on the surface of a different liquid have been studied by a photomicrographic method. The angles are subject to wide variations, and are especially sensitive to alterations in the interfacial tension between the two liquids. It has been shown, further, that these angles differ from those calculated on the basis of Neumann's triangle, and the causes of the difference have been investigated.

The contact angles at a junction of three liquids have been investigated with reference to the theory of emulsification. It has been suggested that emulsification by soap may be determined by the existence of a bimolecular soap leaflet at the oil-water interface.

The author desires to thank the Mineralogical Department of this University for the loan of the micro-camera. His thanks are also due to Dr. E. K. Rideal for his assistance and encouragement during this work.

LXXXIV.—*The Determination of the Dissociation Pressures of Hydrated Salts by a Dynamical Method. Part III.*

By JAMES RIDDICK PARTINGTON and REGINALD JOSEPH WINTERTON.

A FULL account of previous work on the subject of dissociation pressures of salt hydrates is given in Parts I and II of this series (Partington, J., 1911, 99, 467; Partington and Huntingford, J., 1923, 123, 160) and by Menzies (*J. Amer. Chem. Soc.*, 1920, 42, 978, 1952).

Since the publication of Part II, two papers have appeared in which a method similar to that described has been employed (Schumb, *J. Amer. Chem. Soc.*, 1923, 45, 342; Baxter and Cooper, *ibid.*, 1924, 46, 923. These workers used a method almost identical with that used by Baxter and Lansing, *ibid.*, 1920, 42, 419, entailing the measurement of the volume of air aspirated over the salt).

In this research the original method of Parts I and II has been employed, which is essentially as follows. Air, dried over calcium chloride and phosphoric oxide, is passed successively over the salt, through phosphoric oxide tubes, through a water bubbler, and finally through a further apparatus for absorbing water vapour. Since the salt and the water are both maintained at the same temperature, the weights of water absorbed in the respective series of tubes are, apart from small corrections applied, directly proportional to the vapour pressures of the salt and of the water.

*Apparatus.*—The U-tube containing the salt was 2 cm. in internal diameter and the total length of the column of salt was 50 cm. It was connected with a trap to condense part of the water vapour before the moist air reached the absorption tubes (see Part I). The water bubbler had a similar trap fitted. This part of the apparatus was immersed in an electrically controlled thermostat, steady to within  $\pm 0.01^\circ$ .

The absorption apparatus consisted of two U-tubes fitted with glass stoppers and filled with phosphoric oxide and glass wool. Only the first tube was weighed, the other acting as a guard tube between the absorption tube proper and the water bubbler or the aspirator. The traps and corresponding absorption tubes were weighed together.

Air was drawn through this apparatus by an aspirator bottle of 10 litres capacity, out of which water was siphoned. This bottle was fitted with a mercury manometer to indicate the difference in pressure between the atmosphere and the inside of the bottle.

Before passing through the apparatus, the air was dried and freed from carbon dioxide by passage through (i) a sulphuric acid bubbler which also served to indicate the rate of flow, (ii) a series of caustic soda tubes, (iii) a calcium chloride tube, and finally (iv) a phosphoric oxide tube, since this reagent was used in the absorption tubes.

When in use the ground joints were cemented outside with Faraday wax, with the exception of the joints in the traps, which were lubricated with petroleum jelly. Both the wax and the jelly were removed by cotton wool and benzene before the respective parts were weighed. The traps and tubes were weighed against counterpoises of similar structure.

*Materials.*—(1) *Disodium hydrogen phosphate dodecahydrate*,  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ . A.R. Salt from B.D.H. was used after one recrystallisation. A small amount of the heptahydrate was prepared by crystallising the salt above  $36^\circ$ , the transition point between these two hydrates being at  $35.4^\circ$  (D'Ans and Schreiner, *Z. physikal. Chem.*, 1911, **75**, 99). An intimate mixture of the two powdered hydrates was used. This overcame the necessity of passing air through the salt for a considerable time before the actual determinations were commenced, as had been done previously, since the two phases were present from the start.

(2) *Disodium hydrogen arsenate hydrates*. In Part II, dissociation pressures of sodium arsenate dodecahydrate were determined at  $25^\circ$ ,  $30^\circ$ , and  $35^\circ$ . It was pointed out that the result at  $25^\circ$ , viz., 11.10 mm., did not agree with that obtained by Lescœur (*Compt. rend.* 1887, **164**, 1171; *Ann. Chim. Phys.*, 1890, **21**, 556), viz., 9.8 mm. at that temperature. At  $30^\circ$  the difference was only 0.25 mm. Lescœur had, however, indicated a transition point at  $23^\circ$  between two hydrates to which he assigned the formulæ " $2\text{NaO}, \text{AsO}^5, 25\text{HO}$ " and " $2\text{NaO}, \text{AsO}^5, 15\text{HO}$ ," which correspond with the dodeca- and hepta-hydrates  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O}$  and  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ . Confirmation of this transition was obtained by Rosenheim and Thon (*Z. anorg. Chem.*, 1927, **167**, 7), who found that the solubility curve for sodium arsenate in water shows a marked transition at  $22^\circ$  between these two hydrates. It was clear, therefore, that the determinations above  $20^\circ$  were in need of revision.

Tilden (J., 1884, **45**, 269) gives the m. p. of sodium arsenate dodecahydrate as  $28^\circ$ , but if this were correct the results in Part II could not have been obtained, since the apparatus employed would have become choked with the fused salt. Lescœur says that the salt partially melts at  $23^\circ$ . Actually, at  $22^\circ$ , we found that the salt becomes only damp, and this increases with temperature until the salt finally becomes completely liquid; this liquid becomes clear at

56.2°, and is then a true solution of the heptahydrate. The liquid, when supercooled to, say, 40° and seeded with a crystal of salt, deposits crystals of the heptahydrate and the temperature rises to 56.2°. There is a similar evolution of heat at 22°, but this is not so well marked. The original tube used in Part II was available and it showed that the salt used had not undergone fusion.

It was hoped that the dissociation-pressure curves would also show the transition point at 22° with some accuracy, but it became clear that the solubility curve (Rosenheim and Thon, *loc. cit.*) provided a more accurate result, as the angle between the dissociation-pressure curves is small. We have therefore, in calculating the heats of hydration and plotting the curves, assumed that the latter actually cut at 22°, an assumption which was made very probable by the actual results.

The dodecahydrate was prepared by crystallising the salt below 22°; it is efflorescent at room temperature in air. The heptahydrate was similarly prepared by crystallisation above 22°, *viz.*, at about 30°; this hydrate does not effloresce appreciably at room temperature in air. The anhydrous salt was obtained by heating the crystalline salt at 120° until it lost its water of crystallisation. The appropriate pairs of phases were then intimately mixed and used in the U-tubes as indicated above.

### Results.

The method of working out the results is the same as that used in Part II of this series. The equation derived,\* with which the results are calculated, is

$$p = \frac{p'KB}{B + p'K} = \frac{\frac{w_1}{w_2} \pi \cdot \left( \frac{B-b}{B-b-\pi} \right) B}{B + \frac{w_1}{w_2} \pi \cdot \left( \frac{B-b}{B-b-\pi} \right)} \quad (1)$$

where  $p$  is the dissociation pressure of the salt at  $t^\circ$ ;  $w_1$  and  $w_2$  are the weights (in grams) of water vapour absorbed from the salt and the water, respectively;  $\pi$  is the vapour pressure of water at  $t^\circ$ ;  $B$  is the barometric height; and  $b$  is the difference of levels in the gauge fitted to the aspirator. All pressures are given in mm. of mercury.

This method corrects for: (a) the pressure difference between the air in the bottle and the atmosphere; (b) the head of water in the bubbler; (c) the larger volume of the moist air in equilibrium with the water as compared with that in equilibrium with the salt.

\* The formula given on p. 167 of Part II was incorrectly reproduced, but all the results given in that paper were in fact calculated by the correct formula as now given.

## Discussion.

The foregoing results are collected in Table I, and Fig. 1 shows the curves obtained by plotting  $p$  against  $t$  and also  $\log p$  against  $1/T$  (where  $T = t + 273^\circ$ ). The logarithmic plots are straight

lines, and in the case of sodium arsenate there is a definite intersection of the lines for the two hydrates. It has been pointed out, however, that this is not a very accurate method of finding the transition point.

For comparison with those of other authors, the present results were plotted and the values for 15° and 20° interpolated. Where possible, results for 15°, 20°, 25°, and 30° were found by a similar process from results of previous workers. In the case of Lescœur's results for sodium arsenate this was not possible, as the points did not lie on a regular curve. The same was found to be the case with the results of Müller Erzbach (*Ber.*, 1887, 20, 137; *Z. physikal. Chem.*, 1896, 19, 134) above 20°.

*Sodium arsenate.* Lescœur gives, for this salt, three series of vapour pressures, one for each of the two hydrates, and one for the saturated solution. His results for the dodecahydrate and the solution led to comparatively smooth curves and the vapour pressure is given for both as 16 mm. at 20°; but those for the dodeca- and the hepta-hydrate do not agree with ours, being: at 15°, 11.5 mm. and 3.4 mm. respectively, and at 20°, 16 mm. and 4.6 mm. respectively. The only comparable results are:

At 25°: This research 10 mm.; Lescœur 9.8 mm.

At 30°: This research 14.39 mm.; Lescœur 15 mm.

*Sodium phosphate.* The results given by Lescœur (*Ann. Chim. Phys.*, 1890, 21, 548) for this salt are identical in every way with those given by Debray (*Compt. rend.*, 1868, 66, 194). Table II compares the results of several previous workers with the present results.

phosphate may be compared with those of Baxter and Cooper (*loc. cit.*), Q being given in g.-cals. :

	Q <sub>15-20°</sub> .	Q <sub>20-25°</sub> .	Q <sub>25-30°</sub> .
Baxter and Cooper .....	11,340	12,180	—
Present work .....	11,697	11,795	11,978

The three series of heats of hydration show an increase with rise of temperature, as Baxter and Cooper also found for sodium phosphate, acetate, and carbonate. For the last two salts, however, directly determined values show the opposite effect.

In the case of sodium phosphate hydrates, data are available for the heats of solution at 18° and a dilution of 400 mols. of water per mol. of salt. For the dodecahydrate, Thomsen (*J. pr. Chem.*, 1878; 17, 174) gives —22,820 g.-cals., and Pfaundler (*Ber.*, 1871, 4, 775) —22,500 g.-cals. For the heptahydrate at the same dilution and temperature, Pfaundler (*loc. cit.*) gives —11,300 g.-cals. Pfaundler's values give the heat of the reaction

as 11,200 g.-cals. (*i.e.*, 2240 g.-cals. per mol. of water) at 18°, which is in satisfactory agreement with the results obtained from the dissociation pressures.

Another method available for the calculation of the heats of hydration of the salts is based on Nernst's heat theorem. This gives for the intrinsic energy change (here the quantity of heat liberated as found thermochemically) :

$$Q = Q_0 + \alpha T^2 + \beta T^3 \quad (3)$$

and for the free-energy change :

$$A_T = Q_0 - \alpha T^2 - \frac{\beta}{2} T^3 \quad (4)$$

$\alpha$  and  $\beta$  being the same constants in both equations. The values of  $A_T$  (in g.-cals.) may be found from the dissociation pressures by the equation

$$A_T = RT \log_e \pi/p \quad (5)$$

where  $p$  and  $\pi$  have the values assigned in equation (1) and  $R = 1.9875$ .

The most satisfactory method for calculating  $Q_0$  and  $\alpha$  ( $\beta$  being negligibly small) from the equations obtained by applying (4) to each experimental temperature is that of least squares. By substituting the values of  $Q_0$  and  $\alpha$  so obtained in equation (3) we obtain the values of  $Q$  for various temperatures. Table IV compares the results thus derived with those calculated by the Clapeyron-Clausius equation (2) as in Table IV: the former are somewhat lower than the latter.

TABLE IV.

Reaction.	Temp.	$Q_0$ per mol. H <sub>2</sub> O.	$\alpha \times 10^5$ .	$A_T$ , per mol. of H <sub>2</sub> O.	$Q$ , per mol. of H <sub>2</sub> O.	$Q$ for whole reaction, eq. (3).	$Q$ for whole reaction, eq. (2).
Na <sub>2</sub> HAsO <sub>4</sub> ·12H <sub>2</sub> O → Na <sub>2</sub> HAsO <sub>4</sub> ·7H <sub>2</sub> O + 5H <sub>2</sub> O(liq.)	14.90° 20	542.43	43.71	506.20 504.90	578.8 579.9	2,894 2,899	2,895
Na <sub>2</sub> HAsO <sub>4</sub> ·7H <sub>2</sub> O → Na <sub>2</sub> HAsO <sub>4</sub> + 7H <sub>2</sub> O(liq.)	24.92 30 35	1646.9	1278	510.40 477.36 434.21	2781.2 2820.3 2858.3	19,468 19,742 20,008	21,455 21,644
Na <sub>2</sub> HPO <sub>4</sub> ·12H <sub>2</sub> O → Na <sub>2</sub> HPO <sub>4</sub> ·7H <sub>2</sub> O + 5H <sub>2</sub> O(liq.)	14.90 20 24.92 30	1186.8	1180	196.95 177.17 153.77 97.76	2175.8 2209.6 2241.8 2280.1	10,879 11,048 11,209 11,400	11,697 11,795 11,978

For sodium phosphate dodecahydrate, by the method just employed, Müller (*J. Chim. physique*, 1909, 7, 534) found from Frowein's results (*loc. cit.*) that  $Q = 2215.3$  g.-cals. per mol. of water at 18° ( $Q_0 = 1200.58$ ;  $\alpha = 1198.27 \times 10^{-5}$ ).

To values of the specific heats of the dodeca- and hepta-hydrates of sodium phosphate as found by Nernst, Koref, and Lindemann (*Sitzungsber. Preuss. Akad. Wiss. Berlin*, 1910, 12, 247), viz., between 34.4° and 1.9°, 0.3723 for the dodecahydrate, and 0.3230 for the heptahydrate, an equation of the type

$$dQ/dT = C_A + C_B - C_C = \alpha t. \quad (6)$$

has been applied, in which  $C_A$ ,  $C_B$ , and  $C_C$  are the molecular heats of the heptahydrate, of 5H<sub>2</sub>O(liq.), and of the dodecahydrate, respectively. Since the specific heats were determined over a wide range,  $t$  is not accurately defined but it was taken as 18°, this being approximately the mean of 34.4° and 1.9°;  $\alpha$  then becomes 0.1501, which is about ten times the value calculated previously.

There being no data concerning the specific heats of the hydrates of sodium arsenate, these were determined approximately over the

range  $+16^{\circ}$  to  $-12^{\circ}$ , the method of mixtures being used with carbon tetrachloride as the calorimetric liquid. The value 0.206 was taken as the specific heat of carbon tetrachloride at  $-12^{\circ}$  by interpolation from the results of Latimer (*J. Amer. Chem. Soc.*, 1922, 44, 90), Mills and MacRae (*J. Physical Chem.*, 1911, 15, 54), and Timofejew (*Iszv. Kiew polyt. Inst.*, 1905, 1).

The results so obtained were: Dodecahydrate, 0.414 g.-cal./g.; heptahydrate, 0.350 g.-cal./g., whence the respective molecular heats are 166.3 and 109.3 g.-cals. Then, from equation (6), for the reaction  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O} \longrightarrow \text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O} + 5\text{H}_2\text{O}(\text{liq.})$ ,  $\alpha = 0.1178$ , again about ten times that previously calculated.

### Summary.

The dissociation pressures of sodium arsenate hydrates have been redetermined, and some values for sodium phosphate hydrates are also given. The results obtained are:

For the reaction  $\text{Na}_2\text{HAsO}_4 \cdot 12\text{H}_2\text{O} \longrightarrow \text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O} + 5\text{H}_2\text{O}$ , at  $14.90^{\circ}$ , 5.24 mm.; and at  $20^{\circ}$ , 7.36 mm.

For the reaction  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O} \longrightarrow \text{Na}_2\text{HAsO}_4 + 7\text{H}_2\text{O}$ , at  $24.92^{\circ}$ , 9.98 mm.; at  $30^{\circ}$ , 14.39 mm.; and at  $35^{\circ}$ , 20.73 mm.

For the reaction  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O} \longrightarrow \text{Na}_2\text{HPO}_4 \cdot 7\text{H}_2\text{O} + 5\text{H}_2\text{O}$ , at  $14.90^{\circ}$ , 8.93 mm.; at  $20^{\circ}$ , 12.93 mm.; at  $24.92^{\circ}$ , 19.10 mm.; and at  $30^{\circ}$ , 27.05 mm.

The dissociation pressure-temperature curves for sodium arsenate show a transition at about  $22^{\circ}$  between the hepta- and the dodecahydrate.

The heats of hydration of the same reactions have been calculated at several temperatures by the aid of the Clapeyron-Clausius and the Nernst equation.

The specific heats of the two hydrates of sodium arsenate have been approximately determined.

UNIVERSITY OF LONDON.

[Received, February 6th, 1930.]

## LXXXV.—The Ternary System Zinc Oxide-Zinc Chloride-Water.

By HAROLD CECIL HOLLAND.

IN the literature some 16 different oxychlorides of zinc are described (see, e.g., "Gmelins Handbuch der anorganischen Chemie," 1924, "Zink," p. 175; Dietrich and Johnston, *J. Amer. Chem. Soc.*, 1927, 49, 1419), but only a few need be cited in detail. From solubility determinations of zinc oxide in aqueous zinc chloride solutions,

Driot (*Compt. rend.*, 1910, **150**, 1426) inferred the existence of  $\text{ZnCl}_2 \cdot 4\text{ZnO} \cdot 6\text{H}_2\text{O}$  and  $\text{ZnCl}_2 \cdot \text{ZnO} \cdot 1\frac{1}{2}\text{H}_2\text{O}$ , both of which he isolated. By treating diamminozinc chloride,  $\text{ZnCl}_2 \cdot 2\text{NH}_3 \cdot \text{H}_2\text{O}$ , with hot water, André (*ibid.*, 1882, **94**, 903, 1524; 1888, **106**, 854) obtained an oxychloride to which he gave the formula  $\text{ZnCl}_2 \cdot 8\text{ZnO} \cdot 10\text{H}_2\text{O}$ ; and by adding water to a syrupy solution of zinc chloride, he obtained a compound described as  $\text{ZnCl}_2 \cdot 5\text{ZnO} \cdot 8\text{H}_2\text{O}$ , which was also prepared by Perrot (*Bull. Soc. chim.*, 1895, **13**, 975; 1901, **25**, 786) by adding water to the anhydrous salt.

There is little doubt that several of the supposed oxychlorides are mixtures and not chemical individuals, for analyses of solid phases are necessarily vitiated either by the retention of mother-liquor or by decomposition during washing. It was therefore decided to carry out a phase-rule investigation of the system in order to determine the formulæ of any oxychlorides which might exist in stable equilibrium with solutions.

Although the system is a three-component one, Jänecke's method of representation (*Z. physikal. Chem.*, 1908, **51**, 32; 1911, **71**, 1) was preferred to the triangular method. The compositions of the solid phases were found by Schreinemaker's "residue" method (*Z. physikal. Chem.*, 1893, **11**, 76).

#### EXPERIMENTAL.

The reagents used in the preparations and analyses were of a high standard of purity, and all volumetric apparatus was standardised before use. Chloride was estimated by the Volhard method with *N*/10-silver nitrate and *N*/20-potassium thiocyanate, and zinc by titration with potassium ferrocyanide, a concentrated sulphuric acid solution of diphenylbenzidine being used as indicator (Cane and Cady, *J. Amer. Chem. Soc.*, 1927, **49**, 356): fresh indicator solution had to be made every few weeks in order to get the best results. All solutions were standardised in triplicate and checked fortnightly.

The composition of the mixtures was arranged so as to give only a small amount of solid phase. At first they were prepared from zinc oxide and hydrochloric acid, but, as the most concentrated acid contains only 19.1 equivs. % of hydrogen chloride, the majority were prepared from zinc oxide and chloride and water. By adding some of the water and the zinc oxide in the form of a paste, followed by the hydrochloric acid or zinc chloride dissolved in the remainder of the water, a mixture was obtained free from lumps. If any lumps were present, the mixture, while still hot, was shaken so that the fine precipitate of oxychloride was held in suspension during transference to another bottle, which was then sealed and placed in a rotary shaker in a thermostat at  $25^\circ \pm 0.1^\circ$  or at  $50^\circ \pm 0.05^\circ$ . After the

required period of shaking, the bottle was placed in a clamp at the side of the thermostat to allow the precipitated oxychloride to settle. Some of the clear solution (5, 10, or 25 c.c. as convenient) was drawn off in a pipette and transferred to a weighing bottle; from the weights, the densities of the solutions were obtained. The solid was separated from most of the solution on a Hoesch funnel, and a weighed sample was taken (during filtration the solid was not allowed to become dry, as this would cause change in composition); for the concentrated mixtures at 25° and for all at 50°, the solid was obtained by transferring the remainder of the mixture to a weighing bottle at the temperature concerned, allowing the precipitate to settle, and then drawing off the supernatant liquid. The samples were washed into standard flasks, acidified with dilute sulphuric acid to dissolve oxychlorides, and analysed. From the weights of zinc and chlorine in a known weight of solution or residue the amounts of zinc chloride and oxide and hence of water were obtained.

In the tables the compositions of the solutions and residues are given in terms of  $x$  and  $y$ , the solid phase being shown by the letter corresponding to the intersection of the tie lines in the diagrams; thus  $E = \text{ZnCl}_2 \cdot 5\text{ZnO} \cdot 8\text{H}_2\text{O}$ ;  $F = \text{ZnCl}_2 \cdot \text{ZnO} \cdot 2\text{H}_2\text{O}$ ;  $G = \text{ZnCl}_2 \cdot \text{ZnO} \cdot \text{H}_2\text{O}$ .

FIG. 2.

Since the time of shaking required for the mixtures to reach equilibrium was dependent on the concentration, two complexes (Nos. 3 and 4) of similar composition were prepared. Although one of these was shaken at 25° for 24 hours and the other for 72 hours, the same solid phase was present in each case, showing that for mixtures of this or higher concentration one day's shaking was sufficient. When several very dilute mixtures were shaken for only

3 days, the conjugation lines did not intersect at a point; but when two such complexes (Nos. 1 and 2) were shaken for 21 days, these lines intersected those of other complexes at a definite point *E* (Fig. 1) corresponding to  $\text{ZnCl}_2, 5\text{ZnO}, 8\text{H}_2\text{O}$ , showing that 3 days' shaking was insufficient. This compound is the same as that obtained by André and by Perrot (*loc. cit.*). As the solution of complex 1 having this solid phase had  $x = y = 0.001$ , it is clear that the range of existence of zinc oxide or hydroxide in contact with solutions containing zinc chloride must be very small.

No evidence was obtained for the existence of the solid,  $\text{ZnCl}_2, \text{ZnO}, 1\frac{1}{2}\text{H}_2\text{O}$ , reported by Driot (*loc. cit.*). As the curve *ab* was increasing at the expense of the others with decrease in temperature, it is quite probable that his solution coincided with the transition point of the curve so that his solid was a mixture of  $\text{ZnCl}_2, \text{ZnO}, 2\text{H}_2\text{O}$  and  $\text{ZnCl}_2, \text{ZnO}, \text{H}_2\text{O}$ . This explanation is strengthened by the fact that he reported only one solution having the solid phase  $\text{ZnCl}_2, \text{ZnO}, 1\frac{1}{2}\text{H}_2\text{O}$  in equilibrium.

At  $50^\circ$ , the diagram (Fig. 2) was of the same form as at  $25^\circ$ , the only difference being that the area *Gcb* had encroached upon the area *Fba*, showing that  $\text{ZnCl}_2, \text{ZnO}, \text{H}_2\text{O}$  can exist in stable equilibrium with solutions containing less zinc chloride than at  $25^\circ$ .

It is of interest that several other elements of Group II of the periodic system give oxychlorides corresponding with two of those now found for zinc: e.g.,  $\text{CaCl}_2, \text{CaO}, 2\text{H}_2\text{O}$ ,  $\text{MgCl}_2, \text{MgO}, \text{H}_2\text{O}$ , and  $\text{CdCl}_2, \text{CdO}, \text{H}_2\text{O}$ .

#### Summary.

1. Equilibria existing in the three-component system  $\text{ZnO}-\text{ZnCl}_2-\text{H}_2\text{O}$  at  $25^\circ$  and  $50^\circ$  have been studied, and the compositions of the stable solid phases determined.

2. Evidence has been obtained for the existence of two new oxychlorides of zinc, viz.,  $\text{ZnCl}_2, \text{ZnO}, 2\text{H}_2\text{O}$  and  $\text{ZnCl}_2, \text{ZnO}, \text{H}_2\text{O}$ ; and only one of those formerly described, viz.,  $\text{ZnCl}_2, 5\text{ZnO}, 8\text{H}_2\text{O}$ , exists in stable equilibrium in the range of concentrations used.

3. The same series of solid phases was found at  $25^\circ$  as at  $50^\circ$ .

In conclusion, I wish to thank Dr. Denham and Mr. Packer for their interest in this work.

CANTERBURY COLLEGE, NEW ZEALAND. [Received, January 28th, 1930.]

LXXXVI.—Crystalline  $\alpha$ -Methylmannofuranoside ( $\gamma$ -Methylmannoside). Part I.

By WALTER NORMAN HAWORTH and CHARLES RAYMOND PORTER.

UNTIL very recently the synthesis of homogeneous forms of the  $\gamma$ -alkylhexosides had not been possible owing to the lack of appropriate experimental methods. Latterly it has been shown, however, that the crystalline  $\alpha$ - and  $\beta$ -forms of ethylglucofuranosides ( $\gamma$ -ethylglucosides) are obtainable through the sugar carbonates (Haworth and Porter, J., 1929, 2796). A further example of this mode of synthesis is now communicated from which it is seen that crystalline  $\alpha$ -methylmannofuranoside (the  $\alpha$ -form of  $\gamma$ -methylmannoside) is derivable from mannose dicarbonate (Haworth and Porter, this vol., p. 151). The mannose dicarbonate (mannofuranose dicarbonate) (I) undergoes methylation with either diazomethane or methyl iodide and silver oxide and yields the crystalline *methylmannofuranoside dicarbonate* (II). Elimination of the carbonate residue from the latter by the agency of barium hydroxide leads to the formation of the desired crystalline  $\alpha$ -methylmannofuranoside (III).

This substance is hydrolysed with much greater rapidity than the normal  $\alpha$ -methylmannopyranoside, although it is slightly more stable towards *N*/100-hydrochloric acid than the corresponding glucofuranoside. The physical properties of this new five-atom ring form of methylmannoside are compared with those of the pre-existing six-atom ring form which was prepared by Fischer and Beensch (*Ber.*, 1896, 29, 2927).

	M. p.	$[\alpha]^{20}_D$
$\alpha$ -Methylmannofuranoside .....	118—119°	+113°
$\alpha$ -Methylmannopyranoside .....	190—191	+ 79

In the following paper by Haworth, Hirst, and Webb the chemical properties of the new methylmannoside are described and the proof of its constitution (III) is adduced. It is expected that further experiments which are being conducted will lead to the isolation of the stereoisomeric  $\beta$ -methylmannofuranoside.

## EXPERIMENTAL.

*Methylation of Mannofuranose Dicarbonate.*—(a) *With diazomethane.* Diazomethane obtained from 0.5 c.c. of nitrosomethylurethane was distilled together with 4 c.c. of dry ether into 0.5 g. of mannose dicarbonate dissolved in 4 c.c. of dry dioxan (containing a trace of ether) which had been cooled to  $0^{\circ}$ . The cooling was continued during 2 hours. The solution acquired a yellow colour, gas was evolved, and a small amount of yellow syrup separated. By pouring off the solution and allowing it to evaporate at the ordinary temperature, about 0.1 g. of a crystalline material was obtained, m. p.  $170$ – $172^{\circ}$ , identical with the methylmannofuranoside dicarbonate obtained in the following way.

(b) *With methyl iodide and silver oxide.* Mannose dicarbonate (0.4 g.) was dissolved in methyl iodide containing a little acetone and small amounts of silver oxide were added at intervals during  $\frac{1}{2}$  hour, whilst the solution was heated below the boiling point. Prolonged contact with large excesses of silver oxide is harmful. The solution was filtered and the residue was extracted with boiling acetone. The original filtrate and the acetone extracts were evaporated and the residue was again treated with the methylating agents as before. The filtrate from the second treatment yielded on evaporation 0.15 g. of a crystalline product, sparingly soluble in ethyl acetate and obtainable from this solvent as colourless crystals, m. p.  $172$ – $173^{\circ}$  (decomp.) (Found: C, 43.75; H, 4.3; OMe, 12.2.  $C_9H_{16}O_8$  requires C, 43.9; H, 4.1; OMe, 12.6%).

The methylmannofuranoside dicarbonate did not reduce Fehling's solution, but gave a precipitate of barium carbonate on being warmed with barium hydroxide solution. It did not undergo rapid hydrolysis with *N*/10-hydrochloric acid; but after being heated with *N*-hydrochloric acid at  $90^{\circ}$ , it gave a product which rapidly reduced Fehling's solution. It showed  $[\alpha]_{D}^{25} + 87^{\circ}$ ;  $[\alpha]_{5461}^{25} + 98^{\circ}$  (c, 2.45 in acetone).

*$\alpha$ -Methylmannofuranoside.*—The above dicarbonate, dissolved in a little acetone, was warmed gently with excess of barium hydroxide solution. Barium carbonate was precipitated, and after removal of the excess of barium hydroxide by means of carbon dioxide the filtrate was evaporated at  $45^{\circ}$ ; the residue was extracted with ethyl acetate and then with methyl alcohol. Evaporation of either of these extracts gave crystals (yield, 95% of the theoretical). This product, recrystallised from methyl alcohol containing ether, formed colourless needles, m. p.  $118$ – $119^{\circ}$ , showing  $[\alpha]_{D}^{25} + 113^{\circ}$  (c, 1.1 in water);  $[\alpha]_{D}^{25} + 117^{\circ}$ ;  $[\alpha]_{5780}^{25} + 123^{\circ}$ ;  $[\alpha]_{5461}^{25} + 137^{\circ}$  (c, 0.8 in methyl alcohol) (Found: C, 43.25; H, 7.5; OMe, 16.1.  $C_7H_{14}O_6$  requires C, 43.25; H, 7.2; OMe, 16.0%).

$\alpha$ -Methylmannofuranoside is readily soluble in water or alcohol but sparingly soluble in ethyl acetate. It undergoes hydrolysis with *N*/100-hydrochloric acid during a period of 2 hours. Its m. p. is depressed on admixture with  $\alpha$ -methylmannopyranoside.

The authors are indebted to the Department of Scientific and Industrial Research for a grant in aid of this work.

### LXXXVII.—Crystalline $\alpha$ -Methylmannofuranoside ( $\gamma$ -Methylmannoside). Part II.

By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and  
JOHN IVOR WEBB.

WHILE the preceding research was in progress, leading to the synthesis of crystalline  $\alpha$ -methylmannofuranoside from mannose dicarbonate, we were also engaged on the preparation of the same product by a more direct procedure: the condensation of mannose with methyl alcohol in the presence of 1% hydrogen chloride. The neutralised solution yielded a syrup, which was separated from unchanged mannose by solution in ethyl acetate. During the evaporation of this solvent from the extract a copious crop of crystalline  $\alpha$ -methylmannofuranoside separated in a yield of 30%, even though the solution had not been nucleated intentionally with a specimen of the mannofuranoside from the preceding synthetic preparation. This occurrence was repeated as frequently as we performed the mannose-methyl alcohol condensation, and it became evident that, once a nucleus was available,  $\alpha$ -methylmannofuranoside could be obtained almost as readily as  $\alpha$ -methylmannopyranoside (normal  $\alpha$ -methylmannoside). We have therefore been able to isolate considerable quantities of this new substance and have instituted a complete investigation of its properties.

This novel variety of  $\alpha$ -methylmannoside is shown to possess the five-atom ring constitution of a furanoside and it therefore falls into line, both in chemical behaviour and in structure, with other  $\gamma$ -sugar derivatives (compare Haworth and Porter, *J.*, 1929, 2796, and earlier papers). It is hydrolysed completely to mannose on being heated at 100° during 2 hours with *N*/100-hydrochloric acid. The velocity coefficient was calculated to be  $k = 0.015$  (mins. and decimal logarithms), whereas the corresponding six-atom ring form or  $\alpha$ -methylmannopyranoside shows a velocity coefficient  $k = 0.0002$

(Phelps and Hudson, *J. Amer. Chem. Soc.*, 1926, **48**, 503). The pyranoside is, indeed, little affected by heating for this period with acid of this dilution and requires many hours' heating at  $100^\circ$  even with  $N/10$ -acid for complete hydrolysis.

In contact with 15% alkali at  $60^\circ$  the  $\alpha$ -methylmannofuranoside is unaffected during  $1\frac{1}{2}$  hours and is quantitatively recovered after this treatment. It may be handled and preserved in the laboratory without its undergoing any change and requires the observance of no special precautions.

$\alpha$ -Methylmannofuranoside (I) undergoes acetylation to give a crystalline *tetra-acetyl* derivative, which may be contrasted with the previously known three forms of *tetra-acetyl* methylmannoside (compare Dale, *J. Amer. Chem. Soc.*, 1924, **46**, 1050).

Methylation with methyl sulphate and alkali effects a quantitative conversion of (I) into the crystalline *tetramethyl*  $\alpha$ -methylmannofuranoside (II). The tetramethyl derivative (II) is very slightly more stable than the initial unmethylated mannoside, and on being heated at  $100^\circ$  during 8 hours with  $N/100$ -hydrochloric acid it is completely transformed into the free methylated sugar, *tetramethyl mannofuranose* (III). Under identical conditions tetramethyl  $\alpha$ -methylmannopyranoside undergoes little, if any, hydrolysis. Oxidation of (III) with bromine water yielded the crystalline

2:3:5:6-tetramethyl  $\gamma$ -mannonolactone (IV). This lactone had already been prepared from mannose-diacetone (VI) by Goodyear

and Haworth (J., 1927, 3136), who determined its structure by oxidative degradation to *i*-dimethoxysuccinic acid (V), identified through its crystalline ester or methylamide.

These experimental results furnish a proof of the constitution of the new  $\alpha$ -methylmannofuranoside (I) and demonstrate the presence of a five-atom ring. From a parallel series of transformations the six-atom ring structure of  $\alpha$ -methylmannopyranoside (normal  $\alpha$ -methylmannoside) has been derived.

These observations are the more significant in view of the work of Irvine and Burt (J., 1924, 125, 1343), who have recorded the isolation, by the same procedure that we have adopted, of a liquid specimen of  $\gamma$ -methylmannoside. They have ascribed to it exceptional properties. They reported that  $\gamma$ -methylmannoside has only a transient existence and undergoes spontaneous conversion into  $\alpha$ -methylmannopyranoside (VII). We have found, on the contrary, that the  $\gamma$ -mannoside can be preserved indefinitely, without suffering any change. They also observed that  $\gamma$ -methylmannoside changes its ring structure during methylation and is partly converted into tetramethyl  $\alpha$ -methylmannopyranoside. We differ from this view inasmuch as we have observed a quantitative conversion of the  $\gamma$ -mannoside (I) into its crystalline tetramethyl derivative (II) without ring displacement, either by means of methyl sulphate and alkali or of methyl iodide and silver oxide.

These discrepancies are traceable to the statement by Irvine and Burt that, in the initial condensation of mannose with methyl-alcoholic hydrogen chloride, "almost one-half of the sugar was recovered unchanged, the remainder being converted into the new  $\gamma$ -form of methylmannoside." By making this initial assumption they were led to a mistaken view of the nature of their products. As might have been deduced from general principles, this reaction does not give exclusively  $\gamma$ -methylmannosides. Apart from the unchanged mannose which is obtained, extraction of the neutralised product with ethyl acetate yields a mixture of at least four modifications of methylmannoside which were originally present in the acidified methyl-alcoholic solution before its neutralisation. The proportions of these in the neutralised product are not affected on its being kept, nor do the four under-mentioned mannosides undergo interconversion when they are individually isolated. As indicated in the experimental section, we have recovered from this ethyl acetate extract (a) crystalline  $\alpha$ -methylmannopyranoside (VII), (b) the corresponding  $\beta$ -methylmannopyranoside (as its crystalline tetra-acetate), (c) crystalline  $\alpha$ -methylmannofuranoside (the  $\gamma$ -mannoside), and have found evidence also of the presence of (d)  $\beta$ -methylmannofuranoside. A corresponding mixture is obtain-

able also by the method originally adopted by Fischer (*Ber.*, 1914, 47, 1980) for the preparation of  $\gamma$ -methylglucoside, the latter furanoside forms being present along with the  $\alpha$ - and  $\beta$ -glucopyranosides.

In view of these facts it is not surprising that preservation of Irvine and Burt's specimen of  $\gamma$ -methylmannoside led to the separation of crystalline  $\alpha$ -methylmannopyranoside from the mixture, or that during subsequent conversions into the tetramethyl derivatives evidence of this pyranose form was repeatedly encountered. Their final product, when freed ultimately from this impurity as they suggest, must also have contained  $\beta$ -methylmannopyranoside.

Other discrepancies are: (1) the figures given for the rate of condensation of tetramethyl  $\gamma$ -mannose with acid methyl alcohol are at variance with those that we have recorded. A few of their figures for the earlier part of the reaction can be regarded as approximate, but only if their time intervals are read as *hours* and not as *minutes*. (2) Irvine and Burt record analytical figures for a "tetramethyl dimannose" which they isolated, but these are in agreement neither with the figures required for this compound nor for any closely related alternative.

The above-mentioned misconceptions have led to some confusion in another connexion. For instance, Hudson (*J. Amer. Chem. Soc.*, 1926, 48, 1434) has been influenced by Irvine and Burt's observations in formulating his views on the ring structure of sugars.

#### EXPERIMENTAL.

*Preparation of  $\alpha$ -Methylmannofuranoside.*—Mannose (10 g.) was dissolved by shaking in cold dry 1% methyl-alcoholic hydrogen chloride (200 c.c.). After 24 hours at 20°, the acid was neutralised with silver carbonate and the neutral solution was evaporated to dryness under diminished pressure in the presence of barium carbonate. The resultant syrup was extracted ten times with cold ethyl acetate by agitation on a mechanical shaker and the combined ethyl acetate extracts were evaporated under diminished pressure. A syrup remained which crystallised spontaneously once a nucleus of  $\alpha$ -methylmannofuranoside (Haworth and Porter, preceding paper) had been introduced into the laboratory. Recrystallisation from methyl alcohol-ether gave pure  $\alpha$ -methylmannofuranoside, m. p. 118–119°,  $[\alpha]_D^{20} + 113^\circ$  in water (c, 1.0). A mixed m. p. with a sample prepared by Haworth and Porter showed no depression. The yield of pure material (six times crystallised) was 4.5 g. from 15 g. of mannose. The mother-liquors from the crystallisations yielded a small quantity (0.2 g.) of  $\alpha$ -methylmannopyranoside, m. p. 190°,  $[\alpha]_D^{20} + 79^\circ$  in water, and it is shown below that they contained also  $\beta$ -methylmannopyranoside.

Control experiments showed that departure from the conditions laid down above resulted in inferior yields of crystalline material. In particular, no advantage could be gained by using heavy concentrations of hydrogen chloride in the initial condensation.

Samples of crystalline  $\alpha$ -methylmannofuranoside were kept for several months in an ordinary stoppered bottle in the laboratory. In no case was there any sign of transformation into the pyranose form (contrast Irvine and Burt, *loc. cit.*) and the m. p. and specific rotation remained unaltered.

*Hydrolysis of  $\alpha$ -Methylmannofuranoside with N/100-Hydrochloric Acid.*—At 100° in N/100-aqueous hydrochloric acid, hydrolysis of  $\alpha$ -methylmannofuranoside was complete in about 2 hours. The course of the reaction was followed polarimetrically :

<i>t</i> (mins.) ...	0	15	30	45	60	75	90	120	135
$[\alpha]_D^{20}$ .....	+113°	72·3°	51·4°	35°	28°	22·6°	18·6°	15·6°	14·8°
								(constant)	

From these figures the velocity coefficient for the unimolecular reaction at 100° was calculated to be  $k = 0.015$  (mins. and decimal logarithms).

*Stability of  $\alpha$ -Methylmannofuranoside in the Presence of Alkali.*—In 15% aqueous sodium hydroxide solution  $\alpha$ -methylmannofuranoside showed  $[\alpha]_D^{20} + 86^\circ$ . This value is lower than that observed for aqueous solutions and a similar difference was found in the case of  $\alpha$ -methylmannopyranoside, which has  $[\alpha]_D^{20} + 79^\circ$  in water and  $[\alpha]_D^{20} + 69^\circ$  in 15% aqueous sodium hydroxide (*c.* 1.3).

The alkaline solution of  $\alpha$ -methylmannofuranoside remained unaltered in rotation after being heated for 90 minutes at 60°. It was then neutralised by passing carbon dioxide through it and was afterwards evaporated to dryness. The residue was extracted with boiling alcohol, and after removal of the alcohol under diminished pressure the mixture of solid and syrup which remained was treated with boiling ethyl acetate. Evaporation of the latter left crystalline  $\alpha$ -methylmannofuranoside (yield, almost quantitative), which after one recrystallisation from methyl alcohol and ether had m. p. 116°. A mixed m. p. with authentic  $\alpha$ -methylmannofuranoside showed no depression.

*Tetra-acetyl  $\alpha$ -Methylmannofuranoside.*—A solution of  $\alpha$ -methylmannofuranoside (1 g.) in pyridine (8 c.c.) and acetic anhydride (10 c.c.) was kept at 0° for 2 days. It was then poured into water (100 c.c.) and the oil which separated was extracted with chloroform. The chloroform solution was shaken with sodium bicarbonate solution until neutral, washed with water, and evaporated under diminished pressure to a syrup, which still contained pyridine. This was removed by distillation in steam at 40°, after which the residue

was dried at  $40^\circ/10$  mm. for 3 hours, giving a syrup which resisted crystallisation. A small sample left on a watch-glass ultimately solidified and after inoculation with this the main portion crystallised completely (yield, 1.8 g.). Recrystallisation from aqueous alcohol gave *tetra-acetyl  $\alpha$ -methylmannofuranoside* as colourless needles, m. p.  $63^\circ$ ,  $[\alpha]_D^{25} + 107^\circ$  in chloroform (c, 1.0). This substance was non-reducing and was soluble in acetone, ether, alcohol, and chloroform, slightly soluble in water and almost insoluble in light petroleum (b. p.  $60-80^\circ$ ) (Found: C, 49.9; H, 6.4; OMe, 8.6;  $\text{CH}_3\cdot\text{CO}$ , 48.0.  $\text{C}_{15}\text{H}_{22}\text{O}_{10}$  requires C, 49.7; H, 6.1; OMe, 8.6;  $\text{CH}_3\cdot\text{CO}$ , 47.5%). The m. p. of *tetra-acetyl  $\alpha$ -methylpyranoside* is also  $63^\circ$ , but in admixture with *tetra-acetyl  $\alpha$ -methylfuranoside* the m. p. was depressed to  $40-45^\circ$ .

*Acetylation of the Syrupy Residues obtained during the Preparation of  $\alpha$ -Methylmannofuranoside.*—The mother-liquors from the crystallisation of  $\alpha$ -methylmannofuranoside were evaporated to dryness under diminished pressure and the syrup which remained was acetylated with pyridine and acetic anhydride in the manner already described. The product was a syrup from which crystalline material separated on the addition of ether. This solid substance (0.4 g. from 15 g. of mannose) after recrystallisation from absolute alcohol showed m. p.  $156^\circ$ , alone or when mixed with *tetra-acetyl  $\beta$ -methylmannopyranoside*. It follows, therefore, that the ethyl acetate extract of the syrup obtained by condensing mannose with cold methyl-alcoholic hydrogen chloride contained  $\beta$ -methylmannofuranoside in addition to  $\alpha$ -methylmannofuranoside and  $\alpha$ -methylmannopyranoside.

After removal of *tetra-acetyl  $\beta$ -methylmannopyranoside* an uncrystallisable syrup remained which probably consisted mainly of *tetra-acetyl  $\beta$ -methylmannofuranoside*.

*Preparation of Tetramethyl  $\alpha$ -Methylmannofuranoside.*—(a) *By means of methyl sulphate.* A solution of  $\alpha$ -methylmannofuranoside (3 g.) in acetone (30 c.c.) and water (10 c.c.) was rendered slightly alkaline and treated at  $50-55^\circ$  with methyl sulphate (40 c.c.) and 30% aqueous sodium hydroxide (70 c.c.), care being taken to avoid the development of acidity. The product (3.6 g.), after remethylation in acetone solution by methyl sulphate (20 c.c.) and 30% aqueous sodium hydroxide (35 c.c.), was distilled, giving *tetramethyl  $\alpha$ -methylfuranoside* (3.2 g.) as a colourless oil, b. p. about  $120^\circ/0.23$  mm., which solidified completely.  $[\alpha]_D^{25} + 97^\circ$  in water (c, 1.0). After recrystallisation from light petroleum (b. p.  $40-60^\circ$ ), the substance had m. p.  $24^\circ$ ,  $[\alpha]_D^{25} + 98.6^\circ$  in water (c, 1.0),  $[\alpha]_D^{25} + 65^\circ$ , equilibrium rotation in 1% methyl-alcoholic hydrogen chloride (Found: C, 53.0; H, 8.9; OMe, 59.5.  $\text{C}_{11}\text{H}_{22}\text{O}_6$  requires C, 52.8; H, 8.8; OMe, 62.0%).

(b) *By means of silver oxide and methyl iodide.* A solution of  $\alpha$ -methylmannofuranoside (3 g.) in methyl alcohol (15 c.c.) was treated in the usual way with methyl iodide (40 c.c.) and silver oxide (20 g.). The product was soluble in methyl iodide and after three further treatments with methyl iodide and silver oxide the methylation was complete. The final product was a syrup which gave on distillation tetramethyl  $\alpha$ -methylmannofuranoside (3.3 g.), b. p. about  $90^\circ/0.05$  mm.,  $n_D^{18}$  1.4441,  $[\alpha]_D^{20} + 98^\circ$  in water (c, 4.0). This solidified completely when cooled in the ice-chest. Recrystallisation from light petroleum gave needles, m. p.  $24^\circ$  alone or when mixed with the material described above;  $[\alpha]_D^{19} + 99^\circ$  in water.

A mixture of tetramethyl  $\alpha$ -methylmannofuranoside, m. p.  $24^\circ$ , and tetramethyl  $\alpha$ -methylmannopyranoside, m. p.  $37^\circ$ , had so low a m. p. that it was liquid at  $5^\circ$ . The two substances were further differentiated by comparing their rates of hydrolysis by  $N/100$ -hydrochloric acid at  $100^\circ$ . The furanose derivative was completely hydrolysed in about 8 hours, whereas the pyranose derivative was scarcely affected under these conditions. The following polarimetric observations were made during the hydrolysis of tetramethyl  $\alpha$ -methylmannofuranoside prepared by method (a) :

<i>t</i> (mins.)	0	30	60	120	180	240	330	390	480
$[\alpha]_D^{20}$	+97.6°	89.2°	82.7°	72.0°	62.0°	55.5°	49.2°	43.6°	42.7°
								(constant)	

A similar experiment was carried out with material made by method (b). Hydrolysis was complete in about 8 hours and the polarimetric observations were in exact agreement with those just given.

*Tetramethyl Mannofuranose.*—A solution of tetramethyl  $\alpha$ -methylfuranoside (2 g.) in  $N/100$ -aqueous hydrochloric acid (50 c.c.) was heated on the water-bath until the specific rotation reached the constant value  $[\alpha]_D^{20} + 43^\circ$  (8 hours). After neutralisation with barium carbonate the solution was evaporated to dryness under diminished pressure and the product was extracted with boiling ether. Removal of the ether left a syrup which on distillation gave *tetramethyl mannofuranose* as a colourless liquid (1.3 g.), b. p.  $124^\circ/0.1$  mm.,  $n_D^{18}$  1.4532,  $[\alpha]_D^{22} + 39^\circ$ , initial value in water (c, 0.54). After 10 minutes, mutarotation was complete and the final equilibrium rotation was  $[\alpha]_D^{22} + 43^\circ$ ;  $[\alpha]_D^{22} + 37^\circ$  in methyl alcohol (c, 0.86) (Found: C, 50.7; H, 8.7; OMe, 51.7.  $C_{10}H_{20}O_6$  requires C, 50.8; H, 8.5; OMe, 52.5%).

The still residue (0.2 g.) deposited a minute quantity of crystalline material which will be the subject of further investigation in view of the known tendency of furanose compounds to undergo auto-condensation.

Tetramethyl mannofuranose condensed readily with cold methyl

alcohol containing 0.25% of hydrogen chloride. The initial specific rotation,  $[\alpha]_D^{25} + 35^\circ$  (c, 0.81) changed to  $31^\circ$  after 2 minutes,  $28^\circ$  (14 mins.),  $22^\circ$  (36 mins.),  $13.5^\circ$  (1 hour),  $3.7^\circ$  ( $1\frac{1}{2}$  hours),  $-2.5^\circ$  ( $2\frac{1}{4}$  hours),  $+6^\circ$  (15 hours),  $+12^\circ$  (17 hours),  $+20^\circ$  (21 hours),  $+31^\circ$  (25 hours),  $45^\circ$  (40 hours),  $59^\circ$  (60 hours),  $63^\circ$  (88 hours),  $67^\circ$  (final constant value after 120 hours, calc. as tetramethyl methylmannofuranoside). The final value is in excellent agreement with that given above for the equilibrium mixture of the  $\alpha$ - and  $\beta$ -forms of tetramethyl methylmannofuranoside ( $+65^\circ$ ). The observations during the earlier stages of the condensation are in agreement with those of Irvine and Burt only if their times are read in hours instead of in minutes. The slower rate of reaction towards the end of the condensation and the lower value of the final rotation recorded by these authors indicate that their product was impure.

*Oxidation of Tetramethyl Mannofuranose.*—Tetramethyl mannofuranose (1.1 g.), dissolved in water (20 c.c.), was treated with bromine (1.5 c.c.) for 3 days at  $35^\circ$ . The reducing action had then disappeared. After removal of the bromine by aeration the solution was neutralised with silver oxide. Charcoal was added to remove colloidal silver and the solution was then filtered. The dissolved silver was next removed by titration with  $N/2$ -aqueous hydrochloric acid and on evaporation of the water under diminished pressure crystalline tetramethyl  $\gamma$ -mannonolactone was obtained (yield, 1.0 g.) which was identical with the lactone previously described by Goodyear and Haworth (*loc. cit.*). After recrystallisation from ether and light petroleum it had m. p.  $108^\circ$ , alone or when mixed with an authentic specimen of tetramethyl  $\gamma$ -mannonolactone,  $[\alpha]_D^{20} + 65^\circ$ , initial value in water (c, 0.87).

The authors are grateful to the Government Grant Committee of the Royal Society for financial assistance towards the cost of materials.

### LXXXVIII.—*Derivatives of Lyxofuranose.*

By HAROLD GRAHAM BOTT, EDMUND LANGLEY HIRST, and  
JAMES ANDREW BUCHAN SMITH.

SINCE the normal variety of trimethyl lyxose obtained by methylating  $\alpha$ -methyl-lyxoside can be transformed successively into a  $\delta$ -lactone and  $\delta$ -trimethoxyglutaric acid (J., 1928, 3147), normal

derivatives of lyxose must belong to the pyranose type of sugar compounds. This conclusion is, however, in direct conflict with the opinions of Phelps and Hudson (*J. Amer. Chem. Soc.*, 1926, **48**, 503; 1928, **50**, 2049), who uphold the view that  $\alpha$ -methyl-lyxoside is furanose in type. The arguments used by these authors are based entirely on optical relationships, and reasons have already been given (*loc. cit.*) for doubting their applicability in the present instance. The question has now been put to a further experimental test by the preparation of derivatives of lyxose which indubitably have the furanose structure. These new substances show no relationship to  $\alpha$ -methyl-lyxoside but are, on the other hand, typical  $\gamma$ -sugar derivatives. Lyxose therefore falls completely into line with all the other aldoses and ketoses which have been examined, in giving a series of "normal" derivatives which are pyranose in type and a series of more labile  $\gamma$ -derivatives which have the furanose structure.

The study of methyl-lyxofuranoside is of particular interest in view of the important claims made by Irvine and Burt (*J.*, 1924, **125**, 1343) concerning the instability of the closely related  $\gamma$ -methylmannoside. The latter substance is said to change spontaneously into the pyranose form and to yield by structural transformation a considerable proportion of the methylated pyranose variety on treatment with methyl sulphate and alkali. On this account we have examined the behaviour of methyl-lyxofuranoside with particular care. No such anomalous properties have been observed. The substance remains unchanged on being kept for prolonged periods, and methylation, either by methyl sulphate or by silver oxide and methyl iodide, proceeds without structural transformation. In view of these observations it seemed unreasonable to suppose that the configurationally related mannose derivative should differ so fundamentally, and experiments were instituted with " $\gamma$ "-methylmannoside in order to decide this point. As a result we are convinced that Irvine and Burt's conclusions are erroneous, and that in fact neither methyl-lyxofuranoside nor methylmannofuranoside suffers ring displacement during methylation. The experimental evidence, in the case of the mannose derivative, is furnished in the preceding paper (Haworth, Hirst, and Webb).

The starting point of the present investigation was methyl-lyxofuranoside (II), which was prepared by the action of cold methyl-alcoholic hydrogen chloride on lyxose (I). The reaction was accompanied by a comparatively rapid rise in specific rotation, followed by a slow fall to a constant equilibrium value. A similar but more rapid series of changes was observed in hot solutions. When the reaction was stopped at the point of maximum rotation,

the product consisted mainly of methyl-lyxofuranoside, but at equilibrium the solution contained mainly normal  $\alpha$ -methyl-lyxoside.

It is well known that similar reactions occur with other reducing sugars and that in certain cases, notably with galactose and arabinose, a rich proportion of the methyl-furanoside is present at equilibrium. Furthermore, the direct methylation of galactose by methyl sulphate and alkali gives a mixture of furanose and pyranose forms and it would be no matter for surprise should conditions be found under which the methylation of glucose by methyl sulphate would yield derivatives of glucofuranose (Whitnah, *J. Amer. Chem. Soc.*, 1929, **51**, 3490). This author apparently believes that structural determinations made by the methylation method may be rendered invalid by the tendency of the free sugars to yield derivatives of both the furanose and the pyranose type. It is therefore necessary to point out that the structures assigned to the methylglucosides and their derivatives do not depend on results obtained by methylating the free sugars, and that in consequence the observations of Whitnah can have no bearing on the different opinions held respectively by Hudson and by Haworth and the present authors concerning the structure of the methylglucosides.

Owing to the excessive solubility of lyxose and its derivatives, pure methyl-lyxofuranoside could not be obtained and the substance was examined in the form of a syrup, which contained both the  $\alpha$ - and the  $\beta$ -form of methyl-lyxofuranoside (75%), together with free lyxose (15%) and methyl-lyxopyranoside (10%). Details of the method of analysis are given in the experimental section. Methyl-lyxofuranoside showed no tendency to change spontaneously into the pyranose form. It was very sensitive to dilute acids, hydrolysis being complete in less than 20 minutes with *N*/15-hydrochloric acid at 95°.

Treatment of the above mixture containing 75% of methyl-lyxofuranoside with methyl sulphate and alkali under conditions which ensured the destruction of free lyxose gave an excellent yield of the fully methylated derivative. This was a liquid which contained *trimethyl methyl-lyxofuranoside* (90%) (III) and *trimethyl methyl-lyxopyranoside* (10%). A mixture of similar composition was obtained by methylation with silver oxide and methyl iodide. It is obvious from these figures that no transformation of furanose derivative into pyranose took place during methylation. *Trimethyl methyl-lyxofuranoside* was very readily hydrolysed by dilute acids and by taking advantage of this property it was possible to obtain *trimethyl lyxofuranose* (IV) almost entirely free from the corresponding pyranose form. This was accomplished by hydrolysing the mixture of normal and  $\gamma$ -trimethyl methyl-lyxosides with *N*/15-

hydrochloric acid at 95°; the trimethyl methyl-lyxopyranoside then remained unaltered and was removed subsequently by fractional distillation. Trimethyl lyxofuranose was isolated as an uncrystallisable liquid with strong reducing properties, which condensed rapidly in the cold with methyl-alcoholic hydrogen chloride. When heated, trimethyl lyxofuranose underwent autocondensation, two molecules uniting with elimination of one molecule of water to give a crystalline non-reducing substance  $C_{16}H_{30}O_9$ , which was shown to be the *hexamethyl* derivative (V) of a non-reducing dipentose containing two lyxofuranose residues. The high value of the specific rotation,  $[\alpha]_D^{20} + 114^\circ$  in water, would appear to show that both glucosidic groups are  $\alpha$ - in configuration. No such autocondensation was observed with trimethyl lyxopyranose (Hirst and Smith, *loc. cit.*) and it is evident that the increased reactivity in the present case is to be ascribed to the presence of the furanose ring structure.

Tetramethyl mannofuranose may be expected to give in a similar way the octamethyl derivative of a disaccharide, and it is possible that this condensation may have been effected by Irvine and Burt (*loc. cit.*, p. 1348). Unfortunately, the evidence provided by these authors is insufficient to show whether the compound formed is similar in type to that described above, and the situation is further complicated by the fact that the product is referred to as tetramethyl dimannose. Even if this name is a misprint for octamethyl dimannose, there still remains the difficulty that the analytical composition of Irvine and Burt's substance corresponded to the formula  $C_{16}H_{26}O_9$ , which they ascribe to tetramethyl dimannose ( $C_{16}H_{30}O_{11}$ ), but which in fact is the formula neither of that substance nor of octamethyl dimannose ( $C_{20}H_{38}O_{11}$ ).

The structure of methyl-lyxofuranoside and its methylated derivatives was established by the preparation of crystalline trimethyl  $\gamma$ -lyxonolactone, obtained by the action of bromine water on trimethyl lyxofuranose. The phenylhydrazide prepared from this lactone was identical with the phenylhydrazide obtained from the trimethyl  $\gamma$ -lyxonolactone which had been prepared previously by epimerising trimethyl  $\gamma$ -xylonolactone (Haworth and Long, J., 1929, 345). Since the structure of the latter substance as a  $\gamma$ -lactone has been established (Haworth and Porter, J., 1928, 611), it follows that " $\gamma$ "-methyl-lyxoside and its derivatives must belong to the furanose class.

The conversion of trimethyl  $\gamma$ -lyxonolactone into the acid proceeded so slowly in aqueous solution that after 1000 hours equilibrium was far from being attained. The conversion of acid into lactone was equally slow, and in consequence only an approximate

value can be given for the proportion of lactone present at equilibrium. This appeared to be about 55%. There is a marked resemblance in these respects between trimethyl  $\gamma$ -lyxonolactone and the stereochemically related tetramethyl  $\gamma$ -mannonolactone (Drew, Goodyear, and Haworth, J., 1927, 1237).

Confirmatory evidence concerning the structure of the trimethyl  $\gamma$ -lyxonolactone was obtained by methylating crystalline  $\gamma$ -lyxonolactone, which had been prepared by oxidising lyxose with bromine water. A comparison of the corresponding phenylhydrazides served to prove the identity of the trimethyl  $\gamma$ -lyxonolactone thus obtained with the material derived from methyl-lyxofuranoside. It will be seen by reference to the experimental section that the methylation of  $\gamma$ -lyxonolactone by silver oxide and methyl iodide is complicated by the tendency of the lactone ring to open in the presence of the water eliminated during the methylation process. From the silver lyxonate then formed, methylated derivatives of methyl lyxonate are obtained.

Still further evidence of the presence of a furanose ring structure in trimethyl methyl-lyxofuranoside was provided by oxidising the substance with nitric acid under conditions which give a quantitative yield of trimethoxyglutaric acid from trimethyl-lyxopyranose. In the present instance the product was mainly *i*-dimethoxysuccinic acid (VII), no trace of which is obtained under these conditions from trimethyl-lyxopyranose. The behaviour during the oxidation,

and the yield of *i*-dimethoxysuccinic acid, which was identified in the form of its crystalline methyl ester, conform exactly with observations recorded during similar oxidation experiments with other methylated furanose derivatives.

When the mixture containing methyl-lyxofuranoside (75%), methyl-lyxopyranoside (10%), and lyxose (15%) was methylated with silver oxide and methyl iodide the main product was, as indicated above, trimethyl methyl-lyxoside, but the process was accompanied by complex oxidative changes which were probably due to the action of silver oxide on the free lyxose present. In addition to trimethyl methyl-lyxoside there was obtained a small amount (4%) of a crystalline substance which analysis showed to be a *methyl* ester of formula  $C_4H_5O_2(OMe)_2 \cdot CO_2Me$ . The possibility that the molecular weight corresponds to some multiple of the simple formula  $C_3H_{14}O_6$  has not been definitely excluded, but the low b. p. of the substance renders such a contingency very improbable. Further experiments are in progress by which it is hoped to determine the structure of this oxidation product.

#### EXPERIMENTAL.

*Methyl-lyxofuranoside*.—Polarimetric observations on a solution of lyxose in 1% methyl-alcoholic hydrogen chloride at 20° showed that the specific rotation increased gradually to a maximum value  $[\alpha]_D^{20} + 72^\circ$  (10 hours) and thereafter decreased to a constant value  $[\alpha]_D^{20} + 42^\circ$  (100 hours). Similar changes took place with more rapidity in hot solutions, and the final product was mainly  $\alpha$ -methyl-lyxoside. Accordingly, lyxose (10 g.) was dissolved in cold 1% methyl-alcoholic hydrogen chloride (300 c.c.) and kept at 20° until the maximum value  $[\alpha]_D^{20} + 73^\circ$  was attained (10 hours). The acid was then neutralised with silver carbonate, and the methyl alcohol removed at 30° under diminished pressure in the presence of a little silver carbonate. The syrup which remained was extracted three times with ethyl acetate at 20° and the extracts were evaporated to dryness at 30°/15 mm. A stiff syrup remained (10 g.) which was perfectly stable when kept in a dry atmosphere free from acid fumes. It contained methyl-lyxofuranoside, methyl-lyxopyranoside and free lyxose.  $[\alpha]_D^{20} + 62^\circ$  in water ( $c = 1.07$ ).

On treatment with *N*/15-hydrochloric acid at 95° rapid hydrolysis of the methyl-lyxofuranoside took place:  $[\alpha]_D^{20} + 62^\circ$  (initial);  $-4^\circ$  (10 mins.);  $-6^\circ$  (20 mins., constant value). The rate of hydrolysis is much more rapid than that of  $\alpha$ -methyl-lyxoside under similar conditions (Phelps and Hudson, *loc. cit.*). The concentration of hydrochloric acid was then increased to *N*/2 and the heating continued. Hydrolysis of the pyranoside was complete in

50 minutes, the final rotation value being  $[\alpha]_D^{20} - 13^\circ$  (calc. as free lyxose), which is very close to the recognised equilibrium value for lyxose.

The amount of free lyxose (15%) was estimated by the Willstätter-Schudel method (*Ber.*, 1918, 51, 780; Goebel, *J. Biol. Chem.*, 1927, 72, 801). Control estimations in which pure lyxose was used gave quantitative results. From the above figures,  $[\alpha]_D + 40^\circ$  being taken as the probable rotation value for the mixture of  $\alpha$ - and  $\beta$ -methyl-lyxopyranosides, it was calculated that the reaction product consisted of free lyxose (15%), methyl-lyxopyranoside (10%), and methyl lyxofuranoside (75%) (Found: OMe, 16.8. Calc. for the above mixture, 15.9%).

*Methylation of Methyl-lyxofuranoside by Methyl Sulphate.*—The mixture described in the previous section was dissolved in acetone (6 g. in 15 c.c.) and treated in the usual manner with methyl sulphate (40 c.c.) and 30% aqueous sodium hydroxide (70 c.c.). The temperature ranged from 55–70° and excess of alkali was added at the beginning of the reaction to destroy the free lyxose. Methylation of the product (5.2 g.) was completed by the use of Purdie's reagents, and the resultant non-reducing syrup (5.2 g.,  $n_D^{17} 1.4477$ ) was distilled, giving a colourless hygroscopic liquid (4.8 g.), b. p. about 90°/0.06 mm.,  $n_D^{17} 1.4457$ ,  $[\alpha]_D^{20} + 52^\circ$  in water ( $c = 0.6$ ),  $[\alpha]_D^{20} + 41^\circ$  in methyl alcohol ( $c = 1.3$ ),  $[\alpha]_D^{20} + 52^\circ$ , equilibrium value after heating with 1% methyl-alcoholic hydrogen chloride. In *N*/15-aqueous hydrochloric acid at 95° hydrolysis of the trimethyl methylfuranosidic portion of the distillate occurred rapidly:  $[\alpha]_D^{20} + 52^\circ$  (initial value);  $+ 48^\circ$  (10 mins.);  $+ 37^\circ$  (30 mins.);  $+ 34^\circ$  (50 mins., constant value). After a further 50 minutes' heating with boiling *N*/2-hydrochloric acid the constant value  $[\alpha]_D^{20} + 31^\circ$  (calculated as trimethyl methyl-lyxoside) was attained, the presence of a small amount of trimethyl methyl-lyxopyranoside being thus indicated. Since trimethyl lyxopyranose has  $[\alpha]_D^{20} - 22^\circ$  (equilibrium value in water) and trimethyl lyxofuranose has  $[\alpha]_D^{20} + 39^\circ$  (equilibrium value in water; see below), it follows that the quantities of *trimethyl methyl-lyxofuranoside* and *trimethyl methyl-lyxopyranoside* in the distillate were about 90% and 10% respectively (Found: C, 52.1; H, 8.6; OMe, 58.5.  $C_9H_{18}O_5$  requires C, 52.4; H, 8.7; OMe, 60.2%).

*Trimethyl Lyxofuranose.*—The mixture (4 g.) of trimethyl methyl-lyxofuranoside and trimethyl methyl-lyxopyranoside was heated at 100° with *N*/15-hydrochloric acid (100 c.c.) until the rotation was  $[\alpha]_D^{20} + 32^\circ$  (1 hour). Under these conditions hydrolysis of the pyranose form would be inappreciable. The solution was neutralised with silver carbonate, filtered, and evaporated under

diminished pressure to a mobile syrup, which was dissolved in ether. After removal of the ether the product was distilled, giving two fractions: (a) a mixture of trimethyl lyxofuranose and unhydrolysed trimethyl methyl-lyxopyranoside (0.83 g.), b. p. about  $95^{\circ}/0.04$  mm.,  $n_D^{18}$  1.4531; (b) *trimethyl lyxofuranose* (2.3 g.), b. p. about  $95^{\circ}/0.04$  mm.,  $n_D^{18}$  1.4580,  $[\alpha]_D^{20} + 39^{\circ}$  in water ( $c = 1.05$ ). This rotation is in good agreement with that obtained for trimethyl lyxofuranose by hydrolysis of a crystalline condensation compound (see below). Furthermore, only trimethyl  $\gamma$ -lyxonolactone was obtained by oxidation of the trimethyl lyxofuranose, which must therefore be free from contamination by its pyranose isomeride (Found: C, 49.8; H, 8.4; OMe, 48.1.  $C_8H_{16}O_5$  requires C, 50.0; H, 8.3; OMe, 48.4%).

Trimethyl lyxofuranose condensed rapidly with methyl alcohol containing 1% of hydrogen chloride at  $20^{\circ}$ :  $[\alpha]_D^{20} + 15^{\circ}$  (4 mins. after dissolution);  $+ 13^{\circ}$  (7 mins.);  $+ 13^{\circ}$  (10 mins.);  $+ 14^{\circ}$  (18 mins.);  $+ 21^{\circ}$  (30 mins.);  $+ 36^{\circ}$  (60 mins.);  $+ 42^{\circ}$  (90 mins.);  $+ 45^{\circ}$  (120 mins.);  $+ 55^{\circ}$  (300 mins.);  $+ 60^{\circ}$  (final equilibrium value). Under similar conditions the condensation of trimethyl lyxopyranose with methyl alcohol was very slow:  $[\alpha]_D^{20} - 9^{\circ}$  (initial value);  $- 12^{\circ}$  (150 mins.);  $- 18^{\circ}$  (3000 mins.). The equilibrium value for the pyranose form is  $[\alpha]_D^{20} + 21^{\circ}$  (Hirst and Smith, *loc. cit.*). In both cases the  $\beta$ -isomeride of the methyl-lyxoside is formed more rapidly than the  $\alpha$ -variety.

Fraction (a) was hydrolysed by boiling for 30 minutes with 2*N*-hydrochloric acid. The distilled product (yield, 70%) was a colourless liquid, b. p.  $95-100^{\circ}/0.03$  mm.,  $n_D^{18}$  1.4605,  $[\alpha]_D^{20} + 16^{\circ}$  in water ( $c = 0.7$ ) (Found: OMe, 46.5. Calc., 48.4%). These figures show that the distillate was trimethyl lyxose containing about 60% of the furanose form ( $[\alpha]_D + 39^{\circ}$ ) and 40% of the pyranose form ( $[\alpha]_D - 22^{\circ}$ ). This is equivalent to the presence of 11% of the pyranose form in the trimethyl methyl-lyxoside, in good agreement with the value 10% previously obtained.

*Condensation of Trimethyl Lyxofuranose to give a Hexamethyl Dipentose.*—When trimethyl lyxofuranose was distilled slowly, only a portion of it could be recovered unchanged. The remainder was a colourless liquid, b. p. about  $160^{\circ}/0.05$  mm., which solidified on cooling. After being drained on porous earthenware and recrystallised from light petroleum (b. p.  $40-60^{\circ}$ ), it gave bunches of needles, m. p.  $77^{\circ}$ , which had no action on boiling Fehling's solution but reduced it strongly after hydrolysis with 3% hydrochloric acid. During the hydrolysis the specific rotation,  $[\alpha]_D^{20} + 114^{\circ}$  (initial value), decreased in 15 minutes to a constant value  $+ 43^{\circ}$  ( $[\alpha]_D^{20} + 41^{\circ}$ , calculated as trimethyl lyxose). The physical and chemical

properties of the new substance indicated that it was the *hexamethyl* derivative of a non-reducing dipentose formed by the autocondensation of two molecules of trimethyl lyxofuranose and this view was confirmed by analysis (Found : C, 52.3; H, 8.0; OMe, 49.3.  $C_{16}H_{30}O_9$  requires C, 52.4; H, 8.2; OMe, 50.8%).

*Trimethyl  $\gamma$ -Lyxonolactone*.—A solution of trimethyl lyxofuranose (1.6 g.) in water (20 c.c.) was treated with bromine (2 c.c.), and kept for 4 days at 35–40°: the reducing properties had then disappeared. The bromine was removed by aeration, an excess of silver oxide was added, and the filtered solution was titrated exactly with hydrochloric acid to liberate the trimethyl lyxonic acid from its silver salt. On evaporation under diminished pressure, followed by heating at 100°/10 mm. to complete the lactonisation, a syrup was obtained which was freed from some inorganic material by solution in ether. On removal of the solvent crystalline trimethyl lyxonolactone was obtained (1.4 g.) which on distillation gave a solid crystalline mass (1.3 g.), b. p. 170°/12 mm., m. p. 37–40°,  $n_D^{20} 1.4569$ ,  $[\alpha]_D^{20} + 82.5^\circ$  in water (initial value, decreasing with extreme slowness). Recrystallisation from ether–light petroleum (b. p. 40–60°) gave needles 4–5 cm. long, m. p. 44°,  $[\alpha]_D^{20} + 82.5^\circ$  in water ( $c = 0.5$ ) (Found : C, 50.5; H, 7.0; OMe, 49.3. Calc. for  $C_8H_{14}O_5$ : C, 50.5; H, 7.4; OMe, 49.0%).

If the trimethyl lyxofuranose had been contaminated with trimethyl lyxopyranose, the specific rotation of the freshly distilled lactone before recrystallisation would have been less than  $[\alpha]_D^{20} + 82^\circ$ , owing to the presence of some trimethyl  $\delta$ -lyxonolactone ( $[\alpha]_D^{20} + 35.5^\circ$ ). The above observations therefore provide additional evidence of the homogeneity of the trimethyl lyxofuranose.

When an ethereal solution of the lactone was heated with the calculated quantity of phenylhydrazine, the corresponding phenylhydrazide was formed. This was washed with ether and on recrystallisation from benzene gave needles, m. p. 140° alone or in admixture with the phenylhydrazide of the acid obtained by the epimerisation of trimethyl xylonolactone (Haworth and Long, *loc. cit.*) (Found : C, 56.2; H, 7.3; N, 9.6; OMe, 31.5. Calc. for  $C_{14}H_{22}O_5N_2$ : C, 56.4; H, 7.4; N, 9.4; OMe, 31.2%).

*Hydrolysis of Trimethyl  $\gamma$ -Lyxonolactone*.—The hydrolysis of the crystalline lactone in aqueous solution was studied polarimetrically. Mutarotation was extremely slow and the behaviour throughout was that of a  $\gamma$ -lactone. The rotation of the free acid was determined in the usual manner by forming the sodium salt, adding the equivalent amount of hydrochloric acid, and determining the rotation immediately.  $[\alpha]^{20} - 21^\circ$  in water ( $c = 0.5$ , calculated as lactone).

*Conversion of lactone into acid.*

Time (hours).	$[\alpha]_D^{20}$ .	% of lactone present.	Time (hours).	$[\alpha]_D^{20}$ .	% of lactone present.
0	+82.5°	100	474	65.0°	83.0
24	80	97.6	551	63.9	82.0
73	77.7	95.3	644	62.3	80.4
145	75.1	92.8	883	57.0	75.3
378	67.1	85.1	1000	56.5	74.8

The conversion of the acid into lactone in aqueous solution proceeded so slowly that equilibrium had not been attained at the end of 500 hours. A direct determination of the proportion of acid and lactone present at equilibrium was therefore impracticable, but an approximate value (55% of lactone) was deduced by extrapolation.

*Conversion of acid into lactone.*

Time (hours).	$[\alpha]_D^{20}$ .	% of lactone present.	Time (hours).	$[\alpha]_D^{20}$ .	% of lactone present.
0	-20.8°	0	75	+6.4°	26
24	-16.0	4.6	140	14.4	34
50	-4.4	16	500	25.6	45

*Methylation of  $\gamma$ -Lyxonolactone.*—Lyxonolactone was prepared from lyxose by heating the sugar with bromine water at 30° for several days. Hydrobromic acid was removed by means of silver oxide and the resulting solution of silver lyxonate was then treated with the exact quantity of hydrochloric acid required to precipitate the silver. Evaporation of the water in a vacuum left a syrup which soon crystallised and pure lyxonolactone, m. p. 109°, was obtained after one recrystallisation from ethyl acetate.

This lactone (2 g.) was methylated in the usual way with Purdie's reagents. Six consecutive treatments were carried out, the addition of methyl alcohol being necessary in the first three in order to effect solution. Fractional distillation of the final product showed that a complex mixture of substances had been formed. The following fractions were taken: (a) 0.14 g., bath temp. 107°/0.04 mm.,  $n_D^{14}$  1.4350; (b) 0.9 g., bath temp. 115°/0.08 mm.,  $n_D^{13}$  1.4372; (c) 0.27 g., bath temp. 125°/0.03 mm.,  $n_D^{12}$  1.4381; (d) 0.72 g., bath temp. 140–150°/0.03 mm.,  $n_D^{11}$  1.4484. The fractions (a), (b) and (c) were esteric in nature and contained substances which were more highly methylated than trimethyl-lyxonolactone, possibly methyl tetramethyl-lyxonate,  $C_{10}H_{20}O_6$ , and methyl trimethyl-lyxonate,  $C_9H_{18}O_6$  [Found for (b): C, 49.5; H, 8.3; OMe, 64.5.  $C_{10}H_{20}O_6$  requires C, 50.8; H, 8.5; OMe, 65.6%.  $C_9H_{18}O_6$  requires C, 48.7; H, 8.1; OMe, 55.8%].

Fraction (d) was mainly trimethyl lyxonolactone (Found: C, 50.4; H, 8.3; OMe, 53.0%). It was not sufficiently pure to crystal-

lise, but the presence of trimethyl  $\gamma$ -lyxonolactone was proved by preparing from it the corresponding phenylhydrazide, which was formed in good yield when an ethereal solution of the liquid was heated on the water-bath with phenylhydrazine. One recrystallisation from benzene sufficed to give the pure phenylhydrazide, m. p.  $140^{\circ}$  (alone or when mixed with the phenylhydrazide of the acid obtained from trimethyl lyxofuranose).

*Oxidation of Trimethyl Methyl-lyxofuranoside with Nitric Acid.*—Trimethyl methyl-lyxofuranoside (2 g.) was heated for 8 hours at  $90^{\circ}$  with nitric acid ( $d$  1.42; 20 c.c.). Evolution of nitrous fumes had then almost ceased. The remaining nitric acid was removed by distillation under diminished pressure at  $50^{\circ}$ , with frequent addition of water. The stiff syrup obtained was boiled for 6 hours with 2% methyl-alcoholic hydrogen chloride. After neutralisation of the acid by silver carbonate the methyl alcohol was removed by distillation under diminished pressure and the product was distilled, giving a colourless liquid (0.9 g.), b. p.  $135\text{--}140^{\circ}/12$  mm. No methyl oxalate could be detected and there was no still residue. The distillate, after nucleation with a crystal of methyl *i*-dimethoxy-succinate, began to crystallise. After being kept for several weeks, the solid was drained on porous tile and recrystallised from ether-light petroleum, giving flat plates (0.4 g.), m. p.  $68^{\circ}$  alone or when mixed with an authentic specimen prepared from *i*-tartaric acid.

*Methylation of Methyl-lyxofuranoside by Purdie's Reagents.*—The crude methyl-lyxofuranoside described above (10 g.) was methylated six times with silver oxide and methyl iodide. The product was distilled, giving 7.9 g., b. p.  $70\text{--}74^{\circ}/0.08$  mm., and 3.5 g., b. p.  $75\text{--}90^{\circ}/0.08$  mm. A small quantity (4%) of a crystalline oxidation product (A) separated from both fractions. This was removed by draining on porous tile, after which the liquid was recovered by extraction with chloroform and redistilled; b. p.  $75^{\circ}/0.1$  mm.,  $n_D^{20}$  1.4431,  $[\alpha]_D^{20} + 41^{\circ}$  in water ( $c = 3.6$ ),  $[\alpha]_D^{20} + 53^{\circ}$  in 1% methyl-alcoholic hydrogen chloride (equilibrium value after being heated at  $100^{\circ}$  for 6 hours). The distillate was mainly trimethyl methyl-lyxofuranoside, but contained also the corresponding pyranoside (15–20%) and probably also a little of the above-mentioned crystalline product (Found: OMe, 56.8%). Hydrolysis with dilute hydrochloric acid gave the corresponding mixture of trimethyl lyxofuranose and trimethyl lyxopyranose. This had b. p.  $95^{\circ}/0.04$  mm.,  $n_D^{20}$  1.4598,  $[\alpha]_D^{20} + 27^{\circ}$  in water ( $c = 3.3$ ) (Found: OMe, 47.5%). Oxidation with bromine water gave the mixed  $\gamma$ - and  $\delta$ -lactones as a liquid, b. p.  $108^{\circ}/0.1$  mm.,  $n_D^{20}$  1.4553,  $[\alpha]_D^{20} + 76^{\circ}$  in water (initial value);  $+ 65^{\circ}$  (23 hours);  $+ 63^{\circ}$  (41 hours);  $+ 58^{\circ}$  (90 hours);  $+ 50^{\circ}$  (200 hours);  $+ 45^{\circ}$  (300 hours);  $+ 41^{\circ}$  (900 hours).

The comparatively rapid fall in rotation during the first 50 hours, followed by the slow change which still persisted after 1000 hours, is characteristic of a mixture of a  $\gamma$ - and a  $\delta$ -lactone. Since the trimethyl  $\gamma$ - and  $\delta$ -lyxonolactones have respectively  $[\alpha]_D^{20} + 82.5^\circ$  and  $[\alpha]_D^{20} + 36^\circ$ , the proportion of  $\delta$ -lactone was about 15%. After some time the trimethyl  $\gamma$ -lyxonolactone crystallised; m. p.  $44^\circ$ . Preparation of the phenylhydrazide from the liquid which drained away from the crystalline  $\gamma$ -lactone gave mainly the phenylhydrazide obtainable from trimethyl  $\delta$ -lyxonolactone.

The crystalline oxidation product (A) was easily soluble in the usual organic solvents, soluble with difficulty in water, and was recrystallised from light petroleum, giving long colourless needles, m. p.  $127-128^\circ$ ,  $[\alpha]_D^{20} + 175^\circ$  in water ( $c = 0.53$ ). The substance was neutral to litmus and had no action on boiling Fehling's solution. The presence of an ester group was proved by titration with hot alkali, and after alkaline hydrolysis the high specific rotation was retained. When the ester was heated for 2 hours at  $80^\circ$  with 3% hydrochloric acid, the rotation decreased to  $0^\circ$ ; the resulting solution, after exact neutralisation with sodium hydroxide, did not reduce boiling Fehling's solution but quickly decolorised neutral permanganate [Found: C, 46.5; H, 6.8; OMe, 45.1;  $\text{CO}_2\text{Me}$ , 28.0.  $\text{C}_4\text{H}_5\text{O}_2(\text{OMe})_2 \cdot \text{CO}_2\text{Me}$  requires C, 46.6; H, 6.8; OMe, 45.1;  $\text{CO}_2\text{Me}$ , 28.6%].

The authors wish to express their thanks to Professor W. N. Haworth, F.R.S., for his interest in this work. They are grateful also to the Department of Scientific and Industrial Research for the award of a maintenance grant to one of them (J. A. B. S.) and to the Chemical Society for a grant which has in part defrayed the cost of the materials.

### LXXXIX.—*Trypanocidal Action and Chemical Constitution. Part IX. Aromatic Acids containing an Amide Group.*

By GEORGE ALECK CROCKER GOUGH and HAROLD KING.

THE activity of the cotton dye (I) on *Trypanosoma equiperdum* in rats (Dunning and Macht, *J. Pharm. Exp. Ther.*, 1928, **32**, 205) suggested to us an investigation of the colourless substance (II),

which would bear to (I) the same relation as Bayer 205 to trypan-red and afridol-violet (compare Balaban and King, J., 1927, 3068).

To facilitate synthesis, antimony was replaced by arsenic. The arsenic analogue of (I) was found to be active but not permanently curative. Arsinous and arsinic acids of type (II) prepared from Freund's acid and H-acid were inactive, even if the substantive character was increased (Balaban and King, *loc. cit.*) by changing the structure to (III). The current theory of the activity of arsinic

acids is that they must first be reduced by living tissues to the much more toxic oxides, and it occurred to us that the amide link might possibly remove these substances out of the range of reduction potential of the mammalian tissues.

Accordingly, *benzamide-p-arsinic acid* (IV) was prepared, but it proved to have a therapeutic activity far exceeding that of *p-amino-*

phenylarsinic acid, the starting point of Ehrlich's series of active arsenicals. This interesting discovery made an extensive study of other benzamidearsinic acid derivatives particularly desirable, since no compound of this type had previously been described. A number of substituted benzarsinic acids are known, but no one has converted these carboxylic acids into their simple amides.

The parent substance, benzoyl chloride *p*-dichloroarsine, lends itself to development in a wide variety of ways, for the lone chlorine atom can be replaced by primary or secondary amino-groups or by simple derivatives of these with formation of a series of amides of the type (V). The following table shows the results obtained when a simple series of aromatic amides was tested on an experimental infection of *Trypanosoma equiperdum* in mice, *T* signifying the maximum dose tolerated, expressed in milligrams per gram of mouse, *C* the minimum curative dose, and *r* the number of days during which the blood stream remained free from trypanosomes.

If it is borne in mind that the aim of this kind of work is to discover a substance in which the margin between *C* and *T* is as wide as possible, and that the substances should be "permanently" curative, i.e., that *r* should be greater than a month, it will be observed that trypanocidal activity falls off in the monosubstituted alkylamides with increasing weight of the substituting group, and very rapidly in the disubstituted amides.

Attention was then directed to the meta-series of amides from benz-*m*-arsinic acid, but they proved to be definitely weaker than those of the para-series.

Many of the amides described above, both meta- and para-substituted and containing the arsenic in the quinquevalent state, produced nervous symptoms of chronic poisoning in mice. An attempt was therefore made to prepare derivatives of benzamide-*p*-arsinic acid which would show an equally good therapeutic index without producing any untoward symptoms.

When the modified alkyl groups  $\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OH}$  and  $\cdot\text{CH}_2\cdot\text{CO}\cdot\text{NH}_2$  are introduced into the amino-group of *p*-aminophenylarsinic acid,

two valuable trypanocidal agents, etharsenol (VI) and tryparsamide (VII) respectively, are known to be obtained. It was, therefore, of

interest to attempt the preparation of their analogues (VIII) and (IX) from benz-*p*-arsinic acid. Although benzoyl chloride *p*-dichloroarsine readily reacted with  $\beta$ -aminoethyl alcohol with formation of an arsinous acid which on oxidation gave (VIII), attempts to prepare (IX) were not immediately successful. Hippuro-*p*-arsine oxide (X) when subjected to the action of phosphorus pentachloride in the presence of acetyl chloride gave the trichloro-compound (XI), but this on treatment with ammonia under many conditions always regenerated hippuroarsine oxide. When, however, ammonia was replaced by ethylamine, the *ethylamide* of hippuro-*arsinic acid* (XII) was readily obtained.

The following table shows the activity of these and some related substances in comparison with benzamide-*p*-arsinic acid. R signifies  $-\text{C}_6\text{H}_4\cdot\text{AsO}_3\text{H}_2$  and R' the reduced form  $-\text{C}_6\text{H}_4\cdot\text{AsO}_2\text{H}_2$ .

Of this series the ethylamide of hippuroarsinic acid (XII) proved the most useful, and on the highest dose tried there were no nervous symptoms noticeable in mice. The lower homologues of this acid, hippuramide-*p*-arsinic acid and its *N*-methyl derivatives, will be described in a subsequent communication.

Another way of avoiding the undesirable symptoms evoked by benzamide-*p*-arsinic acid would be by use of the corresponding arsinous acid, for since this has more than 30 times the acute toxicity of the acid containing quinquevalent arsenic, and might have a correspondingly high curative power, the amount of arsenic administered would be correspondingly small. Although this arsinous acid produces no nervous symptoms, it is by no means so effective (compare the first table) as the arsinic acid and it occurred to us that it might be possible to render it more effective by esterification with a suitable alcohol. The ester might then be expected to have an increased efficiency, since slow hydrolysis would liberate the toxic arsinous acid over a period of time. For this purpose we chose  $\alpha$ -thiolacetic acid, which had already been condensed with 3-amino-

4-hydroxyphenylarsinous acid by Voegtlin, Dyer, and Leonard (*U.S. Public Health Rep.*, 1923, **38**, 1911). When an aqueous suspension of benzamide-*p*-arsinous acid was boiled with  $\alpha$ -thiolacetic acid, condensation took place rapidly with formation of crystalline *di(carboxymethyl) benzamide-p-thioarsinite* (XIII).

On its maximum tolerated dose, this substance produced no nervous symptoms and it was more effective than the arsenious acid.

Benzamide- <i>p</i> -thioarsinite .....	0.05	0.03	>30

We had made this compound and had examined its oxidation with iodine when an important paper appeared by Barber (J., 1929, 1020) on the condensation of thiol acids with arsenic acids. We believe, however, that some of the results of this author bear a simpler interpretation than that given by him. Barber observed that the arylthioarsinites in alkaline solution, with sodium hydrogen carbonate, for instance, give an intense nitroprusside reaction which he attributed to the intact arylthioarsinite molecule. In support of this he states that the arylthioarsinites do not undergo hydrolytic fission with alkali, because the alkali-metal salts of the *di(carboxymethyl) arylthioarsinites* can be obtained from strongly alkaline solution. Such a view is, however, untenable. *Di(carboxymethyl) benzamide-p-thioarsinite* (XIII) is soluble in cold sodium hydrogen carbonate solution and gives an intense nitroprusside reaction indistinguishable in tint from that due to  $\alpha$ -thiolacetic acid. The free acid also dissolves sparingly in water and gives the transient blue colour with ferric chloride characteristic of  $\alpha$ -thiolacetic acid. Both these reactions are specific for thiol groups, and indicate partial hydrolysis of the thioarsinites in weakly alkaline solution and even in water. When a feebly alkaline solution of *di(carboxymethyl) benzamide-p-thioarsinite* was treated with one molecular proportion of hydrogen peroxide, benzamide-*p*-arsinic acid was isolated together with unchanged thioarsinite. This result is inconsistent with an exclusive initial addition of oxygen to the arsenic atom of the intact ester molecule, followed by hydrolysis, a process which would seem to follow on Barber's view of the properties of these compounds, but is consistent with oxidation of the hydrolytic products, arylarsinous acid and  $\alpha$ -thiolacetic acid, formed in alkaline solution. The occurrence of some oxidation of the intact ester molecule is not, however, excluded. In further support of the ease of hydrolysis of *di(carboxymethyl) benzamide-*

*p*-thioarsinite is the observation of our biological colleagues, Miss Durham and Miss Strangeways, that at high dilutions trypanosomes exposed to its action are rendered non-infective, a property usually recognised as specific for the arylarsinous acids or oxides.

The effect of introducing a second substituent into the phenyl nucleus of benzamidearsinic acid has been examined in a few cases and others are still under investigation. *Salicylamide-5-arsinic acid* (XIV) and *isophthalamic acid 6-arsinic acid* (XV) have been prepared, but not *isophthalamide-4-arsinic acid*. The toxicities and

therapeutic activities of these substances compared with some intermediate and allied products are recorded below.

	<i>T.</i>	<i>C.</i>	<i>r.</i>
<i>p</i> -Tolylarsinic acid .....	0.005	[inactive]	
<i>m</i> -Xylarsinic acid .....	0.03	[inactive]	
<i>iso</i> Phthalic acid 4-arsinic acid .....	0.03	[inactive]

<i>iso</i> Phthalamic acid 6-arsinic acid .....	0.05	[inactive]	
Salicylic acid 5-arsinic acid .....	1.5	[inactive]	
Methyl salicylate-5-arsinic acid .....	0.02	[inactive]	
Salicylamide-5-arsinic acid .....	0.75	0.3	5

The preparation of salicylamide-5-arsinic acid and *isophthalamic acid 6-arsinic acid* presents some points of interest. When salicylic acid 5-arsinic acid (XVI) prepared by the Bart-Schmidt reaction from 5-aminosalicylic acid is esterified with methyl-alcoholic sulphuric acid, the degree of esterification increases with the amount of sulphuric acid used. At the same time fission of arsenic as arsenious acid increases so that the most favourable conditions for the esterification are uncertain. If the sulphuric acid is replaced by dry hydrogen chloride, the *methyl ester* (XVII) may again be isolated together with some *methyl salicylate-5-dichloroarsine* (XVIII). The latter substance is formed by loss of labile chlorine atoms which react with the solvent. Similarly in the esterification of *isophthalic acid 4-arsinic acid* by methyl-alcoholic hydrogen chloride in boiling solution, reduction to *methyl isophthalate dichloroarsine* is complete. Indeed, this action of dry hydrogen chloride on arsinic acids appears to be a general one. For the preparation of methyl salicylate-5-arsinic acid (XVII) it is, however, preferable to reduce salicylic acid 5-arsinic acid by sulphurous acid in concentrated hydrochloric acid solution directly to *salicylic acid dichloroarsine* (XIX), as this is more easily isolated than the intermediate product *salicylic acid*

arsinous acid (XX), which separates when the reaction is carried out in dilute hydrochloric acid solution. Salicylic acid dichloro-

arsine (XIX), like salicylic acid arsinous acid (XX), is then readily esterified by methyl-alcoholic hydrogen chloride to methyl salicylate-5-dichloroarsine (XVIII). Careful oxidation of a suspension of this in aqueous sodium hydrogen carbonate at  $0^\circ$  with hydrogen peroxide gives methyl salicylate-5-arsinic acid (XVII), and by the action of ammonia on the ester in dilute methyl alcohol at  $100^\circ$  salicylamide-5-arsinic acid (XIV) is obtained.

The difficulties attending the preparation of *isophthalamide*-4-arsinic acid have not yet been surmounted. When *isophthalic acid* 4-arsinic acid (XXI) is allowed to react with thionyl chloride, it gives almost exclusively the half acid chloride of *isophthalic acid* dichloroarsine, for on treatment with ammonia and oxidation with hydrogen peroxide *isophthalamide* 6-arsinic acid (XV) is obtained.

With  $5\frac{1}{2}$  molecular proportions of phosphorus pentachloride, the products isolated are the same *isophthalamide* 6-arsinic acid, 4-chloro*isophthalamide* (XXII), and 3:4-dichlorobenzamide; and with  $6\frac{1}{2}$  molecular proportions, only the last two substances are obtained, the whole of the arsinic acid group having been replaced by chlorine. The constitution of 4-chloro*isophthalamide* follows from its hydrolysis to 4-chloro*isophthalic acid*, and that of 3:4-dichlorobenzamide follows from its hydrolysis to 3:4-dichlorobenzoic acid (XXIII) which was identical with the acid obtained (later communication) by a similar series of reactions from terephthalic acid arsinic acid (XXIV).

When *isophthalic acid 4-arsinic acid* is esterified in synthetic methyl alcohol by saturation with hydrogen chloride at  $0^{\circ}$ , crystalline *methyl isophthalate arsinetetrachloride* separates after a few hours. This tetrachloride dissolves in sodium hydrogen carbonate solution at  $0^{\circ}$  and yields *methyl isophthalate-4-arsinic acid* on acidification. If, however, purified methyl alcohol (wood spirit) is used in the esterification, no separation of an arsinetetrachloride occurs at  $0^{\circ}$ , but when the solution is boiled, reduction takes place with formation of *methyl isophthalate dichloroarsine*, which is isolated as *methyl isophthalate-4-arsinous acid* by pouring the reaction mixture into sodium hydrogen carbonate solution. On oxidation the arsinous acid yields *methyl isophthalate-4-arsinic acid*.

When *methyl isophthalate-4-arsinic acid* is allowed to react with ammonia ( $d$  0.88) at  $0^{\circ}$  for 14 days, the sole product of amidation is the same *isophthalamide acid 6-arsinic acid* as is obtained from the acid chlorides.

The marked influence on the trypanocidal activity of benz-*m*- and -*p*-arsinic acids effected by their conversion into amides, recorded in the foregoing pages, made it desirable to prepare benzenesulphonamide-*p*-arsinic acid. *p*-Sulphophenylarsinic acid had been previously prepared by Hewitt, King, and Murch (J., 1926, 1355) and had been shown to be devoid of activity. By the action of phosphorus pentachloride in boiling carbon tetrachloride solution it was converted into *benzenesulphonyl chloride p-dichloroarsine* (XXV), which on graded hydrolysis with water gave *benzenesulphonyl chloride p-arsenoxide* and *sulphophenylarsinous acid*. By the action of ammonia *benzenesulphonamide-p-arsenoxide* (XXVI) was obtained, and this on treatment with hydrogen peroxide gave *benzenesulphon-*

*amide-p-arsinic acid* (XXVII). With hydrochloric acid, however, the arsinous acid gave *benzenesulphonamide-p-dichloroarsine*. The trypanocidal activity of some of these compounds was examined with the following results:

	<i>T.</i>	<i>C.</i>	<i>r.</i>

#### *Therapeutic Considerations.*

Analysis of the results described in the foregoing pages reveals some underlying principles of considerable interest. The first of

these is the important influence of the amide group in converting trypanocidally inactive carboxylic and sulphonic acids into substances of marked activity. It was known that phenylglycineamide-*p*-arsinic acid (tryparsamide) could cure both experimental and clinical trypanosomiasis, but the significance of the aliphatically bound amide group was obscure, since data on analogous derivatives were lacking. In this communication it has, however, now been demonstrated that benz-*m*- and -*p*-arsinic acids, hippuro-*p*-arsinic acid, salicylic acid 5-arsinic acid, *p*-sulphophenylarsinic acid, and the corresponding arsinous acids were tested, are quite inactive on experimental trypanosomiasis in mice; and yet, when they are converted into the corresponding amides, trypanocidal activity appears in every case. The interpretation is simple. Following the injection of these arsinic or arsinous acids into the blood stream as soluble sodium salts, two main processes become operative, excretion and reduction. Those substances containing solubilising groups such as carboxyl or sulpho, whether they are reduced to the arsinous acids or not, will remain as soluble salts by reason of the carboxyl or sulpho-groups, and their excretion will be rapid. On the other hand, those containing amide groups will also be excreted, though possibly at a slower rate, so long as they contain the arsinic acid group and can form neutral soluble salts. When, however, reduction to the arsinous acid has taken place, they will no longer form neutral salts and will, accordingly, be liberated in the colloidal state as free arsinous acids by hydrolysis at the  $p_H$  of the blood stream, and will not be excreted as such. The mechanism of the reduction process and subsequent events may also be pictured from analogous reactions *in vitro*.

It is known that hydrogen sulphide is a very powerful reducing agent, having in fact a reduction potential negative to the hydrogen electrode. It is, therefore, not surprising to find, as Barber (*loc. cit.*) does, that various thiol derivatives of aliphatic acids can reduce arsinic to arsinous acids, condensation then taking place between the arsinous acids and excess of the thiol compound with production of arylthioarsinites, operations which can take place at the ordinary

temperature in neutral solution. It is very probable that similar processes operate in mammalian tissues, for there is abundant evidence of the presence of thiol compounds in tissues, and some for their being concerned in oxidative-reductive processes. That the excess of thiol groups should act as receptors for the arsinous acid group is also very probable; it was, in fact, foreshadowed by Ehrlich many years ago (*Ber.*, 1909, 42, 42). The occurrence of

arsenic in hair after arsenic medication is possibly a manifestation of the property. The further important point, however, now emerges from our experiments, that the arylthioarsinites are slowly hydrolysed even in neutral solution with regeneration of small amounts of arsinous acids.

The view we advanced in the preceding communication of this series (Gough and King, J., 1928, 2432), that the arsinic acids are "reduced to the reactive oxides, and stored as such by condensation in a reversible form," thus receives experimental support. The arylthioarsinites would be formed from proteins of all degrees of complexity containing sulphydryl groups, and would in general escape excretion, and the continuous production of minute amounts of highly toxic arsinous acids by hydrolysis of such complex thioarsinites in the tissues, maintained over an extended period, would be responsible for the complete disappearance of the trypanosomes with resultant cure.

Lastly, the wide variation in the chemotherapeutic efficiency of arsenicals with change of constitution might be ascribed to difference in the ease of reduction of the arsinic to the arsinous acid, difference in the ease of condensation of the arsinous acid with thiol complexes, and difference in the ease of hydrolysis of such complexes. In fact, the striking results obtained for the series of similarly constituted amides shown in the first table (p. 671), where other factors affecting trypanocidal activity might be expected to be reasonably constant, support such a view. As this table shows, introduction of methyl into the amide group causes a diminution in activity, and this diminution is intensified by increase in the size of the alkyl group or by the introduction of more than one. Introduction of weakly positive alkyl groups will cause a drift of electrons towards the arsenic atom relative to the effect of the unsubstituted amide group, and this will be reflected (*a*) in a diminished ease of reduction of the arsinic acid, since the oxygen atom will be more firmly held, and (*b*) in a decreased tendency to co-ordinate with hydroxyl (Gough and King, *loc. cit.*, p. 2429), since the arsenic atom has become more negative, with resultant increased difficulty of hydrolysis. Both properties would lead to diminished trypanocidal activity, as is actually found.

We are deeply indebted to Miss F. M. Durham and Miss W. I. Strangeways for the whole of the biological findings recorded in this paper.

## EXPERIMENTAL.

*Derivatives of Naphthylaminesulphonic Acids.*

1-Amino-3 : 6-disulpho-8-naphthol-7-azobenzene-4'-arsinic Acid (compare D.R.-P. 212018).—4-Aminophenylarsinic acid (8.7 g.) in 80 c.c. of 2*N*-hydrochloric acid was treated at 0° with 3.0 g. of sodium nitrite in 30 c.c. of water and then added slowly to 13.6 g. of H-acid in 150 c.c. of 3*N*-sodium hydroxide solution. After being kept at 0° for 45 minutes, the solution was made just acid to Congo-paper by addition of concentrated hydrochloric acid. After 12 hours the deep-coloured solid was collected on porous plate and purified by solution in the minimum volume of boiling water and addition of one-fifth of that volume of concentrated hydrochloric acid. This operation was repeated three times and gave finally 2.8 g. of homogeneous brick-red needles (Found : loss at 105°, 8.0.  $C_{16}H_{14}O_{10}N_3S_2As \cdot 2\frac{1}{2}H_2O$  requires  $H_2O$ , 7.6%. Found in dried acid : As, 13.3.  $C_{16}H_{14}O_{10}N_3S_2As$  requires As, 13.7%). When pure, this acid requires over 12 parts of boiling water for solution, but will not crystallise therefrom on cooling. It is, however, almost completely precipitated by addition to the solution of one-fifth of its volume of 32% hydrochloric acid.

1-Benzamido-3 : 6-disulphonaphthalene-4'-arsinous Acid.—Freund's acid (9 g.), dissolved in *N*-sodium hydroxide (90 c.c.), was treated in presence of benzene (10 c.c.) with three successive portions of benzoyl chloride *p*-dichloroarsine (each 5.7 g.) in benzene (13 c.c.). *N*-Sodium hydroxide (30 c.c.) was added concurrently with vigorous shaking. After removal of the benzene, the liquid was diluted with an equal volume of water and acidified to Congo-paper and the precipitated benz-*p*-arsinous acid (9.8 g.) was removed. The liquid was then concentrated to 100 c.c. and a further small amount of benz-*p*-arsinous acid removed (0.1 g.). After addition of concentrated hydrochloric acid (7 c.c.) and keeping for 2 hours at -5°, clusters of fine needles separated (11.2 g.). These were recrystallised by solution in warm water (24 c.c.) and addition of concentrated hydrochloric acid (4 c.c.) (Found : loss at 140°, 7.5.  $C_{17}H_{13}O_9NS_2AsNa \cdot H_2O$  requires  $H_2O$ , 6.5% for conversion into oxide. Found in anhydrous oxide : As, 13.1; Na, 4.2.  $C_{17}H_{11}O_8NS_2AsNa$  requires As, 13.5; Na, 4.1%).

1-Benzamido-3 : 6-disulphonaphthalene-4'-arsinic Acid.—The crude arsinous acid (7 g.), dissolved in water (35 c.c.), was treated with the calculated amount of 30% hydrogen peroxide in water (14 c.c.). The solution, which became warm and slightly brown on oxidation, was neutralised to litmus-paper, warmed at 50° for  $\frac{1}{2}$  hour, and evaporated under reduced pressure to 20 c.c., and the reaction

adjusted to neutrality to Congo-paper. The solution was then heated to  $100^{\circ}$  and, after addition of concentrated hydrochloric acid (3 c.c.), allowed to cool. The resultant paste of fine rectangular needles (5.7 g.) was removed and recrystallised by solution in the minimum volume of boiling water, followed by the addition of concentrated hydrochloric acid (5.5 c.c.) (Found: loss at  $140^{\circ}$ , 12.6; As, 12.7; Na, 3.8.  $C_{17}H_{13}O_{10}NS_2AsNa \cdot 3H_2O$  requires  $H_2O$ , 11.9 for conversion into the dioxide; As, 12.3; Na, 3.8%).

*1-Benzamido-3:6-disulpho-8-naphthol-4'-arsinous Acid*.—H-Acid (6.8 g. monosodium salt +  $1.5H_2O$ ), dissolved in *N*-sodium hydroxide (20 c.c.), was treated with 0.5 c.c. portions of a solution of benzoyl chloride *p*-dichloroarsine (11.4 g.) in benzene (20 c.c.) with vigorous shaking. *N*-Sodium hydroxide (40 c.c.) was added concurrently at such a rate as to maintain a slightly alkaline reaction. The liquid was made acid to Congo-paper, and the precipitated benzarsinous acid (3.3 g.) removed. The filtrate was concentrated (to 10.4 c.c., to 76 c.c., and until salt began to separate) at  $50^{\circ}$  and the three successive crops were united and boiled with water (25 c.c.) containing norit. The undissolved portion yielded a further quantity of benzarsinous acid (1.8 g.), and the filtrate, on the addition of concentrated hydrochloric acid, gave the desired *amide* (11.4 g.). This was recrystallised three times from hot water (28, 21, and 16.5 c.c.), concentrated hydrochloric acid (2 c.c.) being added to the clear solution in each operation (Found: loss at  $140^{\circ}$ , 23.8; As, 10.3; Na, 3.8.  $C_{17}H_{13}O_{10}NS_2AsNa \cdot 8H_2O$  requires  $H_2O$ , 23.2 for conversion into the arsenious oxide; As, 10.7; Na, 3.3%).

*1-Benzamido-3:6-disulpho-8-naphthol-4'-arsinic Acid* (II).—A slightly alkaline solution of the foregoing arsinous acid (11.3 g. in 150 c.c.) was treated with the calculated amount of hydrogen peroxide, kept for  $\frac{1}{2}$  hour, and concentrated to 95 c.c. The mass of stout needles which separated was dissolved by warming, and the solution made acid to Congo-paper. On cooling, the desired *arsinic acid* (8.8 g.) separated in fine needles. This, together with a further amount (1.4 g.) obtained from the mother-liquor, was recrystallised from water (18 c.c.) with the addition of concentrated hydrochloric acid (4 c.c.) (Found: loss at  $150^{\circ}$ , 24.8; As, 10.0.  $C_{17}H_{13}O_{11}NS_2AsNa \cdot 10H_2O$  requires  $H_2O$ , 24.6 for conversion into the dioxide; As, 10.2%).

*1-Benzamido-m-benzamido-3:6-disulpho-8-naphthol-4''-arsinous Acid*.—A solution of 1-*m*-aminobenzamido-8-naphthol-3:6-disulphonic acid (7.1 g.; Balaban and King, J., 1927, 90) in *N*-sodium hydroxide (40 c.c.) with benzene (10 c.c.) was treated with 0.5 c.c. portions of a solution of benzoyl chloride *p*-dichloroarsine (9.8 g.) in benzene until it no longer gave a red colour when diazotised and

coupled with  $\beta$ -naphthol. After removal of the benzene, the liquid was made slightly acid to Congo-paper, filtered from benzarsinous acid (1.4 g.), and evaporated (to 35 c.c.) at 50°. After further filtration the liquid was saturated with sodium chloride and kept at 0° for 12 hours, and the crude *arsinous acid* was then removed and recrystallised from water (140 c.c.) by the addition of concentrated hydrochloric acid at 50° until a slight turbidity was produced. The desired product separated in characteristic bunches of needles (Found: loss at 140°, 18.5; As, 9.0.  $C_{24}H_{18}O_{11}N_2S_2AsNa \cdot 8H_2O$  requires  $H_2O$ , 19.9 for conversion into the oxide; As, 9.2%).

*1-Benzamido-m-benzamido-3:6-disulpho-8-naphthol-4''-arsinic Acid (III).*—The foregoing arsinous acid (3.5 g.) was dissolved in half-saturated sodium hydrogen carbonate solution (50 c.c.) and oxidised by the addition of 30% hydrogen peroxide (0.6 g.) in water (10 c.c.). After  $\frac{1}{2}$  hour, the liquid was made slightly acid to Congo-paper and saturated with sodium chloride. The precipitated *arsinic acid* was collected and crystallised by solution in water (18 c.c.) at 50°, followed by the addition of concentrated hydrochloric acid (10 c.c.). On keeping, light pink needles of the required acid separated. These were again recrystallised by the use of water (15 c.c.) and hydrochloric acid (8 c.c.) (Found: loss at 140°, 29.1; As, 7.5.  $C_{24}H_{18}O_{12}N_2S_2AsNa \cdot 14H_2O$  requires  $H_2O$ , 28.7 for conversion into the oxide; As, 8.0%).

#### *Derivatives of p- and m-Benzarsinic Acids.*

*Benzamide-p-arsenious Oxide.*—Benzoyl chloride *p*-dichloroarsine (15 g.), dissolved in benzene (20 c.c.), was added slowly to 2*N*-aqueous ammonia (200 c.c.) and benzene (10 c.c.) with vigorous shaking. The precipitate, which began to separate after the first few additions, was collected (11 g.). Acidification of the filtrate gave benzarsinous acid (1.1 g.). For purification the crude product was reprecipitated from 2*N*-sodium hydroxide. This *arsenious oxide*, like all the benzalkylamidoarsenious oxides examined, is insoluble in dilute ammonia and cold sodium hydrogen carbonate solution and does not show any visible crystalline structure (Found: N, 6.4; As, 35.7.  $C_7H_6O_2NAs$  requires N, 6.6; As, 35.6%).

*Di(carboxymethyl) Benzamide-p-thioarsinite (XIII).*—A suspension of the above arsenious oxide (1 g.) in boiling water (19 c.c.) was treated with  $\alpha$ -thiolacetic acid (1.1 g.). The solid rapidly passed into solution and on cooling, fine needles (1.7 g.) of *di(carboxymethyl) benzamidethioarsinite*, m. p. 168–169°, separated. It was recrystallised from boiling water (25 c.c.) containing a small amount of thiolacetic acid (Found: As, 20.1.  $C_{11}H_{12}O_5NS_2As$  requires As, 19.9%). When titrated with iodine in the presence of starch, one

molecule of this substance reacts rapidly with four atoms of iodine in agreement with the formation of disulphidoacetic acid and benzamide-*p*-arsinic acid. When a slightly alkaline solution of the thioarsinite (0.41 g.) in sodium hydrogen carbonate solution was treated with half the quantity of hydrogen peroxide (0.13 g.) requisite for complete oxidation, the original material (0.21 g.) and benzamide-*p*-arsinic acid (0.08 g.) were readily isolated.

The parent thioarsinite is readily hydrolysed, for a solution in aqueous sodium hydrogen carbonate gives an intense nitroprusside reaction and an aqueous solution of the free acid gives a transient blue colour with ferric chloride. These reactions are not due to traces of  $\alpha$ -thiolacetic acid contaminating the crystalline material, since they are given by odourless samples of the thioarsinites which have been exposed to the air for several months.

*Benzamide-p-arsinic Acid* (IV).—The corresponding arsenious oxide (11 g.) was suspended in water (70 c.c.) containing hydrogen peroxide (5.7 g. of 30% "perhydrol") and heated on the water-bath until solution was complete. On cooling, large plates of *benzamide-p-arsinic acid* (9.1 g.) separated, which were recrystallised from water (58 c.c.). The arsinic acid (7.1 g.) thus obtained is unmelted at 300° and forms crystalline barium and calcium salts (Found: N, 5.5; As, 30.4.  $C_7H_8O_4NAs$  requires N, 5.7; As, 30.6%).

*Benzomethylamide-p-arsinous acid* was prepared similarly by means of aqueous methylamine (Found: As, 30.6.  $C_8H_{10}O_3NAs$  requires As, 30.3%). The corresponding *arsinic acid* crystallised from water in stout needles, unmelted at 300° (Found: N, 5.7.  $C_8H_{10}O_4NAs$  requires N, 5.4%).

*Benzodimethylamide-p-dichloroarsine*.—Benzoyl chloride *p*-dichloroarsine was allowed to react with aqueous dimethylamine in the usual way. After removal of benzene, addition of concentrated hydrochloric acid gave a copious precipitate of small rectangular plates of *benzodimethylamide-p-dichloroarsine*, m. p. 192° (Found: As, 25.4.  $C_9H_{10}ONCl_2As$  requires As, 25.5%). On oxidation in alkaline solution it gave *benzodimethylamide-p-arsinic acid*, m. p. 216–218°, which crystallised from water in small plates (Found: N, 5.0.  $C_9H_{12}O_4NAs$  requires N, 5.1%).

*Benzethylamide-p-arsinous acid* was obtained when benzoyl chloride *p*-dichloroarsine in benzene was allowed to react at 0° with anhydrous ethylamine in benzene, and the mixture treated with acidified water (Found: As, 29.3.  $C_9H_{12}O_3NAs$  requires As, 29.2%). On oxidation it gave star-shaped leaflets of *benzethylamide-p-arsinic acid*, unmelted at 300° (Found: N, 5.3.  $C_9H_{12}O_4NAs$  requires N, 5.1%).

*Benzodiethylamide-p-dichloroarsine* was prepared by digesting

benzoyl chloride *p*-dichloroarsine and diethylamine in boiling benzene, the gum remaining on evaporation being dissolved in caustic alkali and extracted with ether to remove diethylamine. On addition of excess of concentrated hydrochloric acid to the residue *benzodiethylamide-p-dichloroarsine*, m. p. 185—186°, was obtained as a crystalline precipitate (Found: Cl, 21.8; As, 23.2.  $C_{11}H_{14}ONCl_2As$  requires Cl, 22.0; As, 23.3%). On oxidation it gave *benzodiethylamide-p-arsinic acid*, stout prisms, m. p. 193—195°, from water (Found: N, 4.9.  $C_{11}H_{16}O_4NAs$  requires N, 4.7%).

*Benzo-n-propylamide-p-arsenious oxide* was prepared similarly to the monoethyl derivative (Found: As, 29.6; N, 5.6.  $C_{10}H_{12}O_2NAs$  requires As, 29.6; N, 5.5%). On oxidation it gave clusters of needles of *benzo-n-propylamide-p-arsinic acid*, unmelted at 300° (Found: N, 4.8.  $C_{10}H_{14}O_4NAs$  requires N, 4.9%).

*Benzisoamylamide-p-arsenious oxide* was prepared similarly (Found: As, 26.5.  $C_{12}H_{16}O_2NAs$  requires As, 26.7%). On oxidation it gave crystalline *benzisoamylamide-p-arsinic acid*, almost insoluble in boiling water but, unlike the lower homologues, easily soluble in ethyl acetate and in ethyl and methyl alcohols (Found: N, 4.7.  $C_{12}H_{18}O_4NAs$  requires N, 4.4%).

*Benzopiperidide-p-dichloroarsine* was prepared from the reactants in boiling benzene solution. The residue obtained on removal of the solvents was treated with chloroform in the presence of concentrated hydrochloric acid. The chloroform solution on concentration and addition of light petroleum gave *benzopiperidide-p-dichloroarsine*, needles, m. p. 166—167° (Found: As, 22.4.  $C_{12}H_{14}ONCl_2As$  requires As, 22.5%). It gave *benzopiperidide-p-arsinic acid*, needles, m. p. 230° (Found: As, 23.8.  $C_{12}H_{16}O_4NAs$  requires As, 24.0%).

*Benzo-β-hydroxyethylamide-p-arsenious Oxide*.—Benzoyl chloride *p*-dichloroarsine (7.1 g.), dissolved in benzene (20 c.c.), was allowed to react with a solution of ethanolamine (2.3 g.) in water (20 c.c.) and benzene (5 c.c.) with the concurrent addition of 2*N*-sodium hydroxide (50 c.c.) in a manner similar to that used in the preparation of benzamide-*p*-arsenious oxide. When the reaction was complete the liquid was made slightly acid to litmus, saturated sodium hydrogen carbonate solution (50 c.c.) added, and the solid (6 g.) removed. *Benzo-β-hydroxyethylamide-p-arsenious oxide* is obtained in this way free from benzarsinous acid. It crystallises from a large volume of hot water or better from a mixture of ethyl alcohol and water in clusters of small needles (Found: As, 29.5.  $C_9H_{10}O_3NAs$  requires As, 29.4%). On oxidation it gave *benzo-β-hydroxyethylamide-p-arsinic acid* (VIII), glistening leaflets, m. p. 180° (efferv.) (Found: N, 4.7.  $C_9H_{12}O_5NAs$  requires N, 4.8%).

*Hippuryl Chloride p-Dichloroarsine* (XI).—Treatment of benzoyl-

glycine-*p*-arsenious oxide (Hugounenq and Morel, *J. Pharm. Chim.*, 1913, 7, 383) with a chloroform solution of thionyl chloride did not give the required results. When a method similar to that used by Fischer (*Ber.*, 1905, 38, 605) for the preparation of hippuryl chloride was used, a crude hippuryl chloride *p*-dichloroarsine was readily obtained. The arsenious oxide (1 g.), suspended in freshly distilled acetyl chloride, was shaken with phosphorus pentachloride (2.5 g.) for 1 hour. The amorphous product (2.1 g.) was collected and washed with light petroleum (10 c.c.). Although attempts to purify it failed (Found: Cl, 34.6.  $C_9H_7O_2NCl_3As$  requires Cl, 31.1%), it could be used successfully for the next process.

*Benzoylglycine-ethylamide-p-arsinic Acid* (XII).—Finely powdered hippuryl chloride *p*-dichloroarsine (5.3 g.) was added to a solution of anhydrous ethylamine (4.2 g.) in dry ether (75 c.c.) cooled in a freezing mixture. After 2 hours, the solid was collected, ground with water (50 c.c.), and washed with sodium hydrogen carbonate solution. The product was suspended in hot water and treated with 30% hydrogen peroxide, and the resultant solution evaporated at 50° to 10 c.c. On cooling, elongated leaflets, which formed clusters, separated. These were recrystallised from boiling water (34 c.c.) (yield, 6.1 g.). *Benzoylglycine-ethylamide-p-arsinic acid* thus obtained melts at 270° (decomp.) (Found: N, 8.6.  $C_{11}H_{15}O_5N_2As$  requires N, 8.5%).

*Benzoylglycine-n-propylamide-p-arsenious oxide* was prepared by the interaction of *n*-propylamine (0.4 g.) and hippuryl chloride *p*-dichloroarsine (0.3 g.) in ether (30 c.c.). The product was amorphous and very similar to its lower homologue (Found: N, 9.1.  $C_{12}H_{15}O_3N_2As$  requires N, 9.0%).

*β-Diethylaminoethyl Benzoate-p-arsinic Acid*.—A solution of β-diethylaminoethanol (11.1 g.) and benzoyl chloride *p*-dichloroarsine (7.1 g.) in benzene (50 c.c.) was cautiously prepared and refluxed for 1½ hours. The suspension of waxy solid was shaken with water (50 c.c.), and the benzene removed under reduced pressure. After neutralisation of the residue with sodium hydrogen carbonate solution, the thick oil was dissolved by addition of ether (150 c.c.). The ethereal extract was dried but, after removal of the ether, all attempts to crystallise the crude arsinous acid, either as such or as the dichloroarsine hydrochloride, failed. In this behaviour it resembles its stovaine analogue (Fourneau and Ochslin, *Bull. Soc. chim.*, 1912, 11, 912). The oil (4.7 g.) was therefore oxidised directly to the arsinic acid by means of hydrogen peroxide in aqueous suspension. The resultant solution was evaporated to dryness, and the residue extracted with boiling alcohol (20 c.c.); cautious addition of dry ether gave fine needles of β-diethylamino-

*ethyl benzoate-p-arsinic acid*, m. p.  $186^{\circ}$  (decomp.) (Found : N, 3.7.  $C_{13}H_{20}O_5NaAs$  requires N, 3.8%).

*Benzoyl Chloride m-Dichloroarsine*.—*m*-Benzarsinous acid was prepared from *m*-aminobenzoic acid (50 g.) by the Bart reaction, the intermediate arsinic acid being reduced without isolation in the solid state, by sulphur dioxide in the presence of hydrochloric acid; the yield varied between 35 g. and 52 g. In preparing the trichloride, it was found that chilling the light petroleum extract (250–300 c.c.) of the distillation residue of the action of thionyl chloride on the arsinous acid in chloroform gave fluffy bunches of needles of *benzoyl chloride m-dichloroarsine* (27 g.), m. p.  $54$ – $55^{\circ}$  (Found : Cl, 37.6.  $C_7H_4OCl_2As$  requires Cl, 37.3%).

*m-Benzarsinous Acid*.—The foregoing chloride (5 g.) was dissolved by warming in 2*N*-sodium hydroxide (20 c.c.), and the solution made slightly acid to Congo-paper with hydrochloric acid. (Owing to the ease of formation of the dichloroarsine, excess of hydrochloric acid must be avoided.) A white mass of microscopic crystals of *m-benzarsinous acid* (4.2 g.) separated (Found : As, 32.3.  $C_7H_7O_4As$  requires As, 32.6%).

*Benzoic Acid m-Dichloroarsine*.—*m*-Benzarsinous acid (1 g.) was dissolved in a boiling mixture of water (12 c.c.), ethyl alcohol (9 c.c.), and concentrated hydrochloric acid (7 c.c.), and a further quantity (4 c.c.) of hydrochloric acid cautiously added. An oil tended to separate on cooling, but was prevented by addition of more alcohol or by seeding with crystals of an externally crystallised sample. The resultant mass of white prisms was removed and washed with concentrated hydrochloric acid (Found : Cl, 26.6.  $C_7H_5O_2Cl_2As$  requires Cl, 26.6%). This substance is more readily hydrolysed than many other dichloroarsines.

*Benzamide-m-arsenious Oxide*.—This substance (12 g.) was prepared from the corresponding acid chloride and ammonia by the method employed for the *p*-isomeride and obtained as a micro-crystalline powder (Found : As, 35.4.  $C_7H_6O_2NaAs$  requires As, 35.6%).

*Benzamide-m-dichloroarsine*.—The foregoing arsenious oxide (1 g.) was dissolved in a hot mixture of 3*N*-hydrochloric acid (5.5 c.c.) and ethyl alcohol (5.5 c.c.), and concentrated hydrochloric acid (8 c.c.) slowly added at the boiling point. On cooling, large prisms of *benzamide-m-dichloroarsine*, m. p.  $76$ – $80^{\circ}$ , separated (Found : Cl, 26.7.  $C_7H_6ONCl_2As$  requires Cl, 26.7%). On oxidation in alkaline solution it gave *benzamide-m-arsinic acid*, rhombic plates, unmelted at  $300^{\circ}$  (Found : N, 5.6.  $C_7H_5O_4NaAs$  requires N, 5.7%).

*Benzomethylamide-m-arsenious Acid*.—This substance (5.2 g.) was obtained in the same way as its *p*-isomeride (Found : As, 30.6.

$C_8H_{10}O_3NAS$  requires As, 30.9%): on oxidation in alkaline solution it gave fine rods of *benzomethylamide-m-arsinic acid*, m. p.  $238^\circ$  (efferv.) (Found: N, 5.5.  $C_8H_{10}O_4NAS$  requires N, 5.4%).

*Benzisoamylamide-m-arsinic Acid*.—When the corresponding arsinous acid was prepared by the same method as that used for the *p*-isomeride, a thick brown gum was obtained which remained partly solid after being kept for several days at  $0^\circ$ . Accordingly this impure product was oxidised directly to the *arsinic acid* by treatment with 30% hydrogen peroxide (3 g.) and 2*N*-sodium hydroxide solution (30 c.c.). The *arsinic acid* obtained resembled the *p*-isomeride in its solubilities in various solvents. It was finally purified by fourfold precipitation from its solution in saturated sodium hydrogen carbonate solution (yield, 6 g. from 7.1 g. of benzoyl chloride *m*-dichloroarsine) (Found: N, 4.5.  $C_{12}H_{18}O_4NAS$  requires N, 4.4%).

*Nuclear-substituted Benzamidearsinic Acids. Derivatives of Salicylic Acid 5-Arsinic Acid.*

*5-Nitrosalicylic Acid*.—The methods for the preparation of this acid have been critically examined by Raiziss and Proskouriakoff (*J. Amer. Chem. Soc.*, 1922, **44**, 784), but neither the method adopted by these authors nor those recorded in the literature gave satisfactory results. After many trials the following conditions were found to give the 5-nitro-acid consistently in 42% yield. Salicylic acid (100 g.) was slowly added (compare Meldola, Foster, and Brightman, *J.*, 1917, **111**, 536) to a solution of nitric acid (100 c.c., *d* 1.42) in water (800 c.c.) heated on the water-bath. The contents first became dark, but on further heating (3.5 hours) a light yellow powder of 5-nitrosalicylic acid remained at the bottom of the flask. On cooling, a mass of fine needles also separated consisting chiefly of the 3-nitro-isomeride. The total solid was collected and boiled with water (400 c.c.), the liquid filtered hot, and the residue washed with boiling water (100 c.c.). The insoluble portion consisted of the 5-nitro-acid, m. p.  $228^\circ$ . 5-Aminosalicylic acid was prepared from the nitro-acid by the method of Weil, Traun, and Marcel (*Ber.*, 1922, **55**, 2665).

*Salicylic Acid 5-Arsinic Acid (XVI)*.—5-Aminosalicylic acid hydrochloride (50 g.) was dissolved in water (400 c.c.) and concentrated hydrochloric acid (55 c.c.) and diazotised by the addition of 10% sodium nitrite solution (210 c.c.) in the presence of ice chippings (500 g.). A solution of arsenious oxide (30 g.) in 4% aqueous sodium hydroxide (400 c.c.) was then slowly added to the resultant suspension of diazo-oxide, and after the subsequent addition of freshly precipitated copper (prepared from 50 g. of copper sulphate)

the mixture was slowly made faintly alkaline to litmus paper. After 12 hours and readjustment of the reaction from time to time, the liquid was treated with 40% sodium hydroxide solution to decompose complex copper salts and filtered. The filtrate was made acid to Congo-paper and evaporated under reduced pressure at 50° to 400 c.c. A mass of cream-coloured needles of salicylic acid 5-arsinic acid (24 g.) separated on cooling and a further amount (8 g.) was obtained by saturating the mother-liquor with sodium chloride and keeping it at 0°. The total product was dissolved in 2*N*-ammonia, treated with norit, and precipitated at 90° with hydrochloric acid and finally recrystallised from boiling 50% aqueous methyl alcohol. The acid showed all the properties assigned to it by Kahn and Benda (*Ber.*, 1908, **41**, 3863), who prepared it from *o*-toluidine (see also O. and R. Adler, *Ber.*, 1908, **41**, 933; Karrer, *ibid.*, 1915, **48**, 1061). So prepared, it crystallises with one molecule of water of crystallisation (Found in air-dried material: loss at 100°, 6.9; As, 26.7. Calc. for  $C_7H_7O_6As \cdot H_2O$ :  $H_2O$ , 6.4; As, 26.8%).

*Salicylic Acid 5-Arsinous Acid* (XX).—A solution of the above arsinic acid (2 g.) in water (10 c.c.) and concentrated hydrochloric acid (1 c.c.) was saturated with sulphur dioxide in presence of a trace of potassium iodide. After 24 hours, a cream-coloured powder of *salicylic acid 5-arsinous acid* (1.6 g.) separated (Found: As, 30.2.  $C_7H_7O_5As$  requires As, 30.5%).

*Salicylic Acid 5-Dichloroarsine* (XIX).—Salicylic acid 5-arsinic acid (7 g.) was dissolved in a boiling mixture of ethyl alcohol (7 c.c.), water (15 c.c.), and concentrated hydrochloric acid (40 c.c.), a small crystal of potassium iodide added, and the solution saturated with sulphur dioxide. The oil which separated at first rapidly solidified to a mass of compact prisms. After 4 hours, it was collected (6.8 g.) and recrystallised by dissolution in the minimum volume of boiling 50% aqueous methyl alcohol, followed by the addition of concentrated hydrochloric acid until a turbidity was produced (Found: As, 26.4.  $C_7H_5O_5Cl_2As$  requires As, 26.5%).

*Methyl Salicylate-5-arsinic Acid* (XVII).—The esterification of salicylic acid 5-arsinic acid by the Fischer-Speier method proceeds very slowly in 1.5% methyl-alcoholic sulphuric acid; if a 10% methyl-alcoholic solution of salicylic acid 5-arsinic acid containing 10% sulphuric acid is used, the methyl ester may be obtained in 70% yield after 3 hours' refluxing. The ester is most conveniently isolated by removing nearly all the methyl alcohol under reduced pressure at room temperature, followed by addition of water (equal in volume to the residue). *Methyl salicylate-5-arsinic acid*, m. p. 208° (efferv.), crystallises from 4 parts of boiling 50% methyl alcohol in small prisms (Found: MeO, 9.4; As, 27.3.  $C_8H_9O_6As$  requires

MeO, 11.2; As, 27.2%). If the solution is refluxed for a longer period or if more sulphuric acid is used, some of the arsenic acid decomposes with formation of arsenious oxide. Saturation of a boiling 10% methyl-alcoholic solution of the arsenic acid (7 g.) with dry hydrogen chloride, followed by removal of most of the methyl alcohol, causes crystals of methyl salicylate-5-dichloroarsine (2 g.) to separate. Addition of water (20 c.c.) to the filtrate from this product gives methyl salicylate-5-arsinic acid (5 g.).

*Methyl Salicylate-5-dichloroarsine* (XVIII).—(i) *From salicylic acid 5-arsinous acid*. The arsenious acid (10 g.), dissolved in anhydrous methyl alcohol (15 c.c.), was heated with dry hydrogen chloride at 10° until saturated. After 4 hours, methyl salicylate 5-dichloroarsine (10 g.) had separated and was crystallised from boiling benzene. (ii) *From salicylic acid 5-dichloroarsine*. Salicylic acid 5-dichloroarsine (5.1 g.) was dissolved in dry methyl alcohol (6 c.c.) and saturated with hydrogen chloride at 10°. The mass of crystals was removed after 2 hours and a further amount was obtained by adding concentrated hydrochloric acid (5 c.c.) to the filtrate. The total yield was 4.6 g. When crystallised from boiling benzene, *methyl salicylate-5-dichloroarsine*, m. p. 168°, was obtained in small prisms. It proved to be identical both with that obtained from salicylic acid 5-arsinous acid and with that obtained in the treatment of salicylic acid 5-arsinic acid with methyl-alcoholic hydrogen chloride (Found: MeO, 8.2; Cl, 23.8; As, 25.7.  $C_8H_7O_3Cl_2As$  requires MeO, 10.5; Cl, 23.9; As, 25.3%). This substance is soluble in sodium hydroxide, but in sodium hydrogen carbonate solution a white solid (methyl salicylate-5-arsinous acid) remains after the effervescence has ceased. When it is treated with ammonia at room temperature, extensive decomposition takes place.

Methyl salicylate-5-arsinic acid may be conveniently prepared from this dichloroarsine; it is essential, however, to keep the reaction mixture at 0° during the manipulations, otherwise most of the product consists of the carboxylic acid. The dichloroarsine (5.1 g.) was ground under saturated sodium hydrogen carbonate solution (10 c.c.), removed, suspended in a further quantity of this reagent (20 c.c.), and slowly treated with 30% hydrogen peroxide (2.2 g.) in water (10 c.c.). After being kept at 0° for 1 hour, the liquid was made acid, and the precipitated methyl salicylate-5-arsinic acid collected (3.1 g.).

*Salicylamide-5-arsinic Acid* (XIV).—A suspension of the finely ground methyl ester (6 g.) in methyl alcohol (15 c.c.) and aqueous ammonia (20 c.c., *d* 0.88) was heated in a sealed tube at 100° for 5 hours. The free ammonia and part of the solvents were removed under reduced pressure at 50° and the residual solution was made

faintly acid to Congo-paper. Large rhombs separated slowly on keeping. They were purified by dissolving them in the smallest amount of 2*N*-ammonia, adjusting the reaction to faint acidity to litmus, and treating the solution with charcoal. When it was made faintly acid to Congo-paper, *salicylamide-5-arsinic acid*, unmelted at 300°, separated (yield, 3.9 g.) (Found: N, 5.6.  $C_7H_8O_5NaS$  requires N, 5.4%). This amide is much more soluble in dilute hydrochloric acid than in water.

*m-Xylyl-4-arsinic Acid*.—This acid has been previously prepared by Michaelis from tri-*m*-xylylarsine (*Annalen*, 1902, 320, 333). After numerous trials the following conditions were found satisfactory for its preparation from *m*-4-xylidine. A solution of *m*-xylidine (40.5 g.) in concentrated hydrochloric acid (60 c.c.) and water (150 c.c.) was diazotised with 10% sodium nitrite (210 c.c.) in the presence of ice-chippings (450 g.). This solution was run into another consisting of arsenious oxide (45 g.) and 50% aqueous sodium hydroxide (160 c.c.) in water (750 c.c.) which had just previously been heated to 90°, and 20% aqueous copper sulphate (20 c.c.) added. The mixing was complete in 15 minutes and after an hour the liquid was made weakly acid to litmus paper and filtered from tar. Evaporation of the filtrate (to 700 c.c.), followed by acidification to Congo-paper, gave cream-coloured *m*-xylyl-4-arsinic acid (42.6 g.) which was sufficiently pure for oxidation. One crystallisation from 20% aqueous alcohol gave fine elongated leaflets, m. p. 210—212° (Michaelis gives m. p. 210°).

*isoPhthalic Acid 4-Arsinic Acid* (XXI).—This acid was also obtained by Michaelis (*loc. cit.*) by oxidation of the corresponding xylylarsinic acid with permanganate. The large volumes used by Michaelis can be avoided by the following process (compare Maschmann, *Ber.*, 1924, 57, 1763). A vigorously stirred solution of *m*-xylyl-4-arsinic acid (23 g.) in 0.2*N*-sodium hydroxide (500 c.c.; 1 mol.) was treated with small amounts of finely powdered permanganate (35 g.) at 70—75° over a period of several hours. The solution was finally boiled and any excess of permanganate destroyed by alcohol. After filtration the press-cake was re-extracted twice by suspending it in 500 c.c. of 0.2*N*-sodium hydroxide and bringing the mixture to the boiling point with stirring. (The acid is retained tenaciously by the manganese oxides.) The combined filtrates were acidified to Congo-paper and concentrated. The total yield of acid was 73.4% of the theoretical. The purity of the successive crops obtained can be controlled by titration under standard conditions in comparison with a sample of the pure acid.

*Action of Thionyl Chloride on isoPhthalic Acid 4-Arsinic Acid*.—The acid (5.8 g.) was gently boiled for 3½ hours with excess (47 g.)

of freshly distilled thionyl chloride. The residue obtained on removal of the solvent was dissolved in dry toluene and added portionwise to 140 c.c. of chilled 2*N*-ammonia in a bottle and vigorously shaken. The toluene was removed under reduced pressure and perhydrol (2.3 g.) was added to the clear aqueous solution. On concentration to a small volume and acidification, *isophthalamic acid 6-arsinic acid* (XV) separated (yield, 4.45 g.). For analysis it was recrystallised from 30 volumes of boiling water, separating in well-formed glassy prisms (Found: loss at 100°, 5.9, 6.2.  $C_8H_8O_6NAs.H_2O$  requires  $H_2O$ , 5.9%. Found in anhydrous acid: N, 4.9; As, 26.1.  $C_8H_8O_6NAs$  requires N, 4.85; As, 25.9%). This acid also crystallises in short needles. Both forms are unmelted at 300°.

*Action of Phosphorus Pentachloride on isoPhthalic Acid 4-Arsinic Acid.*—(a) *With 5.5 molecular proportions of phosphorus pentachloride.* Finely powdered *isophthalic acid 4-arsinic acid* (5.8 g.) was mixed with 22.9 g. of phosphorus pentachloride and after the vigorous reaction had subsided, during which chlorine was evolved, the product was heated in an oil-bath at 110° (external temperature) for 3 hours. The phosphorus oxychloride was distilled off under reduced pressure and the residue, dissolved in sodium-dried toluene, was added portionwise to 160 c.c. of chilled 2*N*-ammonia with vigorous shaking. The toluene was separated, and the aqueous layer extracted once more with benzene. The combined extracts, evaporated to dryness, left 0.05 g. of 3:4-dichlorobenzamide, m. p. 163° (see below, section b). The aqueous layer was evaporated at 50° to a small volume and deposited 0.8 g. of crude 4-chloro-*isophthalamide* (XXII), m. p. 223—226°. This amide is soluble in 17 parts of boiling water and crystallises in needles, elongated leaflets, and in square plates, m. p. 232—233° (Found: N, 14.2.  $C_8H_7O_2N_2Cl$  requires N, 14.1%). On hydrolysis with boiling *N*-potassium hydroxide solution it gave 4-chloro-*isophthalic acid*. This acid is very sparingly soluble in boiling water, requiring 130 parts for solution. It crystallises therefrom in fine needles, m. p. 290—292° (Found: equiv., 104. Calc., 100.3). In its properties it accords best with those given by Ullmann and Uzbachian (*Ber.*, 1903, 36, 1799).

The mother-liquor of the chloro-*isophthalamide* was made distinctly alkaline by the addition of sodium hydroxide and perhydrol (2.3 g.) was added. On acidification the half-amide of *isophthalic acid 4-arsinic acid* (3.25 g.) separated, identical with that obtained by the use of thionyl chloride.

(b) *With 6.5 molecular proportions of phosphorus pentachloride.* The acid (10.75 g.) was mixed with powdered phosphorus penta-

chloride (50 g.) in a small distillation flask, and the chlorine and phosphorus oxychloride produced were allowed to distil off. The flask was then immersed in an oil-bath kept at 150–160° for 5 hours. Most of the phosphorus oxychloride had distilled off at the end of the first hour's heating. The product was worked up similarly to the foregoing. The benzene-toluene extract on evaporation deposited 0.25 g. of crude 3 : 4-dichlorobenzamide, m. p. 140–156°, which on recrystallisation from 15 c.c. of water separated in large leaflets, m. p. 166–168°. Of this, 0.05 g. was hydrolysed by boiling *N*-potassium hydroxide (1.25 c.c.) and on acidification gave 3 : 4-dichlorobenzoic acid as a felt of microscopic crystals. It was recrystallised from a large volume of boiling water and separated in microscopic pointed leaflets, m. p. 211–212°. The amount available was insufficient for complete analysis, but 0.0372 g. on titration required 2.05 c.c. of *N*/10-alkali, whereas the calculated figure is 1.95 c.c.

The aqueous layer, freed from ammonia and toluene by distillation at 40°, gave 4-chloroisophthalamide (6.0 g.), m. p. 223–227°; the mother-liquor on concentration gave a further 0.65 g. of the same substance. No other product could be found.

*Methyl isoPhthalate-4-arsinous Acid.*—*iso*Phthalic acid 4-arsinic acid (20 g.) was suspended in 150 c.c. of dry purified methyl alcohol (wood spirit), and a current of dry hydrogen chloride passed till saturation was complete at 0°. The clear dark brown solution was then heated for 5 hours under reflux, the passage of dry hydrogen chloride being continued. During this process a dark lower layer containing methyl *isophthalate-4-dichloroarsine* separated. The major portion of the supernatant layer was removed by heating under reduced pressure, and the residue poured into 250 c.c. of saturated sodium hydrogen carbonate solution cooled below 0°. The insoluble grey rubbery mass gradually disintegrated and solidified. It consisted of almost pure *methyl isophthalate-4-arsinous acid* (yield, 19 g.) (Found : MeO, 15.1; As, 24.6.  $C_{10}H_{11}O_6As$  requires MeO, 20.5; As, 24.8%). Treatment of this ester with aqueous methyl-alcoholic ammonia at 100° led to extensive decomposition.

*Methyl isoPhthalate-4-arsinic Acid.*—The arsinous acid (19 g.) was suspended in water (50 c.c.) at 0° and treated with sodium hydrogen carbonate (2.2 mols.) and 30% hydrogen peroxide (1.1 mols.). Rapid effervescence occurred and when solution was complete acidification gave microscopic square plates of *methyl isophthalate-4-arsinic acid* (20.5 g.) (Found : As, 23.6.  $C_{10}H_{11}O_7As$  requires As, 23.6%). This acid is fairly readily soluble in hot water and crystallises therefrom in long needles, which effervesce at 196–197° and then rapidly resolidify. The plate form of crystal

effervesces at  $185^{\circ}$  and then rapidly resolidifies (anhydride formation).

*Methyl isoPhthalate 4-Arsinetetrachloride.*—The dicarboxy-acid (5 g.) was suspended in 35 c.c. of synthetic methyl alcohol at  $-5^{\circ}$ , and the liquid saturated with dry hydrogen chloride. The acid dissolved after 1 hour and after a few more hours pale yellow needles began to separate. When separation was complete the solid was rapidly collected, washed with sodium-dried ether, and quickly dried in a vacuum. The *arsinetetrachloride* (2.5 g.) is highly hygroscopic and has m. p.  $110-115^{\circ}$  (efferv.) (Found: Cl, 31.7.  $C_{10}H_8O_4Cl_4As$  requires Cl, 34.6%). The low chlorine content indicates slight hydrolysis to the oxychloride, since the product was free from trivalent arsenic compounds. When added to saturated sodium hydrogen carbonate solution at  $0^{\circ}$ , it rapidly dissolved and on acidification gave methyl *isophthalate-4-arsinic acid*, identical with the product described above. Characteristic is its separation in microscopic plates on acidification but in needles when recrystallised from water.

*Action of Ammonia on Methyl isoPhthalate-4-arsinic Acid.*—Methyl *isophthalate-4-arsinic acid* (28.4 g. of the plate form) was added to 284 c.c. of ammonia ( $d$  0.88) previously cooled to  $-5^{\circ}$ . The mixture was kept below  $0^{\circ}$  for 14 days, during which the gelatinous ammonium salt which originally separated had disappeared with formation of a loose powder. The ammonia was removed as far as possible at room temperature and then, with some concentration of the solution, at  $45^{\circ}$ . On strong acidification to Congo-paper, a large crop of crystals separated, and on concentration of the mother-liquor at  $50^{\circ}$  further crops were obtained, making 25.2 g. in all. This material was subjected to fractional crystallisation, the more sparingly soluble fractions (16.0 g.) consisting of *isophthalamic acid 6-arsinic acid* identical with that obtained previously. The more soluble fractions were further carefully fractionated, and the nitrogen content and titration equivalents determined. They consisted mainly of the above half-amide mixed with varying proportions of esters. There was no evidence for the presence of a diamide in any fraction.

If the original solution is not acidified strongly to Congo-paper, the product contains an *acid ammonium* salt of *isophthalamic acid 6-arsinic acid* which, being readily soluble in water, separates in the later fractions. It crystallises in fine silky needles (Found: N, 8.9.  $C_8H_{11}O_6N_2As$  requires N, 9.1%). The use of methyl-alcoholic ammonia at higher temperatures was no more successful.

*Derivatives of Sulphophenylarsinic Acid.*

*Benzenesulphonyl Chloride p-Dichloroarsine* (XXV).—*p*-Sulphophenylarsinic acid (13.2 g., prepared as described by Hewitt, King, and Murch, J., 1926, 1369) was suspended in carbon tetrachloride (132 c.c.), and phosphorus pentachloride (58 g.; 6 mols.) added. On warming, hydrogen chloride and chlorine were rapidly evolved. After 1.5 hours' refluxing, the substances volatile at 50°/20 mm. were removed and the residue was poured into a mixture (200 c.c.) of equal volumes of concentrated hydrochloric acid and water. The precipitated oil rapidly solidified (13.1 g.) and when dry was crystallised from benzene. *Benzenesulphonyl chloride p-dichloroarsine* separated in stout rhombs (Found: Cl, 33.2.  $C_6H_4O_2Cl_3SAs$  requires Cl, 33.1%).

*Benzenesulphonyl Chloride p-Arsenious Oxide*.—The corresponding dichloroarsine (1 g.) was ground with water and kept for 12 hours. The amorphous product was pure *benzenesulphonyl chloride p-arsenious oxide* (0.8 g.), almost insoluble in water or organic solvents (Found: Cl, 13.5.  $C_6H_4O_3ClSAs$  requires Cl, 13.3%). The aqueous filtrate contained a small quantity of deliquescent *p-sulphophenylarsinous acid*, which may be more readily prepared by boiling either of the sulphonyl chloride compounds with water and evaporating the resultant solution repeatedly to dryness with water.

*Benzenesulphonamide-p-arsenious Oxide* (XXVI).—Benzene-sulphonyl chloride *p-dichloroarsine* (5.8 g.), dissolved in benzene (15 c.c.), was slowly added to 2*N*-aqueous ammonia with vigorous shaking. Towards the end of the reaction a white solid separated (2 g.), and a further precipitate (2.6 g.) was obtained by removing the benzene and evaporating the aqueous solution (to 30 c.c.). The united crops were dissolved in hot sodium hydrogen carbonate solution and precipitated with acid. *Benzenesulphonamide-p-arsenious oxide* is an amorphous substance which is much more soluble in water than the corresponding benzamide compound (Found: As, 28.2.  $C_6H_6O_3NSAs$  requires As, 28.3%). On treatment with hydrochloric acid it is readily converted into *benzenesulphonamide-p-dichloroarsine*. For the preparation of this substance sufficient ethyl alcohol was added to a suspension of the arsenious oxide (1 g.) in water to give a clear solution on boiling, and concentrated hydrochloric acid (15 c.c.) slowly added. On cooling, a mass of fine needles (0.82 g.) separated, m. p. 176–178° (Found: Cl, 23.3; As, 25.0.  $C_6H_6O_2NCl_2SAs$  requires Cl, 23.5; As, 24.8%).

*Benzenesulphonamide-p-arsinic Acid* (XXVII).—A suspension of benzenesulphonamide-*p-arsenious oxide* (8.7 g.) in water (30 c.c.) was mixed with a solution of 30% hydrogen peroxide (4.4 g.) in

water (20 c.c.). The mixture became hot, most of the solid dissolved, and the undissolved portion became crystalline. The reaction was completed by heating until a clear solution was obtained. On allowing the liquid to cool, stout rhombic tablets of *benzenesulphonamide-p-arsinic acid* separated. They were recrystallised from boiling water (60 c.c.) and gave 6.7 g. of pure amide (Found: N, 4.8.  $C_6H_8O_5NSAs$  requires N, 5.0%).

[Received, January 27th, 1930.]

### XC.—*The Heats of Association of Acetic and Heptioic Acids in the Vapour State.*

By (Miss) TEMPE M. FENTON and WILLIAM EDWARD GARNER.

THE work of Ramsay and Young on the vapour pressures and vapour densities of acetic acid (*Sci. Proc. Roy. Dublin Soc.*, 1910, **12**, 374; *J.*, 1886, **49**, 790) showed that this substance was associated in the vapour state, and that the degree of association decreased with increase in temperature. It is possible to calculate an approximate value for the heat of association from their data by means of the equation  $d \log K_c/dT = -Q_v/RT^2$ . We have now repeated this work and our results are in better concordance with one another than are those of the above authors; the values of  $Q_v$  found from the two investigations are 12,420 and 13,790 cal. per g.-mol., respectively.

The primary object of the present investigation was to determine  $Q_v$  for acids with longer chains, with a view to obtain evidence as to the nature of the linkage between the molecules of acids. The heat of vaporisation of acetic acid at 110° is less than one-half of  $Q_v$  (5,170 cal.; Young), which indicates that the forces holding the molecules together are greater than those causing condensation from the vapour to the liquid state. If the attachment is by means of the two carboxyl groups to give double molecules, then  $Q_v$  should approach a practically constant value as the homologous series of monobasic acids is ascended, and it would be expected that this constant value would be reached when the length of chain exceeded five or six carbon atoms. If, on the other hand, the association occurs by linking through the methylene groups, then the heat of association should increase with increasing length of chain.

Accordingly, heptioic acid has been studied, and shown to be about 10% associated at its boiling point. A value for  $Q_v$  has been determined, viz., 7,050 cal. per g.-mol., but on account of the low

degree of association, this is much less accurate than that of acetic acid. Thus the heat of association decreases with increase in chain length, a result which is in accord with the view that linking occurs through the carboxyl groups, and not through the hydrocarbon chains, and that the residual affinity of the carboxyl group decreases with increasing chain length. Acids with shorter chains must, however, be investigated before this conclusion can be substantiated.

#### EXPERIMENTAL.

*Apparatus.*—The modified form of Ramsay and Young's apparatus used in the present series of experiments consists of two Pyrex-glass tubes A and B, about 90 cm. long, standing in a gas-jar C containing mercury (Fig. 1) and bound together by copper wire, a short asbestos pad being inserted to keep them vertical. C is closed by a rubber bung which carries two other tubes, D and E. D is bent twice at right angles and serves to remove the excess mercury introduced during the setting up of the apparatus. E is connected by means of a piece of glass tubing (fitted with a tap) to a water pump.

FIG. 1.

A and B were heated by the vapour from liquid boiling in the flask F, which is connected by a ground-glass joint to the cylindrical glass jacket G. The top of G has a side tube I connecting with a glass spiral open to the air and a tube leading back to the bottom of F. A spiral of nichrome wire is wound round the tube G, which is heated by an electric current. The wire is wound on strips of asbestos so placed as to leave a window in the back and front of the tube. G rests in a glass trough containing mercury, which consists of the top of a wide-mouthed bottle cut off near the top, the mouth being closed by a rubber bung through which A and B pass.

The whole apparatus from I to K is enclosed in an asbestos-lined box, to protect it from draughts, which has glass windows back and front, the front window consisting of a calibrated glass scale. A fine mark was etched near each end of A, and the volume between these two marks determined for each cm. length of tube.

The thermometers used were either standard or had been checked against standards, at or near the temperatures of the vapours used in the tube G.

*Materials.*—Kahlbaum's acetic acid was used, and its purity was determined by titration with *N*/10-sodium hydroxide which had

been standardised against pure crystallised succinic acid. The acid was found to be 99.2% pure, and was then partly (about two-thirds) frozen, and the liquid separated. This process was repeated, and the solidified acid used for the experiment. The weights of acid used were approximately 0.1, 0.07, and 0.08 g. in three series of experiments.

*Preparation of Tubes for Vapour-density Determination.*—The tubes A and B were left for 24 hours full of freshly made chromic acid solution, and then repeatedly rinsed with distilled water and dried by a current of hot air. Dry mercury was poured into them to a depth of 5–6 cm. at a time, and each portion was boiled to expel any air trapped between the mercury and the walls. The two tubes (which had previously been pushed through the two bungs) were inserted in the gas-jar full of mercury and a weighed quantity of acetic acid contained in a small Victor Meyer bottle was introduced into the calibrated tube. The bung was then pushed firmly into the gas-jar C, the excess mercury being run out through the side tube D. The gas-jar was then anchored by copper wire to the sides of the tray in which the apparatus stood and a forked support attached to a heavy retort-stand was pushed under the bung closing the mercury seal. The tube E was connected to the pump and the apparatus was made gas-tight by means of melted gutta-percha at the glass-rubber connexion.

The jacket and flasks were then fitted on, and the electrical heating was adjusted so that the temperature was about 10–20° below the boiling point of the jacketing liquid. The liquid in the flask was then boiled until steady circulation of the vapour occurred. The temperature was measured by means of three standardised thermometers suspended at intervals between the two experimental tubes.

The pressure was obtained from the difference between the levels of the mercury in the two tubes. Since the temperature of the two tubes was the same, the vapour pressure of mercury and the density of the liquid mercury in the tubes were identical. The difference in level, multiplied by the density of mercury, therefore gave the pressure of the vapour of acetic acid.

To read the mercury level, a diffuse light was placed behind the apparatus so that the meniscus showed black against it. The telescope was first adjusted so that the cross-wires touched the top of the meniscus, and then readjusted until the glass scale was in focus, whereupon the scale reading was taken, decimals of a millimetre being determined by means of a vernier on the cathetometer. The volume was calculated from the height of mercury in the experimental tube and allowance was made for the volume of the

Victor Meyer bottle. The volume correction for expansion of the glass tube is negligible for the range of temperatures used.

From these measurements the ratio of the apparent to the real molecular weight was determined by the formula

$$R = \frac{w}{M} \cdot \frac{22,400}{v} \cdot \frac{T}{273} \cdot \frac{760}{p} \cdot \frac{13.6}{\delta},$$

where  $w$  = weight of acid introduced,  $M$  = molecular weight of acid,  $v$  = volume (in c.c.),  $p$  = observed pressure (in mm.),  $T$  = absolute temperature of experiment, and  $\delta$  = density of mercury at  $T^\circ$  Abs.

FIG. 2.

I. *Acetic acid (authors).* II. *Acetic acid (Young).*  
III. *Heptoic acid.*

Assuming that the association of acetic acid is due to the reaction,  $2\text{CH}_3\cdot\text{CO}_2\text{H} \rightleftharpoons (\text{CH}_3\cdot\text{CO}_2\text{H})_2$ , we have for the equilibrium constant,  $K_p = p_{A_2}/p_A^2$ , where  $p_{A_2}$  is the partial pressure due to double molecules and  $p_A$  that due to single molecules; therefore  $K_p = (R - 1)/p(2 - R)^2$ .

In Table I are collected the data for acetic acid (under the symbols defined above) together with the average value of  $K_c$  calculated from  $K_c = K_p \cdot 760 \cdot T \cdot 22.4/273$ .

The plot of  $\log K_c$  both for our results and for Young's (J., 1886, 49, 790) is given in Fig. 2, and it will be seen that, although both sets lie on straight lines, the two curves are not coincident.

The average values of  $K_c$  are employed in the calculation of the

heat of reaction at constant volume in the usual way and give the results shown in Table II.

TABLE I.  
*Data for acetic acid.*

No. of expts.	Series.	v.	p.	$T - 273^\circ$ .	R.	$K_p \times 10^6$ .	Mean $K_c$ .

X-Ray evidence shows that, in the solid state, the carboxyl groups of adjacent molecules of monobasic acids are attached to one another, and it is not unlikely that the molecules of acetic acid are attached in a similar manner in the vapour state. On this view, the heat of association of acetic acid would be the heat of association of carboxyl groups, and the high value of this heat may be ascribed

to an atomic rearrangement occurring between these groups on association.

*Determination of the Heat of Association for Heptioic Acid.*—The heptioic acid, obtained by repeated fractionation of a specimen from Kahlbaum, had been employed in a determination of heats of crystallisation, and melted at  $-7.5^{\circ}$ ; its purity was found by titration to be 98.79%.

The mode of heating the tube G was modified slightly, since, for the higher temperatures, the fall of temperature along the tube was about  $5^{\circ}$  when the vapour was distilling through it. The wiring was therefore readjusted until the electrical heating by itself gave a fall of only  $6^{\circ}$ ; with the circulating vapour, this gave a satisfactorily constant temperature with a fall of about  $1^{\circ}$ , and the average temperature was taken. The three jacketing vapours used were aniline, benzyl alcohol, and methyl salicylate. The weights of acid used were 0.06 and 0.03 g. approximately. Table III gives the results obtained at four temperatures. Partly owing to the difficulty of maintaining constant temperatures at  $200^{\circ}$  and above, and partly owing to the low degree of association of heptioic acid, the values of  $K_p$  are much less concordant than those obtained for acetic acid; and the corresponding values of  $Q_v$  (Table IV) do not

possess much value by themselves. Nevertheless, the results indicate that the heat of association of heptoic acid is decidedly lower than that of acetic acid. An investigation into the behaviour of acids of intermediate chain length would appear desirable.

*Summary.*

Acetic and heptoic acids have been shown to be associated in the vapour state and the heats of association have been calculated. For acetic acid,  $Q_v = 13,790$  cal. per g.-mol. over the temperature range  $110-184^\circ$ . For heptoic acid,  $Q_v$  appears to vary with temperature; the average value between  $185^\circ$  and  $230^\circ$  is  $7,050$  cal. per g.-mol. Since the heat of evaporation of acetic acid is only  $5,570$  cal. per g.-mol., it is concluded that the double molecules are held together by forces analogous to those of chemical combination.

## XCI.—A Simple Method for the Preparation of Maleic Anhydride.

By FREDERICK ALFRED MASON.

MALEIC acid can now be obtained cheaply and conveniently on a commercial scale by the catalytic oxidation of benzene, but the preparation of maleic anhydride by existing methods involves the use of an expensive dehydrating agent such as acetyl chloride or phosphoric oxide (compare Anschütz, *Ber.*, 1879, **12**, 2281; 1881, **14**, 2789; 1882, **15**, 641; Perkin, *Ber.*, 1881, **14**, 2547; 1882, **15**, 1073; Fittig, *Annalen*, 1877, **188**, 87; Volhardt, *ibid.*, 1892, **268**, 255; Tanatar, *ibid.*, 1893, **273**, 32; Van der Riet, *ibid.*, 1894, **280**, 216). The anhydride cannot be prepared by heating maleic acid just above its melting point (Pelouze, *Ann. Chim.*, 1834, **11**, 266), at  $130^\circ$  in a sealed tube (Skraup, *Monatsh.*, 1893, **14**, 500), at  $190^\circ$  (Tanatar, *loc. cit.*), or with water in a sealed tube (Skraup, *Monatsh.*, 1891, **12**, 107), the chief or sole product being fumaric acid in all cases; neither can it be prepared by distilling maleic acid rapidly in small quantities, since, according to Pelouze, the anhydride and the water in the distillate at once regenerate maleic acid.

It has now been found that the anhydride may be obtained from the acid in excellent yield by distilling the latter with a neutral high-boiling solvent such as xylene or, better, tetrachloroethane. The water formed distills at once with the solvent and as soon as all the water is removed the residue is fractionated under reduced

pressure; the anhydride then distils in a pure form, only about 10% of the acid remaining behind as fumaric acid.

#### EXPERIMENTAL.

A mixture of 100 c.c. of tetrachloroethane and 100 g. of commercial maleic acid was heated, preferably in an oil bath, until 90 c.c. of distillate had been collected, consisting approximately of 75 c.c. of tetrachloroethane and 15 c.c. of water (theory requires 15.5 c.c.), the temperature rising from 120° to 150° as indicated by a thermometer placed in the neck of the flask. The residue was then distilled until the thermometer indicated 190° (b. p. of anhydride 197—199°), the receiver changed, and the residual anhydride distilled under reduced pressure, boiling at 82—84°/15 mm. (reduced pressure is desirable but not essential): 70 g. of anhydride were collected, and the middle fraction on refractionation gave a further 5.5 g., the total yield being 75.5 g. or 89.5% of the theoretical. The residue (8.5 g.) of fumaric acid in the flask was removed with alcohol and still contained a small amount of anhydride.

Similar results were obtained when xylene was used as the solvent, but the water came over much more slowly; for instance, the distillate from a mixture of 50 g. of maleic acid and 100 c.c. of xylene contained 2 c.c., 3 c.c., and 5.5 c.c. of water in 50 c.c., 70 c.c., and 80 c.c. respectively.

The anhydride so obtained has a boiling point of 197—199° (uncorr.) and a setting point of 52° (Fittig gives 196° and 60°). It is easily soluble in most organic solvents and crystallises well on cooling. On exposure to the air it absorbs moisture, re-forming maleic acid.

Attention must be directed to the fact that the vapour of the anhydride, although having no perceptible odour at the ordinary temperature, attacks the mucous membrane of the nose and after some time causes inflammation and a heavy catarrh of the nasal passages, the symptoms resembling those of a severe "common cold."

The experiments were carried out in the Organic Chemical Laboratories at Oxford and thanks are due to Imperial Chemical Industries Ltd. for permission to publish the results.

## XCII.—*Further Degradative Experiments in the Morphine Group.*

By ROBERT SIDNEY CAHN.

THE following experiments are a continuation of earlier work (J., 1926, 2562) which had as its object the preparation, with a view to later synthesis, of 3:4-dimethoxy-13-ethyloctahydrophenanthrene (I) from the natural alkaloids of the morphine group. They have had to be discontinued \* short of ultimate success and are here placed on record for reference.

The route chosen must give no opportunity for wandering of the ethanamine side chain from C13 to C14 or other positions (compare Schöpf and Bardowsky, *Annalen*, 1927, 458, 148), and it is therefore worth noting that both dihydrothebainone, the initial material of the previous experiments, and dihydrothebaine, that of this series, undoubtedly contain the ethanamine chain attached to C13 and that no wandering was possible under the conditions of the later reactions.

By heating the methiodide of dihydrothebainemethine † (II) with amyl-alcoholic potassium hydroxide, Freund and Speyer (*Ber.*, 1920, 53, 2250) obtained the vinyl compound (III) mixed with a red impurity. They gave the melting point of (III) as 150—151°, but their analyses showed the product to be impure. The formation of the red impurity has been confirmed, but the vinyl compound has been obtained pure by transforming the methiodide by means of silver oxide into the methohydroxide and refluxing this in isocamyl-alcoholic solution; the pure substance melts at 120—121°.

Hydrochloric acid readily hydrolyses 6-methoxy-13-vinyltetrahydromorphenol methyl ether (III) to 6-keto-13-vinylhexahydromorphenol methyl ether (IV), which absorbs two molecules of

\* The author's skin became sensitive to the catalytic reduction products of thebaine. (Cure: frequent bathing with very hot boracic solution.)

† For nomenclature, see J., 1926, 2564, footnote.

hydrogen in the presence of platinised charcoal to give 6-keto-13-ethyloctahydromorphenol methyl ether (V). The ether bridge in (V)

is reduced by aluminium amalgam and moist ether, yielding 6-keto-13-ethyloctahydromorphol 3-methyl ether (VI), which has been prepared by a different route by Wieland and Kotake (*Annalen*, 1925, 444, 87). Neither method gives a good yield, probably because of partial reduction of the keto-group. Attempts to proceed further with the small quantity of (VI) available were unsuccessful.

The methohydroxide of dihydrothebainemethine (II) on decomposing gives only 30% of the vinyl compound (III), and 50% of the methine formed by loss of methyl alcohol can be recovered. The latter reaction was found to occur almost exclusively with three bases in the previous investigation (Cahn, *loc. cit.*), but reaches only negligible proportions in other cases, *e.g.*, thebenol and thebenone. Notwithstanding certain apparent regularities, it seems impossible to foretell the course of the degradation of these complicated bases; for instance, hydroxydihydrocodeinonemethine, which is structurally intermediate between the examples mentioned above, may be compared with the base (II), giving 48% of trimethylamine, whereas the closely related dihydromethylhydroxydihydrothebainonemethine gives less than 10% (Freund and Speyer, *J. pr. Chem.*, 1916, 94, 135; Schöpf, *Annalen*, 1927, 452, 256). The contradictions do not appear capable of explanation along the lines of the theoretical views of Ingold and his collaborators (*J.*, 1927, 997; 1928, 3125). In particular are they noteworthy when the deduction is drawn that the elimination of methyl alcohol from substances of the type  $R-CH_2-CH_2-NMe_3OH$  reaches a limit of 25% when R is *n*-butyl, and the statement is made (*J.*, 1929, 2338) that there is no known instance of "a complete disappearance of the reaction leading to an olefin, a tertiary amine and water." The consideration that the many-branched nature of the morphine radicals should increase the elimination of methyl alcohol applies equally to all these bases.

## EXPERIMENTAL.

All the analyses recorded in this paper are microanalyses made by Dr. Ing. A. Schoeller of Berlin.

**6-Methoxy-13-vinyltetrahydromorphenol Methyl Ether (III).**—A hot solution of dihydrothebainemethine methiodide (14 g.) in methyl alcohol (350 c.c.) was poured on silver oxide (precipitated from 7 g. of silver nitrate and washed free from alkali with water and then three times with methyl alcohol), cooled at once, shaken mechanically for 30 minutes, and filtered. The solvent was removed by distillation, and a solution of the residual oily quaternary hydroxide in *isoamyl* alcohol (140 c.c.) refluxed for 5½ hours. After removal of the *amyl* alcohol in steam, an insoluble oil was obtained which readily solidified. It was collected and dissolved in hot glacial acetic acid, the solution poured into ether, and the whole shaken with water. On basification of the acid layer pure dihydrothebainemethine (4.8 g.; 50% of the theoretical quantity) was precipitated. From the ethereal layer, dried over calcium chloride and evaporated, the vinyl compound (III) was obtained as a solid residue (2.5 g.; yield, 30%): on crystallisation from alcohol or slightly diluted acetic acid it formed colourless plates, m. p. 120–121° (Found: C, 76.2; H, 6.5; MeO, 21.9. Calc. for  $C_{18}H_{18}O_3$ : C, 76.55; H, 6.4; 2MeO, 22.0%). The same substance was on one occasion obtained, mixed with small red prisms, by heating the quaternary hydroxide for 2 hours on the steam-bath and working up the product as above, but several attempts to repeat the experiment failed.

**6-Keto-13-vinylhexahydromorphenol Methyl Ether (IV).**—Concentrated hydrochloric acid (1.5 c.c.) and a solution of the dimethoxy-compound (III) (1.4 g.) in alcohol (14 c.c.) were heated together for 30 minutes on the water-bath and hot water was then added until a turbidity was produced. The ketone (IV) (1.36 g.), which was deposited on cooling, crystallised from alcohol in colourless elongated prisms, m. p. 149°.

**6-Keto-13-ethyloctahydromorphenol Methyl Ether (V).**—A solution of the substance (IV) (1.2 g.) in alcohol (120 c.c.), containing 1 g. of charcoal on which the palladium from 0.2 g. of palladous chloride had been precipitated, was stirred in the presence of hydrogen. Absorption ceased after 275 c.c. of hydrogen (all volumes are corrected to N.T.P.) had been absorbed in 3 minutes. In a blank experiment the same amount of catalyst in alcohol (120 c.c.) adsorbed 81 c.c. The effective absorption was therefore 194 c.c. (2 mols. = 191 c.c.). After the reduction the solution was filtered and concentrated to small bulk; on cooling, substance (V) (1.1 g.) was deposited in clusters of rods, m. p. 113° (Found: C, 74.9; H, 7.3.

$C_{17}H_{20}O_3$  requires C, 74.9; H, 7.4%). The *semicarbazone*, crystallised from a little alcohol, melted at  $191^\circ$  after previous sintering (Found: N, 12.75.  $C_{18}H_{23}O_3N_3$  requires N, 12.8%).

6-*Keto-13-ethylotahydromorphol 3-Methyl Ether* (VI).—Freshly amalgamated aluminium (8 g.) was added to a solution of the substance (V) (0.5 g.) in wet ether (50 c.c.) and drops of water were added occasionally with shaking during 16 hours. After filtration and evaporation of the solvent the substance (VI) was obtained as an oil which soon solidified; after two crystallisations from alcohol it formed long prisms, m. p.  $148-150^\circ$  (Wieland and Kotake, *loc. cit.*, give  $148-150^\circ$ ). The low yield (0.25 g. after one crystallisation) was doubtless due to partial reduction of the keto-group, for in a later experiment with a larger proportion of amalgam the oily product would not solidify. In attempts to eliminate the oxygen from ring III the crystalline material and the oily product were subjected to reduction by Clemmensen's method, but an uncrystallisable oil was obtained in both cases. These last oils did not yield well-defined products when refluxed in benzene solution with methyl sulphate or methyl iodide in the presence of potassium carbonate. An attempt to methylate the crystalline substance (VI) by methyl sulphate and sodium hydroxide solution also failed.

The author is indebted to the Department of Scientific and Industrial Research for a grant, by the aid of which the early part of this work was carried out.

### XCIII.—*Influence of Poles and Polar Linkings on the Course pursued by Elimination Reactions. Part VII. A Generalised Form of the Olefinic Degradation of Sulphones.*

By GEOFFREY WILLIAM FENTON and CHRISTOPHER KELK INGOLD.

It was shown in Parts III and IV (J., 1928, 3127; 1929, 2338) that sulphones in the presence of concentrated potassium hydroxide solution undergo a degradation the mechanism of which is almost certainly identical in type with that which was applied in Parts I and II (J., 1927, 997; 1928, 3125) to the decomposition of quaternary ammonium hydroxides. The normal products of the degradation of sulphones are an olefin and a sulphinic acid, and the facility with which the reaction proceeds depends on the extent to

which the  $C_\gamma$ - $C_\omega$  part of the alkyl group ultimately eliminated as an olefin activates or de-activates the  $\beta$ -hydrogen atom attacked by hydroxide ion :

The straight arrow in the formula represents a de-activating effect, because electron-repulsion towards  $C_\beta$  must diminish the tendency of the  $\beta$ -hydrogen atom to separate in the kationic form; and in this connexion it was observed that, under the conditions used, the reaction became sluggish or failed altogether when R was a higher alkyl group than methyl. It also failed if there were two de-activating groups attached to  $C_\beta$ , even when these were only methyl groups. Although substitution at  $C_\alpha$  is not expected adversely to affect the degradation to any marked extent (the investigation of diisopropylsulphone supports this assumption), the reaction in the form in which we have described it is evidently far from being as general as the corresponding decomposition of quaternary ammonium hydroxides, and this is in agreement with the smaller electron-affinity of  $-\text{SO}_2\text{R}$  than of  $-\text{NR}_3^\oplus$  (see Parts III and IV).

Obviously, however, the sulphone degradation might be made general by the use of a more basic anion (*i.e.*, one with greater proton affinity) than hydroxide; and for this purpose the methoxide and ethoxide ions suggested themselves (Ingold and Shoppee, J., 1929, 447; Kon and Linstead, *ibid.*, p. 1269).

We find that the degradation can readily be generalised by the replacement of aqueous potassium hydroxide by alcoholic sodium ethoxide: all the sulphones which resisted the former reagent have been found to undergo the degradation in the presence of the latter.

No.	Sulphone.	Olefin.	KOH.	NaOEt.
1	Phenyl- $\beta$ -phenylethyl*	Styrene	*	*
2	Diethyl	Ethylene	*	*
3	Ethyl- <i>n</i> -propyl	"	*	—
4	Ethyl- <i>iso</i> amyl	"	*	—
5	Ethyl- <i>n</i> -octyl	"	*	—
6	Diisopropyl	Propylene	*	—
7	Di- <i>n</i> -propyl	"	*	*
8	Di- <i>n</i> -butyl	$\Delta^2$ - <i>n</i> -Butylene	Little action	*
9	Di- <i>n</i> -octyl	$\Delta^2$ - <i>n</i> -Octene	No action	*
10	Di- <i>iso</i> amyl	$\Delta^2$ - <i>iso</i> Amylene	"	*
11	Diisobutyl	<i>iso</i> Butylene	"	*

\* With potassium hydroxide the products were styrene, benzene, and sulphur dioxide, but when sodium ethoxide was used the benzenesulphinic acid formed was isolated as such. In all the other cases the sulphinic acid was obtained with either reagent.

The above is a tabular summary of the observations recorded

in Parts III and IV and in this paper. The examples studied are arranged in order of the theoretically anticipated inhibition to the elimination of the olefin formed. A star indicates that degradation by the reagent indicated has been observed, and a line that the corresponding experiment was not tried.

#### EXPERIMENTAL.

*Preliminary Experiments.*—Di-*n*-octylsulphone (Part III) was used because the liquid olefin *n*-octene could scarcely be confused with any unsaturated substance which might arise from the sodium ethoxide. The sulphone (4 parts), freshly prepared sodium ethoxide (10 parts), and alcohol (1.5 parts) were heated in a metal bath and the products were passed through water and bromine and into a eudiometer. Reaction occurred at just below 200° (bath temperature) and an oily product, but no gas, was evolved. The liquid product was identified by its b. p. 122—123°, and by conversion into its dibromide, as  $\Delta^a$ -*n*-octene. In a similar experiment the bath temperature was carried to 300° after the subsidence of the original reaction; and at this temperature both saturated and unsaturated gases were evolved. The unsaturated gas was represented by a small amount of oil which was obtained after destruction of the excess of bromine in the bromine trap. The gas collected in the eudiometer contained oxygen, nitrogen (which was used for sweeping), and hydrogen, but no hydrocarbons. The *n*-octene obtained in this experiment (yield, 50%; b. p. 120—125°) gave, on ozonolysis, formaldehyde as volatile product and an oil having the odour of heptaldehyde. We conclude that the gaseous products evolved at 300° come from the sodium ethoxide and that the  $\Delta^a$ -*n*-octene, formed at 200°, has not undergone displacement of the double linking.

*General Method.*—The aliphatic sulphones were heated with sodium ethoxide as above, but only until the initial reaction ceased; in no case was the bath temperature raised above 235°. The volatile products were passed directly into bromine, the excess of which was afterwards destroyed with water and sulphur dioxide; the bromides were drawn off, dried and weighed, distilled, and in some cases analysed. The sulphinic acids were isolated in the form of their silver salts, as described in Part III. The treatment of phenyl- $\beta$ -phenylethylsulphone was different. In order to avoid the risk of the nuclear bromination of styrene by an excess of bromine, the hydrocarbon was collected as such in a trap containing water at 0°, and then extracted with chloroform; the dried chloroform solution was treated with dry bromine in chloroform until coloured, and the styrene dibromide, obtained on evaporation, was identified and

weighed. The benzenesulphinic acid was isolated, as such, from the residue by acidification of its aqueous solution and extraction with ether.

*Results.*—These are recorded in tabular form. The *silver* salts, the analytical data for which are italicised, are new.  $\alpha\beta$ -Dibromo-n-octane also is new, since, although it was prepared and analysed by Ingold and Vass in connexion with their work on quaternary ammonium hydroxides, the description and data were inadvertently omitted from the paper.

#### XCIV.—Influence of Poles and Polar Linkings on the Course pursued by Elimination Reactions. Part VIII. The Methylenic and Paraffinic Degradations of Sulphones.

By CHRISTOPHER KELK INGOLD and JOE ARTHUR JESSOP.

THE following scheme summarises the three known ways in which a radical may be eliminated as a hydrocarbon in the thermal degradation of an "onium" hydroxide. The table also indicates the conclusions which have been reached with regard to the characteristics of the ejected radical which favour each mode of elimination and the changes necessitated in the electron-groups (Hanhart and Ingold, J., 1927, 997; Ingold and Vass, J., 1928, 3125; Fenton and Ingold, J., 1929, 2342; Ingold and Jessop, *ibid.*, p. 2357).

## Eliminated radical.

Elimination reaction.	Eliminated as	Structural requirement.	Facilitation by electron-sink at	Valency octets of	
				"onium" element.	hydrocarbon radical.
(1) Olefinic	R minus $H_\beta$	$H_\beta$	$C_\beta$	Preserved	Preserved
(2) Methylenic	R minus $H_\alpha^*$	$H_\alpha$	$C_\alpha$	Preserved	To sextet
(3) Paraffinic	R plus $H_\alpha$	—	$C_\alpha$	To decet	Preserved

\* The bivalent carbon compound may polymerise or isomerise.

Reaction (1), which preserves all octets, is common to ammonium and phosphonium hydroxides. In the former series, when the constitutional conditions inhibit (1) and strongly favour (2) and (3), the observed reaction is (2), and not (3); this is connected with the presumed inability of nitrogen to enlarge its octet (Sidgwick). In the latter series, when (1) is suppressed, the observed reaction is not (2), but (3); it is inferred that the phosphorus octet has a considerable tendency towards enlargement. Fenton and Ingold have shown (J., 1928, 3127; 1929, 2338; preceding paper) that sulphones in the presence of alkali undergo reaction (1); it remained to discover which type of decomposition, (2) or (3), would supervene when (1) was inhibited. The answer, contained in this paper, is that both occur; and that sulphone sulphur apparently shares, on the one hand, the tendency of phosphonium phosphorus to enlarge its electron group, and, on the other, the ability of ammonium nitrogen to deplete the electron group of a neighbouring carbon atom:

The following table summarises the observations. In two of the sulphones examined, no  $\alpha$ -hydrogen atom was present and methylenic degradation was therefore impossible; these underwent paraffinic decomposition. In the remaining five examples an  $\alpha$ -hydrogen atom was present, and both reactions were shown to proceed side by side, with the exceptions that in one case the evidence for paraffinic degradation, and in another the evidence that the same decomposition occurs in a second direction, is incomplete (indicated by parentheses in the table). It should also be mentioned that whereas the extrusion of methylene and benzyldiene was diagnosed by the recovery of ethylene and stilbene respectively, the bis-*oo'*-diphenylene-ethylene into which fluorenylidene would be expected to pass was not isolated as such, but as diphenyl-*o*-carboxylic acid, into which the unsaturated hydrocarbon is known to pass in the presence of alkali under the conditions employed.

	Sulphone $RR'SO_2$ .		Group eliminated as hydro-carbon.	
	Group R.	Group R'.	Reaction (2).	Reaction (3).
$H_a$ absent	{ Phenyl <i>p</i> -Tolyl	Phenyl 9-Phenyl-9-fluorenyl		Phenyl Phenylfluorenyl
	{ <i>p</i> -Tolyl Benzyl	9-Fluorenyl Benzyl	Fluorenyl Benzyl	Fluorenyl (Benzyl)
$H_a$ present	{ Phenyl Methyl	Benzyl Benzyl	Benzyl Benzyl	Benzyl Benzyl
	{ Methyl	<i>p</i> -Tolyl	Methyl	Methyl ( <i>p</i> -tolyl)

In the above series methylenic elimination (reaction 2) has been observed with three groups, namely, fluorenyl, benzyl and methyl. In the ammonium hydroxide series, apparently only the first of these is capable of this form of extrusion: stilbene and ethylene have never been proved to arise in the decompositions of ammonium hydroxides containing only benzyl or methyl groups. Furthermore, the direction of the methylenic decomposition of benzylmethylsulphone shows that the reaction is more prone to occur with the benzyl than with the methyl group. Hence the complete order of facility of methylenic extrusion is 9-fluorenyl > benzyl > methyl; which is the order of anionic stability, as the theory of the reaction demands (Fenton and Ingold, J., 1929, 2342; Ingold and Jessop, *loc. cit.*). This statement will be understood to relate only to *one* of the several factors which it would be necessary to envisage in a *general* discussion of bivalent carbon stability.

As regards the paraffinic degradation of sulphones (reaction 3), it need be stated only that the order in which the radicals examined tend to this form of elimination is consistent with that found in connexion with the thermal decomposition of phosphonium hydroxides. Actually the relation, fluorenyl > simple aryl, is additional; but it constitutes a further confirmation of the view that tendency to ejection increases with the anionic stability of the group.

#### EXPERIMENTAL.

*Preparation of Sulphones.*—9-Bromofluorene (10 g.) was heated for 15 minutes on the steam-bath with a solution prepared from sodium *p*-toluenesulphinate dihydrate (12 g.) and alcohol (20 c.c.). Sodium bromide separated, and the mixture was evaporated to dryness, and the residue heated for 1 hour at 100° in a stream of dry air to dehydrate the excess of sodium salt. The dried product was extracted repeatedly with boiling benzene until the extracts failed to crystallise on cooling. 9-Fluorenyl-*p*-tolylsulphone separated in iridescent plates (12.5 g.), m. p. 226–227° (Found: C, 75.2; H, 5.2.  $C_{26}H_{16}O_2S$  requires C, 75.0; H, 5.0%).

9-Hydroxy-9-phenylfluorene was prepared as described by Ullmann and Würstemberger (*Ber.*, 1904, 37, 73), and purified by crystallising it twice from carbon tetrachloride (compare Kliegl,

*Ber.*, 1905, **38**, 288), crushing the solvated crystals, and air-drying the powder over-night at 40°. The product had m. p. 85–87° and, notwithstanding the observed efflorescence, appeared still to contain solvent of crystallisation. A warm solution of the product (18 g.) in glacial acetic acid (18 c.c.) was treated with a warm solution (18 c.c.) of hydrogen bromide in the same solvent (600 g./l.), and the non-homogeneous mixture was rapidly stirred until solid appeared and then heated at 80° for 0.5 hour. The product (20 g.) obtained by filtering the cooled solution and washing the precipitate with cold glacial acetic acid had m. p. 99–100°, and, after crystallisation from ligroin, m. p. 101–101.5° (compare Staudinger, *Ber.*, 1906, **39**, 3060). A further quantity (1 g.) was recovered by adding a limited amount of water to the acetic acid solution.

When this bromide was treated with an alcoholic solution of hydrated sodium *p*-toluenesulphinate, as in the preceding preparation, the product was 9-ethoxy-9-phenylfluorene. Sodium *p*-toluenesulphinate (8 g.), dried at 100°, was therefore boiled for 40 hours with a solution of the bromide (12 g.) in dry benzene (50 c.c.). The suspension was filtered while hot, and the residue extracted with hot benzene until it became completely soluble in water.

The 9-phenyl-9-fluorenyl-*p*-tolylsulphone, which was crystallised twice (8.0 g.), separated from benzene in needles or stout prisms, m. p. 211–212° (Found: C, 78.7; H, 5.3.  $C_{26}H_{20}O_2S$  requires C, 78.8; H, 5.1%).

*Decomposition with Potassium Hydroxide.*—The reactions were carried out by the general method illustrated in the earlier papers by Fenton and Ingold.

The degradation of diphenylsulphone has already been described by Otto (*Ber.*, 1886, **19**, 2425), who observed the formation of phenol as a main product but did not record the production of benzene. Under corresponding conditions we find that both benzene (identified as the *m*-dinitro-derivative) and phenol (benzoyl derivative) are formed in quantity, and that, at temperatures below that at which benzenesulphinic acid would be largely decomposed, this acid is absent but benzene is formed and benzenesulphonic acid and phenol are also present. The initial fission products are therefore benzene and benzenesulphonic acid, not phenol and benzenesulphinic acid.

The volatile products from the decomposition of 9-phenyl-9-fluorenyl-*p*-tolylsulphone (6 g.) consisted of toluene (0.3 g.; 2:4-dinitro-derivative) and 9-phenylfluorene (0.1 g.; sublimed under reduced pressure as needles, m. p. and mixed m. p. 146–147°). The aqueous extract of the non-volatile portion yielded a small amount of cresol (qualitative tests), which was extracted with

ether after the solution had been treated with carbon dioxide, and *p*-toluenesulphinic acid (1.5 g., m. p. and mixed m. p. 88–89°), which was similarly extracted after acidification. The non-volatile product which was insoluble in water consisted of a brown resin: this was converted into a pale yellow powder by boiling with dilute aqueous ammonia and extracted several times with boiling alcohol, which removed most of the colouring matter. The dried substance (free from nitrogen and sulphur) separated in a solid form resembling lycopodium when its solution in hot chloroform-acetic acid was cooled, but the material, which decomposed above 300° and did not reduce cold permanganate in moist benzene-acetone, did not appear to be crystalline: the microscope revealed small clusters of nearly spherical particles. Considering the difficulties of purification, the analysis [Found: C, 94.0; H, 5.4; *M*, by Rast's method, 932. (C<sub>19</sub>H<sub>12</sub>)<sub>4</sub> requires C, 95.0; H, 5.0%; *M*, 960] appears to show that the substance is a hydrocarbon. Its formation seems analogous to that of the product (C<sub>19</sub>H<sub>14</sub>)<sub>2</sub> obtained by Nef by the action of triethylamine on triphenylmethyl bromide (*Annalen*, 1899, 309, 168). The 9-phenylfluorene required for comparison was prepared from 9-bromo-9-phenylfluorene (2 g.) and thin amalgamated aluminium foil (2 g.) in moist ether (50 c.c.). After being kept for 2 hours at the ordinary temperature, the solution was filtered, dried, and evaporated, and the residue crystallised from alcohol, from which the hydrocarbon separated in feathery needles, m. p. 146–149°. Its solution in ether is strongly fluorescent.

The volatile decomposition products from 9-fluorenyl-*p*-tolylsulphone on fractionation yielded toluene (25%, identified as 2:4-dinitro-derivative) and fluorene (43%), and a further 2% of fluorene was obtained by sublimation at 100° from the brown resin (6% of the weight of the sulphone) constituting the benzene-soluble portion of the non-volatile residue. The aqueous extract of the residue yielded cresol (10%, identified as benzoate), which was extracted with ether after the solution had been treated with carbon dioxide. Acidification of the residual aqueous solution yielded a white precipitate, m. p. 110–112°, consisting of diphenyl-2-carboxylic acid (yield, 15%): it crystallised from ether-ligroin in stout prisms and its solution in concentrated sulphuric acid yielded pure fluorenone (m. p. and mixed m. p.) on dilution with water. This establishes the identity of the acid, which was confirmed by comparison with a specimen obtained from fluorenone, and also with one prepared by the action of hot concentrated potassium hydroxide solution on bis-*oo'*-diphenyl-ethylene. Extraction of the acid filtrate with ether yielded *p*-toluenesulphinic acid (20%), m. p. 89–89.5° (the

recorded m. p. of this acid is 85°, but our numerous specimens all had m. p. 89°).

Phenylbenzylsulphone yielded liquid and solid hydrocarbons, of which the latter was identified as stilbene (m. p. and mixed m. p.; yield, 48%). The liquid hydrocarbons, b. p. 80–105°, were heated in a closed tube with 3% permanganate solution for 4 hours; benzene was then recovered by distillation and converted into its dinitro-derivative, and the presence of toluene in the original mixture was diagnosed by the isolation of benzoic acid by ether-extraction of the decolorised, filtered, and acidified aqueous solution. The alkaline residue from the decomposition yielded sulphur dioxide and phenol.

Dibenzylsulphone yielded toluene, stilbene, and sulphur dioxide.

Benzylmethylsulphone yielded the same products together with methanesulphinic acid and a very small amount of gas. The methanesulphinic acid was isolated as its *silver* salt by the method previously described for propanesulphinic acid (J., 1929, 2340) except that aqueous alcohol was used for the precipitation and crystallisation (Found: C, 6.6; H, 1.75.  $\text{CH}_3\text{O}_2\text{SAg}$  requires C, 6.4; H, 1.6%).

*p*-Tolylmethylsulphone yielded toluene (yield, *ca.* 25%; identified as 2:4-dinitro-derivative), *p*-cresol (*ca.* 30%; identified as benzoate), *p*-toluenesulphinic acid (18%; m. p. and mixed m. p.), and a gas which was swept over with nitrogen and shown to contain methane (13%), ethylene (27%), and a substantial quantity of hydrogen.

We wish to thank the Royal Society for a grant in aid of this investigation.

*XCV.—Influence of Poles and Polar Linkings on the Course pursued by Elimination Reactions. Part IX. Isolation of a Substance believed to contain a Semipolar Double Linking with Participating Carbon.*

By CHRISTOPHER KELK INGOLD and JOE ARTHUR JESSOP.

IN Part VI it was noted (J., 1929, 2357) that, whilst fluorenyl-9-trimethylammonium and fluorenyl-9-triethylammonium bromides are colourless, the aqueous solutions of the corresponding hydroxides are coloured; and the suggestion was made (p. 2359, footnote) that

in either case the hydroxide (I) might be in equilibrium with an anhydride (II) which, since it contains unshared carbon electrons, would probably be coloured and highly reactive. The special structural feature of (II) is the semipolar double linking with carbon at its negative end, and since no compound containing a semipolar double bond between carbon and another element has hitherto been described, attempts were made to isolate the coloured substance:

At the outset it was obvious that (II) could not be present in high concentration, for if it were it should be precipitated; it was not precipitated and the coloured solution was strongly alkaline. Probably the low concentration and the instability of the compound (see Part VI) conspired to defeat the attempts at isolation. We reflected, however, that (II) is analogous to the trialkylamine oxides,  $\overset{\ominus}{\text{O}} - \overset{\oplus}{\text{N}}\text{R}_3$ , which have low thermal stability and a strong tendency to combine with water to form trialkylhydroxylammonium hydroxides,  $\{\text{OH} \cdot \text{NR}_3\}^{\cdot} \text{OH}'$ , analogous to (I); and, further, that dialkylsulphoxides,  $\overset{\ominus}{\text{O}} - \overset{\oplus}{\text{S}}\text{R}_2$ , have much higher thermal stability and exhibit very little tendency to effect an analogous union with water. It followed that a study of the corresponding fluorenyl-sulphonium compounds (III and IV) might reveal an equilibrium much more favourable to the form which it was desired to isolate, and that the anhydride (IV), despite its negative carbon, might possess sufficient thermal stability to permit of isolation:

The initial difficulty here was to prepare a fluorenyl-9-dialkylsulphonium salt. 9-Bromofluorene and dimethyl sulphide showed little tendency to combine either in ether or in benzene or without a solvent; furthermore, attempts to prepare 9-fluorenyl mercaptan by the action of alkali sulphides on 9-bromofluorene led to the formation of 9:9-difluorenyl. At this juncture Richardson and Soper's paper appeared (J., 1929, 1873) in which their cohesion principle was enunciated; perusal of this memoir made it immediately obvious (a) that the combination of 9-bromofluorene with dimethyl sulphide should be strongly catalytically accelerated by a solvent of high cohesion, and (b) that the tendency to thermal decomposition of the required sulphonium bromide, which sets a limit to the temperatures that can be used in its synthesis, would be reduced by such a solvent. Actually, effect (a) was so powerful

that there was no need to make use of the presumed increased stability of the product at high temperatures : we mixed the reagents in nitromethane at the ordinary temperature and observed a rapid and almost quantitative formation of the sulphonium bromide. Several other successful applications of the cohesion principle have since been made in these laboratories, and there can be no doubt about its practical utility in the replacement of empirical by rational technique in synthetic operations.

When a solution of *fluorenyl-9-dimethylsulphonium bromide* was treated with excess of silver oxide, the filtrate was practically neutral. When sodium hydroxide or aqueous ammonia was used instead of silver oxide, *dimethylsulphonium 9-fluorenylidide* (IV; R = Me) was obtained as a yellow crystalline precipitate. It was sufficiently stable to admit of analysis and the determination of its molecular weight in benzene, but after some hours decomposition set in with evolution of dimethyl sulphide. Details relating to the thermal decomposition of the substance are given in the experimental portion, and it will suffice to note here that, although the compound resembles sulfoxides in refusing to form a sulphonium hydroxide by addition of water, it is definitely more basic than are sulfoxides, since it at once reacts with dilute hydrochloric acid, forming the corresponding fluorenyl-9-dimethylsulphonium salt. This is essentially a reversal of the reaction whereby dimethylsulphonium 9-fluorenylidide is formed, and thus it may be said that the constitutional environment of the 9-carbon atom confers on it properties analogous to those of a nitrogen atom :

The probable mechanism underlying this conferment of nitrogen-like properties on carbon is sufficiently indicated in Part VI.

#### EXPERIMENTAL.

*Fluorenyl-9-dimethylsulphonium Salts.*—The *bromide*, irregular hexagonal plates, m. p. 133° (Found : Br, 26.4. C<sub>15</sub>H<sub>15</sub>BrS requires Br, 26.1%), was prepared, as described in the introduction, in cold nitromethane solution, from which it crystallised. The *picrate*, precipitated by addition of aqueous sodium picrate to a solution of the bromide in water, separated from hot water in needles, m. p. 149–150° (Found : C, 55.6; H, 4.0. C<sub>21</sub>H<sub>17</sub>O<sub>7</sub>N<sub>3</sub>S requires C, 55.4; H, 3.7%).

*9:9-Difluorenyl.*—Prior to the above experiments attempts were

made to prepare the same salts by way of fluorenyl mercaptan or sulphide. 9-Bromofluorene and alcoholic sodium hydrogen sulphide were kept together over-night in the cold and the solution was then distilled to half its bulk, poured into water, and made alkaline. 9-Bromofluorene and alcoholic disodium sulphide were similarly kept in the cold and then heated for 2 hours in the steam-bath and poured into water. In each case a crystalline precipitate was obtained which was recrystallised from benzene and identified as 9:9-difluorenyl by its m. p. (242—244°) and by analysis (Found: C, 94.8; H, 5.6. Calc.: C, 94.5; H, 5.5%).

*Action of Bases on Fluorenyl-9-dimethylsulphonium Bromide: Dimethylsulphonium 9-Fluorenylidide.*—(a) *Water.* The sulphonium bromide was heated on a water-bath with water for 2 hours. Dimethyl sulphide was evolved (odour) and 9-fluorenyl alcohol precipitated (m. p. and mixed m. p.). In order to substantiate the obvious explanation of this decomposition, 9-bromofluorene was similarly heated with water; 9-fluorenyl alcohol was then formed in quantity.

(b) *Silver oxide.* On addition of excess of freshly precipitated carbonate-free silver oxide to a cold aqueous solution of the sulphonium bromide, the solution remained practically neutral. Heating the suspension on a water-bath caused the evolution of dimethyl sulphide (odour) and the formation of 9-fluorenyl alcohol (m. p. and mixed m. p.), a large quantity of which separated when the filtrate from the hot suspension was cooled. Extraction of the dried silver oxide residue with benzene yielded a red gum similar in appearance and properties to the non-volatile thermal-decomposition product of dimethylsulphonium 9-fluorenylidide (below).

(c) *Soluble alkalis.* Sodium acetate and sodium carbonate gave no precipitate with an aqueous solution of the sulphonium bromide; but aqueous ammonia, barium hydroxide, and sodium hydroxide yielded *dimethylsulphonium 9-fluorenylidide* as yellow leaflets, m. p. ca. 70—75° (decomp.), on rapid heating, which were washed with water, alcohol, and ether and dried for several hours in a vacuum. It was insoluble in water and ether, slightly soluble in alcohol, and readily soluble in ethyl acetate and benzene (Found: C, 80.3; H, 6.2; *M*, cryoscopic in benzene, 215, 226.  $C_{15}H_{14}S$  requires C, 79.6; H, 6.2%; *M*, 226). The compound began to darken and develop the odour of dimethyl sulphide after exposure to the atmosphere for a few hours (sooner if placed in a closed tube), but could be kept in a vacuum for about 24 hours with little if any signs of decomposition. In solution, however, decomposition was more rapid and the above molecular-weight determination requires explanation. Preliminary experiments showed that in benzene at

its freezing point the decomposition began to be perceptible soon after solution, and that for several hours thereafter there was a steady diminution in the apparent molecular weight. The determinations were therefore plotted against time and extrapolated to zero time. A sample, dried in a vacuum for 2 hours, gave values ranging from 196 to 153 and the extrapolated value at the moment of solution was 215. Another preparation, which had been similarly dried for 16 hours, gave values falling from 209 to 183 and the extrapolated result was 226.

*Reactions of Dimethylsulphonium 9-Fluorenylidide.*—The freshly prepared compound is immediately soluble in cold dilute hydrochloric acid. The solution contains fluorenyl-9-dimethylsulphonium chloride, as is proved by the observations that it yields dimethylsulphonium 9-fluorenylidide on treatment with ammonia, and fluorenyl-9-dimethylsulphonium picrate with aqueous sodium picrate.

The nature of the non-volatile product formed in the spontaneous decomposition which takes place at atmospheric pressure and temperature could not be elucidated. The evolution of dimethyl sulphide, which became perceptible after a few hours, was apparently complete after 4 days, and the residue was a brown amorphous substance which still contained sulphur but could not be crystallised. It was wholly insoluble in hot concentrated hydrochloric acid. By use of benzene and glacial acetic acid and other solvents, various orange and red amorphous products were obtained from it, but none could be crystallised.

Similar results were obtained more quickly by heating, and in this case the dimethyl sulphide was identified by passing the evolved gases through mercuric chloride solution and identifying the precipitated additive compound,  $3\text{HgCl}_2, 2\text{Me}_2\text{S}$ , by mixed m. p. and direct comparison. When the same decomposition was carried out in a diffusion-pump vacuum connected to the top of a mercury barometer, dimethyl sulphide condensed on the mercury, the depression of which, allowing for the vapour pressure of the sulphide, showed that no gas of the type of methane or ethylene was evolved; the sulphide was afterwards collected and converted into trimethylsulphonium iodide for confirmatory identification. The resinous residue (Found: C, 88.7; H, 5.4%) contained sulphur and could not be crystallised; on being strongly heated, it gave a crystalline distillate which proved to be fluorene (m. p. and mixed m. p.).

The solubility of dimethylsulphonium 9-fluorenylidide in acids suggested that it should add on methyl iodide. The reaction was tried under various conditions, but the addition, if any, was masked by the separation of dimethyl sulphide and its conversion into

trimethylsulphonium iodide, decomp. 207—210° (Found: I, 62.5. Calc., 62.2%); the remaining product was amorphous.

The investigation has been aided by a grant from the Royal Society, whom we wish to thank.

### XCVI.—*The Occurrence of Iron Pentacarbonyl in Coal Gas stored under Pressure for 30 Years.*

By JOHN ALBERT NEWTON FRIEND and REECE HENRY VALLANCE.

IN the course of a lecture at King Edward's High School, Birmingham, in 1899, at which one of the authors was present, Dr. T. J. Baker used a cylinder of compressed coal gas. Upon ignition, the flame was normal for coal gas of that period and could not be differentiated from that supplied from the mains. The cylinder was then placed aside and apparently overlooked until the spring of 1929, and the gas was then found to give a luminous and very smoky flame. As this clearly indicated that some material change had taken place in the gas during its prolonged storage, Dr. Baker very kindly handed the cylinder to us for further examination. The gas proved to be heavily charged with the vapour of iron pentacarbonyl, as proved by the following experiments, in which the term "dried" gas refers to the gas after filtration through a plug of cotton wool and passage through a drying tube containing calcium chloride.

*Experiment 1.* The dried gas was ignited at the orifice of a small glass jet, whereby a luminous, smoky flame was obtained. When a cold glass plate was held well into the luminous portion, a black deposit resulted, which consisted partly of carbon; but after treatment with dilute hydrochloric acid, the presence of iron was detected in the solution on addition of the usual reagents. If, however, the cold plate was held a short distance above the flame, a yellow to reddish-brown deposit of ferric oxide was obtained.

The cotton wool was almost imperceptibly darkened on the surface facing the exit from the cylinder, and the solution resulting from its treatment with acid responded to the tests for ferric iron, but not for ferrous. The deposit was therefore probably ferric oxide from the cylinder.

*Experiment 2.* The previous experiment was varied by interposing a wash bottle of concentrated sulphuric acid between the

drying tube and the jet. The flame was now less luminous and entirely free from smoke. It yielded no ferric oxide or other deposit, save water, to a cold plate held above the luminous zone, and only faintly blackened the plate when the latter was held lower down, probably because the acid had not completely absorbed the unsaturated hydrocarbons.

The sulphuric acid turned dark brown and, after dilution, was tested for metals. Iron alone was found, and was present in appreciable quantity.

*Experiment 3.* The dried gas was passed through a glass tube gently heated with a spirit lamp. A brilliant black mirror resulted, which almost completely dissolved in concentrated hydrochloric acid, a few black specks of carbon alone remaining. A white precipitate of ferrous chloride was obtained, which completely dissolved on dilution. Iron was the only metal present in the solution. Upon repeating the experiment with gas that had been passed through concentrated sulphuric acid, no mirror was obtained.

*Experiment 4.* The dried gas was passed through a narrow delivery tube into a wider tube suspended vertically in a glass boiling-tube and immersed in liquid air in a Dewar flask. The uncondensed gas was burned at a platinum jet. The flame was pale blue, and yielded no deposit other than water on a cold plate held either within or above the flame. Carbon dioxide was detected as a product of combustion, but, as this would result from the combustion of methane in any case, the gas was analysed to ascertain whether or not carbon monoxide was present. The analyses are given below, unsaturated hydrocarbons being determined by the bromine method, and carbon monoxide by ammoniacal cuprous chloride; the residual gas consisted of hydrogen, nitrogen, and methane.

Residual gas, % .....	87.00	91.45
Ratio CO : Residual gas .....	0.0833	0.0935

The higher proportion of carbon monoxide in the uncondensed gas was due to partial retention of methane in the boiling tube along with liquid ethylene (see below). The whole of the methane, however, was not condensed, since, on combustion, the residual gas yielded some carbon dioxide.

A solid deposit, pale lemon in colour, collected in the vertical tube. It melted at approximately  $-20^{\circ}$ , yielding a viscous liquid

which became amber-coloured and increased in mobility as the temperature rose to that of the room. A drop introduced into concentrated sulphuric acid decomposed with evolution of gas, and the solution, diluted with water, showed an abundance of ferrous iron but only the merest trace of ferric iron. Upon exposure to air, the liquid slowly decomposed with the formation of brown hydrated ferric oxide. These properties correspond to those of iron pentacarbonyl (Mond and Langer, J., 1891, 59, 1090; Dewar and Jones, *Proc. Roy. Soc.*, 1905, A, 76, 558). Approximately 1.25 g. of the carbonyl collected (Found: Fe, 26.5. Calc. for  $\text{FeC}_5\text{O}_5$ : Fe, 28.5%), and this was probably about half the amount contained in the cylinder at the time we received it. It was slightly contaminated with organic matter of tarry odour.

A colourless liquid had collected in the boiling tube. On removal from the Dewar flask, it boiled vigorously, its temperature as registered by a pentane thermometer being about  $-160^\circ$ . The liquid thus contained appreciable quantities of methane. The remainder was probably ethylene more or less admixed with acetylene, of which it smelled strongly. It was not further investigated.

*Discussion.*—This research is of special interest, inasmuch as it is known that the cylinder gas was, in 1899, free from carbonyl except in such traces as would not be easily detected. Hence the compound must have been produced by the prolonged influence of compressed carbon monoxide on compact iron (*i.e.*, steel) at the ordinary temperature. From the analysis of the uncondensed gas in Expt. 4, it is evident that free carbon monoxide was still present in considerable amount, and this possibly explains the absence of the lower carbonyls of iron. When freshly filled, the pressure of the gas would, in 1899, have approximated to 120 atm. As some of the gas had been used prior to storage, the pressure leading to the formation of carbonyl would probably lie between 50 and 80 atm.

## XCVII.—*The Reaction between Acid Chlorides and Nitrosylsulphuric Acid.*

By WILLIAM JAMES DEVERALL and HARRY WILLIAM WEBB.

ACID chlorides react with nitrosylsulphuric acid in one or both of the following ways:

and the end products undergo intramolecular rearrangement, especially on heating. The results obtained with acetyl and benzoyl chlorides have already been published (Elliott, Kleist, Wilkins, and Webb, J., 1926, 1219), but confirmation of the general nature of (1) and (2) has been obtained by examination of the reactions with the three nitrobenzoyl chlorides and with phthalyl chloride. *o*- and *p*-Nitrobenzoyl chlorides react readily with nitrosylsulphuric acid, but more slowly than benzoyl chloride itself, yielding products,  $(\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CO} \cdot \text{O})_2\text{SO}_2$ , which are completely decomposed by water into sulphuric and nitrobenzoic acids. When these products are heated under an inert liquid, the sulphuric acid obtainable by hydrolysis decreases, the total sulphur content remaining approximately constant; at  $160^\circ$  they are completely converted into a mixture of a sulphonic acid and a sulphone, with some evolution of sulphur dioxide.

*m*-Nitrobenzoyl chloride does not react with nitrosylsulphuric acid, even at  $65^\circ$  in absence of a diluent. This may be due to the general inhibiting effect of the nitro-group on the activity of other substituents (Shoesmith, Hetherington, and Slater, J., 1924, 125, 1312), or to the setting up by this group of alternate chain polarity, but this assumption leads to the anomaly that chlorine of positive polarity is attacked while that of negative polarity is not.

All the methods of determining the relative orienting effects of various substituents in the benzene nucleus (Rule, *ibid.*, p. 1121) show that the groups containing semipolar double bonds have the least effect, and the results now obtained indicate that this is true also of the effect of such groups on the activity of other substituents in the nucleus. None of the three chloronitrobenzenes, for example, reacted with nitrosylsulphuric acid even at relatively high temperatures. On the other hand, the three chlorophenols reacted rapidly with the formation of products,  $\text{OH} \cdot \text{C}_6\text{H}_4 \cdot \text{O} \cdot \text{SO}_2 \cdot \text{OH}$ , which could not be purified satisfactorily. The relative velocity of the reaction shown by measurement of the rate of evolution of nitrosyl chloride was found to be *m*- : *p*- : *o*- = 6.5 : 4 : 3.

Evidence already published (*loc. cit.*) seemed to show that the reaction of nitrosylsulphuric acid with carbonyl chlorides was preceded by the formation of an addition compound to the carbonyl group of the acid chloride. Since the oxygen in a semipolar double bond (such as  $>\text{S} \longrightarrow \text{O}$ ) occupies only one position, addition to such a bond would not be expected to take place, and hence experimental evidence bearing on the necessity for the preliminary formation of an addition product in the reaction between nitrosyl chloride and acid chlorides was obtained by an examination of certain sulphonyl chlorides and related substances. Benzene-

and toluene-sulphonyl chlorides and sulphuryl and thionyl chlorides were all found to be unattacked by the reagent. The three nitro-benzenesulphonyl chlorides were also inert unless heated to 130°, whereupon the *o*- and *p*-derivatives reacted with explosive violence, whilst the *m*-compound was inert. Since complete decomposition ensued, no conclusion can be drawn concerning possible addition. The fact that chloropicrin, which behaves in many respects as a typical acid chloride, was unattacked, also supports the hypothesis of preliminary addition, and similar evidence was obtained from the inertness of chlorides of the type RCl (R = alkyl or aryl group not containing oxygen).

Both forms of phthalyl chloride appear to yield the same end-products. This was to be expected in view of the rapidity with which the unsymmetrical high-melting form changes into the stable low-melting modification. The main reaction with both

forms appears to take the course  $C_6H_4 \begin{smallmatrix} \text{CCl}_2 \\ \text{CO} \end{smallmatrix} O + 2OH \cdot SO_2 \cdot O \cdot NO =$

$C_6H_4 \begin{smallmatrix} \text{CO} \\ \text{CO} \end{smallmatrix} O + OH \cdot SO_2 \cdot O \cdot SO_2 \cdot O \cdot NO + NOCl + HCl$  and from

the symmetrical form we isolated a small quantity of a substance  $C_6H_4(CO)_2O, H_2S_2O_7$ . The condensation products obtained in the course of this investigation have not yet been examined in detail. They were all very hygroscopic and unstable, and owing to their insolubility neither conductivities nor molecular weights could be determined.

No satisfactory explanation can be offered of the fact that groups accepted as semipolar on the basis of the octet theory are relatively inert so far as their effect on the other substituents in the molecule is concerned, but the fact that the experimental results with co-ordination compounds indicate that the linkage in the case of oxygen is more stable than a non-polar double linkage in which oxygen is involved, probably has a bearing on the matter.

#### EXPERIMENTAL.

*p*-Nitrobenzoyl Chloride and Nitrosylsulphuric Acid.—8 G. of *p*-nitrobenzoyl chloride were dissolved in 50 c.c. of dry carbon tetrachloride and warmed at 60° with 2 g. of nitrosylsulphuric acid for 4 hours. The clear liquid was decanted, and the residue washed repeatedly with carbon tetrachloride until free from the chloride, whereby a theoretical yield of *di-p-nitrobenzoylsulphuric acid* was obtained (Found : S, 7.75, 8.3, 8.0; N, 6.7.  $C_{14}H_8O_{10}N_2S$  requires S, 8.1; N, 7.1%). The analytical methods were similar to those used for the corresponding benzoyl derivative (*q.v.*), the substance being completely decomposed on boiling with dilute

hydrochloric acid into sulphuric and *p*-nitrobenzoic acids; when the evolved gases were passed through silver nitrate solution, 97.6% of the theoretical amount of chlorine was obtained.

When the substance was boiled for 3 hours in carbon tetrachloride, the amount of sulphuric acid obtainable on hydrolysis was equivalent to 5.60, 5.51% of sulphur, and the total sulphur content of the product was 7.43%. After 15 hours' refluxing, the corresponding figures were 4.10 and 7.00%. After 12 hours' heating at the boiling point of pentachloroethane (161°), no sulphuric acid was obtainable by prolonged hydrolysis of the product, which appeared to contain a sulphonic acid and a sulphone but was not examined in further detail.

*o*-Nitrobenzoyl Chloride and Nitrosylsulphuric Acid.—Considerable difficulty was found in obtaining this isomeride free from *o*-nitrobenzoic acid and repeated treatment with phosphorus pentachloride was necessary. 6.2 G. of the acid chloride were dissolved in 12 c.c. of carbon tetrachloride and warmed at 60° for 1 hour with 2.1 g. of nitrosylsulphuric acid, the resulting *di-o-nitrobenzoylsulphuric acid* being treated as above (Found: S, 8.2, 8.3%). The velocity of reaction, as measured by the rate of evolution of nitrosyl chloride, was greater than in the case of the para-compound, and some tar was formed.

*Reaction with Phthalyl Chlorides.* (With LIONEL FREDERICK BARRON.)—Nitrosyl chloride was vigorously evolved by reaction in the cold from both forms of this chloride. 30 G. of nitrosylsulphuric acid were treated with 79 g. of *s*-phthalyl chloride out of contact with air. When the reaction had ceased, the product was heated at 50–55° for 30 minutes, and then extracted repeatedly with boiling carbon tetrachloride until no further phthalic anhydride could be extracted. The residual oil solidified on cooling to a light yellow substance (Found: S, 19.3, 19.8.  $C_8H_4O_3 \cdot H_2S_2O_7$  requires S, 19.6%), which was completely decomposed on hydrolysis into sulphuric and phthalic acids. The procedure adopted in the case of *as*-phthalyl chloride was exactly similar, but no condensation product could be isolated; phthalic anhydride was recovered in high yield.

*Reaction with o- and p-Nitrobenzenesulphonyl Chlorides.* (With CHARLES KENNETH WILLIAMS.)—The chlorides were prepared by a modification of Limpricht's method (*Annalen*, 1875, 177, 60). 200 G. of benzene were added slowly to 300 c.c. of fuming sulphuric acid with cooling below 80°; after 2 hours the uncombined benzene was separated, and nitric acid (*d* 1.5) slowly added with constant shaking until no further action was apparent. The product was poured into water and filtered. The filtrate was saturated with

milk of lime, and the filtered solution evaporated and fractionally crystallised. (a) The first crop was boiled with potassium carbonate, and the evaporated filtrate yielded a potassium salt which was converted into the chloride by grinding with phosphorus pentachloride. The mass was washed well with water and extracted with ether; when the extract was dried with calcium chloride, and the ether partly evaporated, the *m*-nitrobenzenesulphonyl chloride crystallised. (b) The middle crop of crystals of the calcium salts from the mother-liquor yielded the *o*-compound by similar treatment, and the final crop yielded a mixture of the *o*- and *p*-compounds, from which the former crystallised on standing, leaving the latter as an oil.

All three isomerides were treated with nitrosylsulphuric acid under conditions precisely similar to those used for the corresponding nitrobenzoyl chlorides, but no evolution of nitrosyl chloride could be detected. When heated at higher temperatures ( $130^{\circ}$ ), the *o*- and *p*-compounds reacted with explosive violence, with rapid evolution of nitrosyl chloride; the *m*-compound was unattacked at  $130^{\circ}$ , and at temperatures sufficiently high to cause reaction it was so explosive that no product other than sulphur trioxide and *m*-nitrobenzenesulphonic acid could be isolated.

A number of aliphatic and aromatic chlorides (*e.g.*, carbon tetrachloride, pentachloroethane, chlorobenzene, and benzyl chloride) were also examined under conditions similar to those used for the nitrobenzoyl chlorides and also at the higher temperatures used for the sulphonyl chlorides. No evolution of nitrosyl chloride could be detected in any case.

*Reaction with Chlorophenols.*—5 G. of the chlorophenol were warmed to  $50^{\circ}$  with 4.5 g. of nitrosylsulphuric acid in the presence of 50 c.c. of carbon tetrachloride. A vigorous reaction with rapid evolution of nitrosyl chloride ensued. The solid was separated and washed with carbon tetrachloride as previously described. The production of tar was far greater than in any other condensation examined, and owing to the instability of the product purification was unsatisfactory.

XCVIII.—*Studies in Polymorphism. Part I. A Preliminary Investigation of the Polymorphism of o-Nitroaniline.*

By JOHN FREDERICK JAMES DIPPY and NORMAN HOLT  
HARTSHORNE.

WHILST studying the influence of various factors on the degree of supercooling of *o*-nitroaniline, one of us (J. F. J. D.) noticed that on certain occasions, notably when supercooling was large or the rate of cooling rapid, the solid was much lighter in colour than was normally the case. Suspecting polymorphism, we examined the behaviour of the substance during its crystallisation in a thin film between a microscope slide and a cover-slip, and found that it does, in fact, crystallise in two forms. Under ordinary conditions solidification starts from a number of nuclei and proceeds from them radially in the form of closely packed needles. Viewed by transmitted light, some of the resulting spherulites are seen to be composed of dark orange crystals, and the remainder of yellowish-green crystals. These two forms have been examined crystallographically under the microscope by Mr. Alan Stuart, of the Geology Department of this College, who reports as follows: "The dark orange crystals—length direction is the direction of fast vibration, pleochroic, straight extinction, biaxial, therefore orthorhombic. The yellowish-green crystals—length direction is the direction of fast vibration, slightly pleochroic, oblique extinction of about  $24^\circ$ , therefore monoclinic or triclinic."

Difficulty was at first experienced in obtaining crystals sufficiently large for this microscopic examination, especially in the case of the green form, which normally appears in extremely fine needles. This difficulty was eventually surmounted by remelting the centre portion only of a freshly crystallised melt on a slide by means of a little circular hot plate. This gave a liquid surrounded by crystals of both forms, and on cooling, each inoculated its own species from the melt. Supercooling was thus prevented and the slow growth which took place just below the melting point resulted in comparatively large crystals.

The crystal structure of *o*-nitroaniline has been studied by the X-ray method by Hermann and Burak (*Z. Krist.*, 1928, 67, 189), who concluded that it was orthorhombic. The only mention of its polymorphism appears to be a statement by Kohman, in a study of the freezing points of binary mixtures of the nitroanilines (*J. Physical Chem.*, 1925, 29, 1048), to the effect that the substance in binary mixture gave indications of existing in an unstable form.

We therefore decided to study the phenomenon in more detail, especially as the regular appearance of the two modifications side by side appeared to facilitate the investigation of certain aspects of polymorphism, such as the rate of stabilisation.

In about two hours after solidification the orange crystals are seen to have commenced to extend their territory at the expense of the green variety, showing that the former is the more stable modification. In addition, isolated crystal grains of the orange form appear in the areas occupied by the green form and continue to grow. This transformation occurs at all temperatures between that of the room and the melting point ( $70^{\circ}$ ), becoming much more rapid as the latter is approached, so within this range the polymorphism is monotropic.

The reason for the simultaneous appearance of the two forms under ordinary conditions of cooling, *i.e.*, radiation to room temperature, is that, within the temperature range in which crystallisation starts, the number of nuclei of each formed and their crystallisation velocities are of the same order, although there is usually a preponderance of the unstable form. More nearly equal quantities are produced if the slides are allowed to radiate to an atmosphere at about  $30^{\circ}$ ; and at still higher temperatures of the environment, the proportion of the stable form is increased until, just below the melting point, no unstable form at all is obtained. The main factor determining this behaviour appears to be the relationship between the crystallisation velocities of the two forms at different temperatures, which is well illustrated by Fig. 1. This photomicrograph depicts the crystallisation on a slide of some nitroaniline that had been melted except for the strip of solid to the right of the line AB, which contained both forms. On cooling, the stable (dark) form at first grew the more rapidly, as is shown by the constriction of the unstable areas; then both forms crystallised at the same speed (CD), and after this stage the stable form separated less rapidly, finally becoming entirely suppressed.

The numbers of nuclei of the two forms, however, appear to go more nearly hand in hand with alteration in the temperature, both increasing considerably as the temperature is lowered. On a slide, a melt which is rapidly cooled or greatly supercooled, appears to the naked eye to crystallise rapidly from a large number of nuclei of the unstable form. Microscopic examination, however, shows that there are numerous crystals of the stable form embedded in the mass, which evidently have not had a chance to grow owing to their small crystallisation velocity at the temperature of their formation. These small stable crystals are also seen under the microscope in the unstable areas of melts which have crystallised more slowly (see

*Direction of falling temperature and crystallisation ( $\times 20$ ).*

next section). They apparently give rise to the previously mentioned, isolated crystal grains visible to the naked eye after stabilisation has proceeded for some time.

*The Rate of Stabilisation.*—In the thin films studied the time taken for the transformation of all the substance into the stable form depends on two factors: (1) the linear stabilisation velocity, *i.e.*, the rate at which the boundary between the stable and the unstable form moves in a direction normal to itself, and (2) the length of the boundary. In any given specimen it may be assumed that (1) remains constant at constant temperature (provided that any impurity present is evenly distributed throughout the film), if the boundary be so long and the crystals so small that the observed effect is a statistical average of the velocities at different crystal faces. Factor (2) will depend mainly on the proportion of the stable form present as small grains, for if this is large, not only will the total length of boundary be very great at the start, but it will increase rapidly as stabilisation proceeds. We have found that both these factors are greatly affected by small variations in the degree of purity of the substance (compare Tammann, "The States of Aggregation," English transl., Constable and Co., 1926, pp. 228 *et seq.*).

The starting point of all these experiments was Schuchardt's "pure" preparation, stated possibly to contain a trace of *p*-nitro-aniline, and hence subsequently referred to as "crude." On slides made from this material and kept at room temperature, stabilisation was very slight after 21 hours (see photomicrographs, Fig. 2) and was not complete until several days had elapsed. A quantity of the crude substance was recrystallised five times from absolute alcohol, a specimen of each stage being retained and dried in the ordinary way. After about one week's storage in a calcium chloride vacuum desiccator they had lost all odour of alcohol. On slides made from these specimens, stabilisation was much more rapid than on those made from the crude substance (Fig. 3; contrast Fig. 2), and was usually complete in 24 hours, this being due to a considerable increase in both the linear stabilisation velocity and the number of small grains. From this result it appeared either (1) that the crude material contained an impurity acting as a retarding agent, or (2) that the recrystallised substance retained traces of alcohol which acted as an accelerator. The second possibility did not appear to be very probable, for the manufacturers had informed us that their product was also recrystallised from alcohol, and it was not likely to have been more completely dried than ours. However, after our specimens had been kept for 12 months in a calcium chloride desiccator, they became distinctly slower, but this appeared

to be due to a diminution in the number of small grains rather than to any alteration in the linear stabilisation velocity.

In order to test the first possibility, mixtures of some of the recrystallised specimens with about 1% of *p*-nitroaniline were made, since this was one of the most likely impurities. According to the results of Kohman (*loc. cit.*), this proportion of the *p*-isomeride lowers the f. p. of *o*-nitroaniline by about 0.6°, which is the average difference found between the purest recrystallised specimens and the crude material (see Table I, p. 731). These mixtures were intermediate between the crude and recrystallised specimens as regards both the linear stabilisation velocity and the number of small grains formed (compare Figs. 4, 3, and 2). The slowness of the crude substance is therefore not due to *p*-nitroaniline alone, although this substance may be partly responsible.

Two other methods of purification were tried, *viz.*, steam-distillation and distillation directly on to a microscope slide. The yield in the first case was small, and the product behaved as regards stabilisation in much the same way as the recrystallised specimens before prolonged drying, but was possibly a little slower. In the second case, one of the recrystallised specimens was placed in a short Pyrex test-tube held in a vertical position by being surrounded with sand contained in a large iron crucible. The latter was heated and the substance fractionally sublimed on to a series of microscope slides laid in succession on the top of the test tube. The first and middle fractions stabilised as rapidly as the recrystallised specimens, but the last fractions were exceedingly slow, the last of all being much slower even than the crude substance, only a very small amount of stabilisation having taken place after 4 days. Under the microscope these slow specimens were seen to be contaminated with a liquid, evidently a decomposition or oxidation product, for the residue in the test tube was charred. This liquid appeared to be much less volatile than the nitroaniline, for, whereas on long keeping, the latter always evaporates considerably at the edges of the cover slip, this liquid did not do so. The slowness of these specimens is evidently connected with this impurity.

In these and all other experiments described in this paper, the slides and cover-slips were treated with hot chromic or chromic-nitric acid mixture, it being ensured by the use of suitable holders that the liquid had free access to all surfaces. They were then washed with distilled water, next with conductivity water, and were finally dried in an air-oven and stored in a calcium chloride desiccator. In the later experiments, they were also steamed for a few minutes before being dried. To prevent decomposition of the substance, the hot plate used for melting the films was fitted with a thermometer

and the temperature was never allowed to rise above  $120^{\circ}$ , nor were the slides left on the plate longer than was absolutely necessary. In preparing the slides, they and the cover-slips were manipulated entirely with forceps. The progress of stabilisation was conveniently followed by projecting the slides at intervals on to a screen by means of an optical lantern.

After the stabilisation process described above is complete, most slides on standing for some weeks develop dark brown patches which gradually extend. This change, which is being further studied, is partly due to the coalescence of the original needles to form larger crystals.

*Freezing Points and Melting Points.*—In order to compare the purity of the different specimens obtained by recrystallisation, an attempt was made to determine their freezing points. This proved to be impossible with the quantities available (about 2 g. of each), for the freezing point registered depended entirely on the bath temperature even when the latter was only  $1^{\circ}$  or  $2^{\circ}$  below the former. This is probably because the substance has a low velocity, or heat of crystallisation, or both. The highest temperature registered by the crude substance was  $68.7^{\circ}$  with the bath at  $67^{\circ}$ , and  $68.9^{\circ}$  with the bath at  $68^{\circ}$ . The thrice recrystallised specimen had a f. p. of  $69.2^{\circ}$  with a bath temperature of  $68^{\circ}$ , and this was the highest temperature observed. (Determinations with the fourth and fifth fractions, however, were not made.) This value may be compared with Kohman's, viz.,  $69.3^{\circ}$  (*loc. cit.*).

Attention was next directed to melting-point determinations. The m. p.'s given in the literature vary from  $68^{\circ}$  to  $71.5^{\circ}$ . The ordinary methods proved quite unsatisfactory, since it seemed impossible to judge with certainty to less than  $0.5^{\circ}$  the temperature at which melting began, even when the melting-point tube was observed with a low-power microscope. In order to remove any unstable form, the tubes were heated at  $60^{\circ}$  for some days, but this did not seem to make any difference. The difficulty was eventually overcome by means of the apparatus shown in Fig. 5, in which the melting of the substance on microscope slides could be observed. This method had the advantage that the melting points of both forms could be determined in one operation. The glass tube, A, which was just wide enough to contain a  $3'' \times 1''$  microscope slide, E, was fitted at the top with a rubber stopper carrying an Anschütz thermometer of the enclosed-scale type, B, graduated from  $60^{\circ}$  to  $85^{\circ}$  in  $0.2^{\circ}$  (made specially for this work by Messrs. Negretti and Zambra), and two  $\frac{1}{8}''$  copper tubes, C and D. The tube C, which was about one yard long, passed to the bottom of A, being coiled outside as shown. The tube D reached just below the

stopper. The slide was supported between the tube C and the thermometer, the bulb of the latter being opposite the centre of the substance under the cover-slip. The whole apparatus was immersed to the level shown in a 2-litre beaker containing water and fitted with a mechanical stirrer, a thermometer, and a movable 2-volt electric bulb enclosed in a frosted glass tube, by means of which any desired portion of the material on the slide could be brightly illuminated from behind. The beaker was heated by a shielded gas flame controlled by a fine adjustment. By attaching D to a filter pump

FIG. 5.

and C to a sulphuric acid wash bottle a rapid current of dry air at the same temperature as the outer bath could be drawn through A. Careful trials showed that, provided the temperature of the bath was not altered more rapidly than  $1^{\circ}$  in 10 minutes and a rapid current of air was drawn through A, the temperature registered by the thermometer kept the same, to within  $0.1^{\circ}$ , as that of the bath. Since the substance on the slide was only separated from the air stream by the thin cover-slip, it did not seem possible for it to lag behind the thermometer in acquiring the temperature of the air, especially as the slide and thermometer had approximately equal volumes and therefore approximately equal heat capacities. (As is well known, glass has very nearly

the same heat capacity as an equal volume of mercury.) If proof were needed, however, it was furnished by the fact that if the temperature of the apparatus were rapidly raised so that there was considerable lag on the part of the thermometer, then the substance on the slide melted at a very much lower reading than when slow heating was used. Thus, under conditions such that the thermometer registered the temperature of the bath, it also registered the temperature of the *o*-nitroaniline. These conditions, already specified, were adhered to during the melting-point determinations.

In carrying out a determination, a freshly crystallised slide containing both the stable and the unstable form was placed in A, and the apparatus rigidly fixed in the bath which had been previously

heated to 65—67°. If this preliminary heating were omitted, it was found that the long time taken to raise the apparatus to the m. p. resulted in complete stabilisation of the substance, so that the m. p. of the unstable form could not be observed. The air stream was then started, and the bath rapidly stirred. When the inner and outer parts were in thermal equilibrium the temperature was allowed to rise at the above-mentioned rate. A suitable portion of the slide, usually near the bulb of the thermometer, was illuminated and observed by means of a low-power microscope. The unstable areas melted first and left crystals of the stable form surrounded by liquid. One or two well-shaped crystals were selected for observation and watched carefully against an eye-piece scale in the microscope. The temperature at which they first showed signs of melting could thus be determined very sharply. The point at which the unstable form commenced to melt could not be determined so precisely, for this form, usually consisted of very small crystals packed closely together, and consequently there were no sharply defined crystal edges visible. Moreover, melting at the boundaries between the stable and the unstable form was often observed to take place at a lower temperature than that at which the bulk of the unstable form melted.\* The temperature recorded as the m. p. was that at which melting some distance from the boundary first became apparent.

Objection may be raised to this method on the ground that substances in thin films have lower melting points than when in bulk; for example, Meissner (*Z. anorg. Chem.*, 1920, **110**, 169) has shown that the m. p. of a film of myristic acid decreases by 0.3° as the thickness diminishes from 10  $\mu$  to 0.8  $\mu$ . Measurements of the thickness of four of our films taken at random gave the values 0.135, 0.155, 0.145, and 0.125 mm., which would appear to be well outside the range of this effect.

The results are given in Table I. With the exception of the crude specimen they refer to material dried for 12 months over calcium chloride.

TABLE I.

Specimen.	Crude.	Fractions of recrystallised specimens.					
		1.	2.	3.	4.	5a.†	5b.†
M. p. of unstable form.	ca. 67.9°	ca. 68.1°	68.1°	68.1° 68.2	68.3°	ca. 68.2°	68.2°
M. p. of stable form.	69.5 69.5	70.05 69.9	69.9	70.1 70.1	70.15 70.15	70.15 70.25	70.1

† Results with two different slides.

\* This may be a surface effect, or may be due to a concentration of traces of impurity at these places. It is also not impossible that, owing to differing molecular complexity, the two forms melt to give for a brief period different liquids, so that the m. p. of one is lowered by contact with the other.

The values for the 3rd, 4th, and 5th fractions show little difference, so that probably the maximum purity possible by the method of purification used was reached. From the average of these three specimens, the m. p. of the unstable form lies  $1.9^{\circ}$  below that of the stable form. The values must, of course, be higher than the true solid-liquid equilibrium temperature. Kohman's value of  $69.3^{\circ}$  seems, however, to be too low, for on one occasion it was noted that when a slide was cooled the crystals started to grow above  $69.5^{\circ}$ . Possibly his determination was influenced by the same factors as were our freezing-point determinations, for he too used a small quantity. It is also possible that his specimen was impure, for he states that sublimation was used as one of the methods of purification and as already stated this may lead to decomposition or oxidation.

*Summary.*

1. *o*-Nitroaniline exists in two polymorphs. One (m. p.  $68.1-68.3^{\circ}$ , monoclinic or triclinic) is unstable at all temperatures between that of the room and the m. p. and changes into a stable form (m. p.  $70.1-70.2^{\circ}$ , orthorhombic).

2. When the substance is crystallised in thin films, both forms are normally obtained, the relative amounts depending on the temperature at which crystallisation begins. This has been connected with the relation between the crystallisation velocities of the two forms at different temperatures.

3. The time taken for the disappearance of the unstable form has been studied with regard to (i) the linear stabilisation velocity at the stable-unstable boundary and (ii) the extent of the boundary; and the effect of impurities on both these factors has also been investigated.

4. An apparatus which enables the melting points of both forms to be determined in the same operation is described.

In conclusion, we wish to express our gratitude to Mr. Alan Stuart for his interest and assistance in the crystallographic part of this work.

# XCIX.—The "Uniform Movement" of Flame in Mixtures of Ethylene, Propylene, or Butylene with Air.

By ELIZABETH HELEN MACLEOD GEORGESON and FRANCIS JOHN HARTWELL.

THE uniform movement of flame, the first stage in its propagation from the open towards the closed end of a tube, provides the most convenient means for comparing the speeds of inflammation of various gas mixtures. This communication presents measurements of the speed of uniform movement of flame in the whole range of inflammable mixtures of air with ethylene, propylene, or butylene. The experiments were carried out in a horizontal tube of 2.5 cm. diameter, and the results are therefore directly comparable with those already obtained for carbon monoxide and the lower members of the paraffin series (Payman, J., 1919, 115, 1446, 1454), for acetylene (Mason and Wheeler, *ibid.*, p. 578), and for hydrogen (Georgeson and Hartwell, J., 1927, 265). The limits of inflammability of the olefins named, in the conditions stated, were determined incidentally.

The apparatus and experimental procedure were similar to those described (J., 1927, 265). The use of a tube of transparent quartz, 2.5 cm. in diameter and 150 cm. long, and a quartz lens, enabled flame photographs to be taken over the whole inflammable range of each gas. The combustible gases, obtained commercially in cylinders, were purified by repeated liquefaction and fractional distillation. The butylene was a mixture, in approximately equal proportions, of  $\Delta^{\alpha}$ - and  $\Delta^{\beta}$ -isomerides (W. L. Wood, private communication). Mixtures with air were prepared over mercury in iron gas-holders and, except when otherwise stated, the gases were roughly dried by passage over calcium chloride, and contained less than 0.1% of water vapour. A sample of each mixture was taken for analysis from the tube prior to ignition. The mixture was fired by passing a spirit-lamp flame, 2—3 cm. high, across the opened flanged end of the tube. Photographs were taken during the progress of the flames over a distance of 12.5—38.5 cm. from the point of ignition.

The values obtained from the photographic records are given in Table I. In each case, the first column contains the percentage (by vol.) of the hydrocarbon, and the second, the speed of uniform movement (in cm./sec.).

Fig. 1 shows the results as speed-percentage curves, together with the curves for the first five paraffin hydrocarbons. For the olefins

as well as for the paraffins the mixtures of maximum speed of uniform movement contain less air than is required for complete combustion. For paraffin hydrocarbons, this has been attributed to the influence of mass action (Payman, J., 1920, 117, 48), and the same explanation may be adopted for the olefins.

FIG. 1.

Table II shows the limits of inflammability in a horizontal glass tube, 2.5 cm. in diameter and 150 cm. long, and also the composition and speed of uniform movement of the maximum speed mixture of each hydrocarbon.

TABLE II.

	Limits of inflammability : hydrocarbon, %.		Maximum speed mixtures.		Theoretical for complete combustion : hydrocarbon, %.
	Lower limit.	Upper limit.	Hydrocarbon, %.	Speed of uniform movement (cm./sec.).	
Ethylene-air .....	3.30	18.25	7.3—7.7	166	6.51

Butylene-air .....	1.93	6.0	3.9—4.1	98	3.36

A peculiarity of the ethylene-air curve is the flattening towards the upper limit.

Chapman (J., 1921, 119, 1677) has given measurements of the speed of uniform movement of flame in ethylene-air mixtures. His results are from 14 to 28% lower than ours. In the course of attempts to explain the difference we found : (i) that the speeds of flame in mixtures of ethylene and air saturated with water vapour

at laboratory temperature were only slightly lower than the speeds in mixtures roughly dried by passage over calcium chloride; (ii) that ethylene, prepared in the laboratory by Newth's method (J., 1901, 79, 915) and purified by condensation of alcohol and ether vapours in vessels cooled by solid carbon dioxide and ether, gave the same flame speeds as those recorded in Table I; (iii) that the speed of uniform movement of ethylene-air mixtures was not affected by variations in length of the explosion tube.

It seemed that the cause of the difference might be found in the methods of registering the flame speeds, for Chapman had recorded automatically the time interval between the fusion of successive screen wires, whereas we had used the photographic method. The latter is now regarded as the more trustworthy, for screen wires are obstacles in the path of the flame, and, moreover, they record only the mean speed of flame between one wire and the next. We therefore fitted a tube with screen wires and made measurements by both methods simultaneously, over the same length of tube. The speed measurements agreed with one another, but were some 3—4 cm./sec. higher than corresponding figures in Table I, a result which the photographs explained by showing a small increase in flame speed near the wires, which presumably function as small constrictions in the tube. So far as we could discover, therefore, the differences between Chapman's figures and ours are not attributable to an error in either method of measurement of flame speeds.

A clue to an explanation was provided by the flame speed of the 7.05% ethylene-air mixture, which was found to be either 114 or 160 cm./sec., approximately. The lower speed was obtained when the ground-glass cap at the firing end of the tube was removed in such a manner as to cause mechanical disturbance of the mixture. Low flame speeds were also regularly induced by firing the mixture while the tube was still "ringing" after a rather sharp blow; in these circumstances speeds of 110—120 cm./sec. were obtained with a maximum speed mixture instead of the normal speed of 166 cm./sec. Mason and Wheeler (J., 1920, 117, 1233) observed a similar effect in the upward propagation of flame in certain methane-air mixtures, and attributed the effect to resonance. We are inclined, therefore, to explain the comparative slowness of Chapman's flames as being due to the incidence of resonance during part of their progress between the screen wires. The photographic registration of flame speeds prevents such an effect from being overlooked.

The upper limit of ethylene in air was found to be 18.25%. At about 14% of ethylene, the colour of the flame changed from bluish-green (below 14%) to yellow (14—18%), and carbon was liberated.

This work has been carried out for the Safety in Mines Research Board, to whom our thanks are due for permission to publish it.

### C.—Aromatic Stibinic Acids containing Phenyl and Quinolyl Radicals.

By GILBERT T. MORGAN and JAMES WILFRED COOK.

IN recent years considerable attention has been directed towards organic antimonials as therapeutic agents in tropical medicine (Schmidt, *Ind. Med. Gaz.*, 1928, 63, 643) and the compounds now described were prepared in the course of a search for active substances of greater stability than *p*-aminophenylstibinic acid, from which many of the successful antimonials are derived.

One of the most promising arsenicals in present use is tryparsamide and Brahmachari (*Indian J. Med. Res.*, 1922, 10, 510) claimed to have isolated the analogous antimony compound (sodium *N*-phenylglycineamide-*p*-stibinate, I). We have made repeated unsuccessful attempts to prepare Brahmachari's substance, the chief difficulty being that *p*-aminophenylstibinic acid decomposes rapidly under the conditions necessary to effect condensation with chloroacetamide. Attempts to overcome this difficulty by introducing the stibinic acid group into a previously formed *N*-phenylglycine molecule (for example, by the Bart-Schmidt reaction with *p*-amino-*N*-phenylglycine or *p*-amino-*N*-acetyl-*N*-phenylglycine) also proved abortive. Moreover, *pp'*-diaminodiphenylstibinic acid and 4-hydroxy-3-aminophenylstibinic acid both decomposed when heated with chloroacetamide in faintly alkaline solution.

*m*-Aminophenylstibinic acid is considerably more stable than its para-isomeride and condenses smoothly with chloroacetamide and with chloroacetomethylamide to yield *N*-phenylglycineamide-*m*-stibinic acid (II) and *N*-phenylglycinemethylamide-*m*-stibinic acid (III) respectively.

*m*-Aminophenylstibinic acid also reacted with cyanic acid to give *m*-carbamidophenylstibinic acid (IV).

4-Chloro-3-aminophenylstibinic acid (V), obtained by oxidation of 4-chloro-3-aminophenylstibinous chloride hydrochloride (Schmidt, *Annalen*, 1920, **421**, 208; *Ber.*, 1926, **59**, 556) with ammoniacal hydrogen peroxide at 0°, failed to react when its sodium salt was heated with chloroacetamide or chloroacetomethylamide in aqueous or alcoholic solution, the reactivity of the primary amino-group being probably depressed by the ortho-chlorine atom.

The chlorine atom in 4-chloro-3-nitrophenylstibinic acid (Schmidt, *Annalen*, 1920, **421**, 188) is considerably less reactive than that in the analogous arsenic acid (D.R.-PP. 285,604, 446,545; Barber, J., 1929, 471), since it does not condense with pyridine or aniline at 100°, with ammonia at 120°, or with diethylamine in boiling alcoholic solution. With piperidine in boiling alcohol, however, 3-nitro-4-piperidinophenylstibinic acid was readily obtained, and this was reduced by ferrous hydroxide to 3-amino-4-piperidinophenylstibinic acid (VI).

(IV.)

(V.)

(VI.)

3-Nitro-4-ethylaminophenylstibinic acid was produced from 4-chloro-3-nitrophenylstibinic acid and ethylamine in alcoholic solution at 120—130°, the reaction being accompanied by partial elimination of antimony from the molecule.

Treatment of an aqueous suspension of 3-amino-4-hydroxyphenylstibinic acid with acetic anhydride led to the formation of a stibinic acid which was probably 3-acetamido-4-hydroxyphenylstibinic acid (VII), but its extreme solubility in water was remarkable, since most aromatic stibinic acids are very sparingly soluble, as is also the analogous arsenic acid (stovarsol), so the possibility of internal condensation to a benzoxazole derivative (VIII) is not excluded.

(VII.)

(VIII.)

The conditions necessary for the production of quinolylstibinic acids by the Bart-Schmidt reaction have been determined (compare Binz and R  th, *Eng. Pat.* 250,287) and *quinolyl-5-stibinic*, *quinolyl-6-stibinic*, and *quinolyl-8-stibinic acids* were obtained from the corresponding aminoquinolines. The stibinic acid group has less in-

fluence than the arsinic acid group in inhibiting the basic character of the quinoline residue, since these stibinic acids are soluble even in dilute acetic acid, whereas Binz and R  th (*Annalen*, 1927, 453, 240) have shown that the corresponding arsinic acids require concentrated mineral acids for salt formation. These quinolylstibinic acids were purified through their sparingly soluble crystalline *stibinic chlorides*, the salt obtained from quinolyl-8-stibinic acid (IX), for example, being represented by structure X :

By evaporation of its solution in dilute acetic acid, quinolyl-8-stibinic acid (IX) is converted into a water-soluble variety which is probably a salt formed by internal neutralisation, since the isomeric 5- and 6-compounds do not behave in this way. An attempt was made to prepare 6-methoxyquinolyl-8-stibinic acid and 6-ethoxyquinolyl-8-stibinic acid from the corresponding alkoxy-aminoquinolines, which themselves are stated to be destructive to blood parasites (*Eng. Pat.* 267,457). The yield of these stibinic acids was, however, very poor and they could not be obtained free from coloured impurities, but it is noteworthy that neither of these derivatives of quinolyl-8-stibinic acid could be converted into a water-soluble form by evaporation of dilute solutions of the acetates.

The trypanocidal action of the compounds now described has been examined by Professor Warrington Yorke under the auspices of the Chemotherapy Committee of the Medical Research Council. The substances were administered intraperitoneally and were found to possess only a slight activity against *T. equiperdum*. The minimum lethal doses (M.L.D.), expressed in mg. per 20 g. mouse, are given in the following table, sodium *m*-aminophenylstibinate being included for comparison.

Substance.	M.L.D.
Sodium <i>m</i> -aminophenylstibinate .....	25
Sodium <i>m</i> -carbamidophenylstibinate .....	25
Sodium <i>N</i> -phenylglycineamide- <i>m</i> -stibinate .....	20
Sodium <i>N</i> -phenylglycinemethylamide- <i>m</i> -stibinate .....	30
Acetylated 3-amino-4-hydroxyphenylstibinic acid (VII or VIII) ...	10
Sodium quinolyl-5-stibinate .....	1.8
Sodium quinolyl-6-stibinate .....	3.6
Quinolyl-8-stibinic acid .....	0.9

## EXPERIMENTAL.

### I. Derivatives of *m*-Aminophenylstibinic Acid.

*m*-Carbamidophenylstibinic Acid (IV).—*m*-Aminophenylstibinic acid (6 g.) was dissolved in *N*-hydrochloric acid (20 c.c.), and the

excess of mineral acid neutralised with sodium hydroxide. 2*N*-Acetic acid (25 c.c.) was added, followed by a concentrated aqueous solution of potassium cyanate (2.5 g.) at 0°. After an hour the precipitate was collected and reprecipitated by hydrochloric acid from its solution in sodium hydroxide. For purification, the product (5.5 g.) was suspended in concentrated hydrochloric acid (50 c.c.) at 0°. After 3 hours the yellow crystalline stibinic chloride was collected, washed with hydrochloric acid, and hydrolysed by water to the stibinic acid, which was washed with water to remove occluded salts and finally dried in a vacuum desiccator. *m*-Carbamidophenylstibinic acid, a white amorphous powder, decomposed on heating, without melting\* (Found: N, 9.5.  $C_7H_7O_3N_2Sb, H_2O$  requires N, 9.1%).

The sodium salt, precipitated on adding alcohol to its neutral solution, formed a white amorphous powder, moderately easily soluble in water (Found: Sb, 39.0.  $C_7H_5O_4N_2NaSb$  requires Sb, 37.0%). Most of the sodium salts gave high analytical figures for antimony. This accords with the observations of Fargher and Gray (*J. Pharm. Exp. Ther.*, 1921—1922, 18, 341), who cite several instances of neutral sodium aryl stibinates containing less than one atom of sodium per molecule.

*N*-Phenylglycineamide-*m*-stibinic Acid (II).—A solution of *m*-aminophenylstibinic acid (5.2 g.) and chloroacetamide (3.6 g.) in *N*-sodium hydroxide (20 c.c.) was heated at 90° for 1½ hours. Sufficient sodium hydroxide was added to dissolve the resulting resinous precipitate and the solution, which still gave a reaction for primary aromatic amine, was treated with a further 1.5 g. of chloroacetamide and heated for another hour to complete the condensation. The clear solution obtained by adding the requisite amount of alkali was acidified with acetic acid, the precipitated stibinic acid was dissolved in 2*N*-hydrochloric acid (15 c.c.), and addition of ice-cold hydrochloric acid (*d* 1.19; 15 c.c.) then resulted in separation of the crystalline stibinic chloride. This chloride was rapidly collected and dissolved in water, the solution made alkaline, and the free stibinic acid reprecipitated by acetic acid (Found: Sb, 39.5; N, 9.0.  $C_8H_9O_3N_2Sb, 1/3H_2O$ † requires Sb, 39.4; N, 9.1%). *N*-Phenylglycineamide-*m*-stibinic acid, a white amorphous powder, was readily soluble in dilute alkali or excess of dilute mineral acids but insoluble

\* None of the stibinic acids described in the sequel had a definite melting point.

† Schmidt (*loc. cit.*) has shown that the vacuum-dried aryl stibinic acids are usually represented by formulæ of the type  $3ArSbO_2, H_2O$  or  $3ArSbO_2, 2H_2O$ . The figures for antimony which we have obtained have led us to adopt similar formulations, although with considerable reserve on account of the instability and difficulty of purification of the compounds.

in dilute acetic acid. When added to its dilute hydrochloric acid solution, sodium nitrite precipitated a gelatinous nitrosoamine.

The *sodium* salt, precipitated by addition of alcohol to its concentrated neutral aqueous solution, was a white amorphous powder readily soluble in water (Found: Sb, 35.9.  $C_8H_{10}O_4N_2NaSb$  requires Sb, 35.5%).

*Sodium N-Phenylglycinemethylamide-m-stibinate* (III).—Condensation of *m*-aminophenylstibinic acid with chloroacetomethylamide was carried out exactly as with chloroacetamide, a double heating with the methylamide being also necessary for complete reaction. Phenylglycinemethylamide-*m*-stibinic acid, when purified through the stibinic chloride, had properties similar to those of the corresponding amide, and gave a strong odour of methylamine when heated with sodium hydroxide solution. The *sodium* salt, which was isolated from its concentrated aqueous solution by addition of alcohol and ether, formed a white amorphous powder completely soluble in about half its weight of water (Found: Sb, 33.1.  $C_9H_{12}O_4N_2NaSb$  requires Sb, 34.1%).

Condensation of *m*-aminophenylstibinic acid with chloroacetylamine proceeded smoothly with the formation of an acid, of which the sodium salt was not precipitated from its aqueous solution even by alcohol and ether.

*pp'-Diacetamidodiphenylstibinous Hydroxide*.—A suspension of *p*-acetamidophenylstibinous chloride hydrochloride (10 g.) in 0.005*N*-sodium hydroxide (1000 c.c.) was boiled for an hour. The solution, filtered hot from antimony oxide, deposited colourless needles on cooling; these, recrystallised from aqueous methyl alcohol, intumesced at 128° (Found: Sb, 29.5. Calc.: Sb, 29.9%). This process is simpler than Schmidt's method of degradation of the triacetamidotriphenylstibine (*Annalen*, 1922, 429, 137).

This secondary hydroxide was oxidised to the diarylstibinic acid by Schmidt's method, and the product (4 g.) hydrolysed at 0° in  $\frac{3}{4}$  hour by *N*-sodium hydroxide solution (25 c.c.). The resulting amino-compound gave only aniline and resinous products on treatment with chloroacetamide.

## II. Condensation of 4-Chloro-3-nitrophenylstibinic Acid with Amines.

*3-Nitro-4-piperidinophenylstibinic Chloride Hydrochloride*.—A solution of 4-chloro-3-nitrophenylstibinic acid (3.28 g.) and piperidine (5.5 c.c.) in alcohol (20 c.c.) was boiled for 3 hours, and the solution poured into water. The orange precipitate (3.5 g.) was dissolved in warm glacial acetic acid (20 c.c.), and the cooled solution treated with concentrated hydrochloric acid (20 c.c.). The crystalline

precipitate was washed with a mixture of hydrochloric acid and acetic acid (1 : 1) and dried over sulphuric acid and solid potassium hydroxide. The *stibinic chloride hydrochloride* formed a colourless microcrystalline powder, decomp. 185—187° (Found : Sb, 24.3.  $C_{11}H_{13}O_2N_2Cl_4Sb.HCl$  requires Sb, 24.1%).

*3-Nitro-4-piperidinophenylstibinic acid hydrochloride*, formed when the foregoing stibinic chloride was suspended in a large volume of water for several hours, was an orange amorphous powder (Found : Sb, 29.3.  $C_{11}H_{13}O_4N_2Sb.H_2O.HCl$  requires Sb, 29.4%).

*3-Nitro-4-piperidinophenylstibinic Acid*.—The hydrochloride of the acid was dissolved in alcohol with 2*N*-sodium hydroxide; the clear solution was acidified with acetic acid. After drying, the gelatinous precipitate was again washed with water to remove occluded salts and obtained as an orange amorphous powder, sparingly soluble in excess of dilute aqueous alkali (Found : Sb, 33.6.  $C_{11}H_{13}O_4N_2Sb.1/3H_2O$  requires Sb, 33.3%).

*3-Amino-4-piperidinophenylstibinic Acid* (VI).—Reduction of the nitro-compound with stannous chloride yielded no crystalline product, but the aminophenylstibinic acid was readily formed when ferrous hydroxide was used. A solution of 3-nitro-4-piperidinophenylstibinic acid (3 g.) in alcohol (15 c.c.) and 6*N*-sodium hydroxide (3 c.c.) was poured into water (150 c.c.), this procedure being adopted in order to obtain the substance in a finely divided state. More 6*N*-sodium hydroxide (30 c.c.) was added to the suspension, followed slowly by a solution of ferrous sulphate (15 g. in 100 c.c. of water). After 1½ hours the hydroxides of iron were removed and the filtrate was acidified with acetic acid. The gelatinous stibinic acid was purified through the stibinic chloride (obtained with ice-cold hydrochloric acid) (Found : Sb, 36.5.  $C_{11}H_{15}O_2N_2Sb.1/3H_2O$  requires Sb, 36.3%).

*3-Amino-4-piperidinophenylstibinic acid* formed a greyish powder, soluble in very dilute mineral acid or alkali, the solutions giving reactions for primary amine. The *sodium* salt was produced when a suspension of the acid (3 g.) in 50% alcohol (80 c.c.) was neutralised with sodium hydroxide, the filtered solution evaporated to dryness, the residue extracted with boiling methyl alcohol, and the extract evaporated to dryness. This salt was too sparingly soluble in water to be used for intravenous injection (Found : Sb, 33.9.  $C_{11}H_{16}O_3N_2NaSb$  requires Sb, 33.0%).

*3-Nitro-4-ethylaminophenylstibinic Chloride*.—A solution of 4-chloro-3-nitrophenylstibinic acid (3.28 g.) in alcoholic ethylamine (12 c.c. of a solution containing 22 g. of ethylamine per 100 c.c.) was heated at 120—130° for 3 hours. After cooling, an orange solid had separated consisting of the nitroethylaminophenylstibinic acid

mixed with antimony oxide. This crude product (1 g.) was ground under concentrated hydrochloric acid (20 c.c.) and the crystals were washed with concentrated hydrochloric acid and dried over sulphuric acid and solid potassium hydroxide. 3-Nitro-4-ethylaminophenylstibinic chloride formed a buff microcrystalline powder with no definite m. p. (Found: Sb, 28.6.  $C_8H_9O_2N_2Cl_4Sb$  requires Sb, 28.4%). This stibinic chloride was immediately hydrolysed by water to the orange 3-nitro-4-ethylaminophenylstibinic acid, obtained pure for analysis by acidifying a dilute solution of the ammonium salt with acetic acid (Found: Sb, 37.1.  $C_8H_9O_4N_2Sb \cdot 1/3H_2O$  requires Sb, 37.4%).

3-Nitro-4-methylaminophenylstibinic chloride was obtained in precisely the same manner as the ethylamino-compound from 4-chloro-3-nitrophenylstibinic acid (3.28 g.) and 15% alcoholic methylamine (15 c.c.) at 120–130° (Found: Sb, 28.8.  $C_7H_7O_2N_2Cl_4Sb$  requires Sb, 29.3%).

### III. Acetylation of 3-Amino-4-hydroxyphenylstibinic Acid.

The potassium salt (16 g.) of 3-nitro-4-hydroxyphenylstibinic acid (Schmidt, *Annalen*, 1920, **421**, 212) was reduced by sodium hydro-sulphite (D.R.-P. 270,488) to the amino-compound, which was suspended in water (12 c.c.) and acetylated by the gradual addition of acetic anhydride (9 c.c.). This treatment led to a clear solution and after 24 hours several volumes of acetone were added to precipitate the stibinic acid (VII or VIII). The substance formed a white amorphous powder extremely soluble in water with an acid reaction, insoluble in acetone, alcohol or glacial acetic acid, and yielding a sodium salt readily soluble in water (Found: Sb, 37.8.  $C_8H_8O_4NSb \cdot H_2O$  requires Sb, 37.8%).

### IV. Quinolylstibinic Acids.

The appropriate aminoquinoline (6 g.; 1/24 g.-mol.) in water (50 c.c.) and concentrated hydrochloric acid (20 c.c.) was diazotised at 0° with sodium nitrite (3 g.). The diazo-solution was added slowly, with simultaneous addition of 6*N*-sodium hydroxide (20 c.c.), to an ice-cold sodium antimonite solution prepared from antimony trichloride (12.6 g.), 5*N*-hydrochloric acid (20 c.c.), and glycerol (20 c.c.), the resulting solution being treated with 6*N*-sodium hydroxide until the precipitate first formed had just redissolved and then diluted to 800 c.c. After being kept at the ordinary temperature over-night, the solution was freed by filtration from the bulk of coloured by-products, and the filtrate acidified with acetic acid. The precipitate was suspended in concentrated hydrochloric acid (50 c.c.) and the product was collected after an hour and washed

with concentrated hydrochloric acid. The stibinic chloride, thus obtained free from antimony oxide, was decomposed by excess of dilute alkali, the stibinic acid being precipitated by acetic acid.

*Quinolyl-5-stibinic Acid.*—The crude stibinic acid (2 g. from 6 g. of 5-aminoquinoline) was converted into stibinic chloride by addition of concentrated hydrochloric acid to its solution in dilute hydrochloric acid, and the *stibinic acid* regenerated in the usual way. A small sample (0.5 g.) was further purified for analysis by extraction with boiling methyl alcohol (200 c.c.). The filtrate was concentrated to small bulk, and the deposit washed with methyl alcohol and dried (Found: Sb, 40.6.  $C_9H_6O_2NSb \cdot H_2O$  requires Sb, 40.6%). This acid formed a buff powder very sparingly soluble in most media, although moderately easily soluble in glacial acetic acid and readily soluble in dilute acids or alkalis. The *sodium* salt was obtained by adding a slight excess of sodium hydroxide to an aqueous suspension of the free acid (2.5 g.). The excess of alkali was neutralised with hydrochloric acid, and the filtrate evaporated to dryness in a vacuum desiccator. The residue was extracted with alcohol (30 c.c.), the solution filtered to remove sodium chloride, and then evaporated to dryness. This sodium salt was readily soluble in water (Found: Sb, 39.6.  $C_9H_7O_3NNaSb$  requires Sb, 37.8%).

*Quinolyl-5-stibinic chloride hydrochloride*, obtained when a solution of the purified stibinic acid in dilute hydrochloric acid was treated at 0° with concentrated hydrochloric acid, was a buff microcrystalline powder, m. p. 222° (Found: Sb, 28.2.  $C_9H_7NCl_5Sb$  requires Sb, 28.4%).

*Quinolyl-6-stibinic Acid.*—The crude stibinic acid (2 g. from 6 g. of 6-aminoquinoline) was purified through the stibinic chloride, and its filtered solution in methyl alcohol evaporated to dryness. The residual *acid* formed a buff powder moderately easily soluble in methyl alcohol and readily soluble in dilute acids or alkalis (Found: Sb, 40.1.  $C_9H_6O_2NSb \cdot H_2O$  requires Sb, 40.6%). The *sodium* salt, prepared and purified in the same manner as sodium quinolyl-5-stibinate, formed a straw-yellow powder readily soluble in water or alcohol (Found: Sb, 38.8.  $C_9H_7O_3NNaSb$  requires Sb, 37.8%).

*Quinolyl-6-stibinic chloride hydrochloride* was obtained, by the addition of concentrated hydrochloric acid to an ice-cold solution of the stibinic acid in dilute hydrochloric acid, as a buff microcrystalline powder, m. p. 237° (Found: Sb, 28.5.  $C_9H_7NCl_5Sb$  requires Sb, 28.4%).

*Quinolyl-8-stibinic Acid (IX).*—(a) *Water-insoluble form.* The crude acid (3.6 g. from 6 g. of 8-aminoquinoline) was purified in the same way as the 6-stibinic acid and formed a light brown powder moderately easily soluble in methyl alcohol, readily soluble in dilute

acids, but soluble only in excess of sodium hydroxide (Found: Sb, 41.3.  $C_9H_6O_2NSb, 2/3H_2O$  requires Sb, 41.4%).

(b) *Water-soluble form.* Purified quinolyl-8-stibinic acid (3 g.) was dissolved in 0.2*N*-acetic acid (50 c.c.), and the solution evaporated to dryness. The residue was redissolved in water, and the solution again evaporated to dryness in a vacuum desiccator. The resulting light brown powder was readily soluble in water, addition of a drop of sodium hydroxide resulting in precipitation of the insoluble form (Found: Sb, 40.2.  $C_9H_6O_2NSb, H_2O$  requires Sb, 40.6%).

*Quinolyl-8-stibinic chloride hydrochloride* (X) separated, when concentrated hydrochloric acid was added to an ice-cold methyl-alcoholic solution of the stibinic acid, in small brownish needles, decomp. 200—210° (Found: Sb, 28.4.  $C_9H_7NCl_5Sb$  requires Sb, 28.4%).
